Figure 39-11 The cartoon shows the location of the atrioventricular node as found most frequently in congenitally corrected transposition with usual atrial arrangement as seen by the surgeon looking through an incision in the morphologically right atrium. In the situation illustrated, we have shown a co-existing ventricular septal defect. Note that the conduction axis runs antero-cephalad relative to the defect (see Fig. 39-12).

and branches into a cord-like right bundle branch, which extends leftwards to reach the morphologically right ventricle, and a fan-like left bundle branch, which cascades down the smooth left ventricular surface.

The precise anatomy of the atrioventricular conduction axis has far-reaching surgical significance in the presence of associated malformations. The close relationship between the non-branching bundle and the pulmonary valvar orifice complicates both closure of ventricular septal defects and relief of obstruction within the morphologically left ventricular outflow tract. Thus, in patients with

perimembranous ventricular septal defects, the bundle has a grossly abnormal position when compared to the regular position of the conduction axis in hearts with ventricular septal defects in the setting of concordant atrioventricular connections. When viewed by the surgeon, it is to the right hand side (Fig. 39-12) rather than to the left hand side as anticipated in a heart with normal junctional anatomy.

In hearts with less malalignment between the atrial and ventricular septums, the regular node may be positioned so as to make contact posteriorly with the ventricular septum. This is produced by such lesions as double outlet from the right ventricle⁸ and severe pulmonary stenosis or atresia.⁹ In the past, it was often stated that the frequent origin of the conduction axis from a regular node in the setting of mirror-imaged atrial arrangement was because of the right-handed ventricular topology. As was shown by Hosseinpour and colleagues,⁹ all cases described with this pattern had better septal alignment because of the presence of severe pulmonary stenosis or pulmonary atresia. Thus, the same rules apply for prediction of the location of the conduction axis in congenitally corrected transposition irrespective of whether there is usual or mirror-imaged atrial arrangement. The key is the extent of septal malalignment. When there is good septal alignment, then both the regular and the anterior nodes can give rise to penetrating bundles, both of which can join with the branching bundle. Should there be a ventricular septal defect, which is usually the case, this can produce a sling of conduction tissues, as initially described by Monkeberg.¹⁰ The vulnerable position of the long non-branching bundle almost certainly explains why heart block remains a frequent complication after surgical closure of associated malformations. Atrioventricular dissociation, nonetheless, may sometimes be present at birth. More frequently, there is progressive acquired atrioventricular dissociation, often culminating in complete heart block.⁴

Figure 39-12 The cartoon shows the view of a perimembranous ventricular septal defect in congenitally corrected transposition through a generous ventriculotomy. In the expected situation, the conduction axis, because of the malalignment gap (see Fig. 39-10) runs antero-cephalad relative to the defect.

Associated Malformations

In the majority of cases encountered clinically, the potential correction of the circulatory pattern produced by the double discordance is uncorrected by the presence of one or more associated malformations. Of these, three are so typical as to be considered almost part of the segmental combination, namely, an interventricular communication, obstruction of the subpulmonary outflow tract, and anomalies of the morphologically tricuspid valve.^{1,2} The morphology of each of these lesions can be variable.

Ventricular Septal Defect

An interventricular communication, if present, and such holes are expected in at least half the patients, is usually perimembranous. It occupies a subpulmonary position, with the diagnostic feature being fibrous continuity between the leaflets of the pulmonary valve and, in usual arrangement, the left-sided tricuspid valve (Fig. 39-13). Such perimembranous defects typically extend posteriorly and inferiorly towards the crux of the heart, opening primarily into the inlet of the morphologically left ventricle. The posterior margin of the defect is then formed by an extensive area of fibrous continuity between the leaflets of the pulmonary, mitral, and tricuspid valves (see Fig. 39-13), with this feature removing the anticipated reversed off-setting of the attachments of the atrioventricular valves. As already explained, the atrioventricular conduction axis runs antero-superiorly relative to these defects (see Fig. 39-13), the opposite of that expected for perimembranous defects in hearts with concordant atrioventricular connections. In rare instances, the defect can be subpulmonary but with exclusively muscular rims. In this setting, the atrioventricular conduction axis will continue to run antero-superiorly. Muscular defects, however, can be found in any other

Figure 39-13 The image shows the typical perimembranous ventricular septal defect found in hearts with congenitally corrected transposition, as viewed from the morphologically left ventricle. Note the fibrous continuity between the leaflets of the pulmonary and left-sided morphologically tricuspid valves. The antero-cephalad position of the conduction axis is marked.

Figure 39-14 The cartoon shows how all types of ventricular septal defect can be found in congenitally corrected transposition. The location of the conduction axis is shown in yellow.

part of the ventricular septum. Should a muscular defect open between the outlets, then the bundle may occupy a postero-inferior position (Fig. 39-14). Defects can also be found in doubly committed and juxta-arterial position, roofed by continuity between the leaflets of the aortic and pulmonary valves, with absence of the septal component of the infundibulum. These defects are particularly common in Asian populations.¹¹

Obstruction of the Morphologically Left Ventricular Outflow Tract

Excluding hearts with pulmonary atresia, stenosis of the outflow tract from the morphologically left ventricle occurs in approximately one-third to one-half of patients with usual atrial arrangement. The stenosis is isolated in less than one-fifth of these cases, being combined in about four-fifths with a ventricular septal defect, and in about one-third also with abnormalities of the morphologically tricuspid valve. The anatomical nature of the stenosis varies.¹² Valvar stenosis is usually accompanied by one or another variety of subpulmonary obstruction. The latter may take the form of muscular hypertrophy of the septum and the ventricular free wall, a fibrous diaphragm, or else an aneurysmal dilation of fibrous tissue derived from the interventricular component of the membranous septum (Fig. 39-15). More rarely, tags may originate from either of the atrioventricular valves, or even from the leaflets of the pulmonary valve.¹² Subvalvar pulmonary obstructions, when present, are intimately related to the non-branching atrioventricular bundle (Fig. 39-16).

Lesions of the Morphologically Tricuspid Valve

There is a marked discrepancy between the incidence of such changes found at autopsy and those recognised during life. Examination of autopsied cases reveals anomalies

Figure 39-15 The cartoon shows the anatomical substrates for obstruction of the outflow tract from the morphologically left ventricle.

Figure 39-16 The image shows a subvalvar fibrous shelf seen from the apex of the morphologically left ventricle in a heart also exhibiting a perimembranous ventricular septal defect. Note the intimate relationship between the shelf and the conduction axis (red dotted line).

of the tricuspid valve in almost nine-tenths of cases, whereas only one in three patients has haemodynamic alterations due to such abnormalities. The commonest underlying pathology is valvar dysplasia, with or without apical displacement of the septal and mural leaflets, the latter of course being the essence of Ebstein's malformation. Unlike the situation in hearts with concordant

atrioventricular connections, atrialisation and thinning of the inlet portion of the morphologically right ventricle, as commonly seen in Ebstein's malformation with concordant atrioventricular connections, are not always found in the setting of congenitally corrected transposition (Fig. 39-17).

In about three-quarters of the cases, the valvar anomalies are combined with a ventricular septal defect. The tricuspid valve can also override and straddle in the setting of congenitally corrected transposition, with hypoplasia of the morphologically right ventricle increasing concomitant with the proportion of the overriding atrioventricular junction connected to the dominant left ventricle (Fig. 39-18). The end-point of this spectrum of overriding is double inlet left ventricle with left-sided incomplete right ventricle, with double inlet being diagnosed when more than half of the overriding junction is connected in the left ventricle. The morphologically mitral valve can also override and straddle, often in combination with double outlet from the right ventricle.⁸ As with overriding of the tricuspid valve, mitral valvar overriding is part of a spectrum of malformation, with the endpoint in this instance being double inlet right ventricle with right-sided incomplete left ventricle. The relationships of dominant and incomplete ventricles in these spectrums, of course, are reversed when congenitally corrected transposition is found in its mirror-imaged variant. The mitral valve can also prolapse with some frequency in the setting of congenitally corrected transposition.¹³

Figure 39-17 The image shows the typical appearance of Ebstein's malformation of the morphologically (morph.) tricuspid valve. The valvar hinge line (blue dotted line) is displaced relative to the left atrioventricular junction (red dotted line), but the mural thickness is the same in the inlet as in the apical trabecular component (arrows).

Figure 39-18 Hypoplasia of the morphologically (morph.) right ventricle, with apex-forming morphologically left ventricle in the setting of straddling and overriding of the left-sided morphologically tricuspid valve.

Disharmonious Segmental Arrangements

In almost all instances, when congenitally corrected transposition is found with usual atrial arrangement, there is left hand ventricular topology, whereas right hand ventricular topology is found when discordant atrioventricular connections are found with mirror-imaged atrial arrangement. On exceedingly rare occasions, the atrioventricular connections can be discordant when there is usual atrial arrangement and right hand ventricular topology.¹⁴ The hearts typically show multiple associated malformations, with rotational abnormalities of the ventricular mass, straddling valves, and juxtaposition of the atrial appendages. Providing the usual rules are followed for determining the morphology of the chambers, there should be no problems these days in diagnosing the malformations, despite their complexity.

Other Ventriculo-arterial Connections

In strict terms, those patients having other ventriculo-arterial connections in combination with discordant atrioventricular connections do not have congenitally corrected transposition. It is convenient, nonetheless, to discuss them in this chapter, since it is the discordant atrioventricular connections which are the most important morphological features. The commonest variant in terms of the ventriculo-arterial connections is single outlet from the heart. In this respect, there are three possibilities: a common arterial trunk, a single pulmonary trunk with aortic atresia, and a single aortic trunk with pulmonary atresia. Of these, the first two are rare.^{15,16} With pulmonary atresia, there is usually a large ventricular septal defect in the subaortic position. This lends itself to tunnelling to the aorta as part of anatomical

correction. The conduction tissue should be anticipated to be antero-superiorly located relative to this defect, arising from an anterior atrioventricular node, so extreme care is needed if enlargement of the defect is attempted as part of an anatomical correction. The problem is then magnified, since it is cases such as these with pulmonary atresia that should be anticipated also to have a regular node, or else a sling of conduction tissue. Thus, the entire ventricular borders of the defect are likely to be occupied by the conduction tissue axis.⁹ Pulmonary atresia can also be found when the ventricular septum is intact.^{17,18} In these cases, the atretic pulmonary artery can usually be traced to the morphologically left ventricle, so it is appropriate to describe these patients as having congenitally corrected transposition with pulmonary atresia. The arrangement of the morphologically left ventricle itself, however, is reminiscent of hypoplastic left heart syndrome, and these patients will be candidates only for functionally univentricular repair.

The rare but important combination of discordant atrioventricular connections with concordant atrioventricular connections can be found either with usual atrial arrangement or in the setting of mirror-imaged atria. Several purported examples of this rare combination have been in patients with isomeric atrial appendages, but in this combination the atrioventricular connections will be biventricular and mixed rather than discordant (see Chapter 1). In some cases, the aorta is posterior and to the right of the pulmonary trunk, albeit with a parallel rather than a spiral arrangement of the arterial trunks. The combination has been described as isolated ventricular inversion, not that this nomenclature contributes much to understanding.¹⁹ The important feature is that, when discordant connections at atrioventricular level are combined with concordant ventriculo-arterial connections, the combination produces the haemodynamics of transposition irrespective of the infundibular morphology. Such patients are ideal candidates for surgical correction by atrial redirection procedures,²⁰ since this provides both anatomical and physiological correction of the circulations, restoring the morphologically left ventricle to its systemic role.

Many of the patients having discordant atrioventricular connections combined with double outlet right ventricle have right-sided hearts and pulmonary stenosis.²¹ It was in a heart such as this that Mönckeberg¹⁰ first described the unusual formation of paired atrioventricular nodes joining to a common atrioventricular bundle, the so-called Mönckeberg sling. The heart described by Mönckeberg¹⁰ was positioned in the right side of the chest, but the segmental combination can exist with any cardiac position. The ventricular septal defect is usually in subpulmonary position, but subaortic, doubly committed, and non-committed defects have all been described. All kinds of relations between the great arterial trunks can also be present. The rarest ventriculo-arterial connection is that of double outlet left ventricle. This must also be anticipated to exist with various arterial relationships, and with the interventricular communication related in varying fashion to the arterial trunks, and with the typical complicating lesions.

Morphogenesis

As we have described in Chapter 3, the definitive chambers of the heart are produced by ballooning from the

primary heart tube, with atrial appendages ballooning in parallel from the atrial component of the tube, while the apical components of the ventricles balloon in series from the inlet and outlet parts of the ventricular loop. If development proceeds in normal fashion, the primary heart tube bends to the right during early development.²² This leaves the atrioventricular canal connected primarily to the part of the loop from which will develop the morphologically left ventricle. Expansion of the canal to the right then permits the right atrium to connect directly with the developing morphologically right ventricle, which itself is positioned rightward relative to the morphologically left ventricle. In certain circumstances, instead of bending to the right during development, the heart tube turns leftward. Such leftward looping places the outlet component of the primary tube, from which will develop the morphologically right ventricle, to the left of the morphologically left ventricle. In this setting, so as to permit the atrioventricular canal to open directly to both ventricles, it must expand leftward rather than rightward, at the same time placing the developing morphologically left atrium in communication with the morphologically right ventricle, and leaving the morphologically right atrium connecting to the morphologically left ventricle. This process, therefore, produces discordant atrioventricular connections. It is not yet known why such disharmonious looping should be associated so frequently also with discordant ventriculo-arterial connections, nor why the presence of discordant atrioventricular connections should be associated so frequently with the typical associated malformations.

INCIDENCE AND AETIOLOGY

Analysis of the patients entered into the New England regional infant cardiac programme identified only 16 infants with congenitally corrected transposition.²³ Patients with congenitally corrected transposition, however, accounted for 0.6% of those with congenitally malformed hearts seen at the Boston Children's Hospital during the period from 1972 to 1987.²⁴ This correlates well with the incidence for congenital corrected transposition of 0.5% calculated by the Baltimore-Washington infant study group.²⁵ The variant with mirror-imaged atrial chambers is said to be very rare, with less than 100 well-documented cases recorded in one review,²⁶ albeit that increasing clinical experience suggests that this may be an underestimate.

The commonest associated cardiac abnormality is a ventricular septal defect, found in just over two-thirds of cases.²⁷ In up to half, there is stenosis in the outflow tract of the subpulmonary morphologically left ventricle.^{27,28} The morphologically tricuspid valve is abnormal in almost all cases seen at autopsy, with varying degrees of displacement into the ventricular cavity and Ebstein-like abnormalities. Rarely the valve can exhibit a double orifice. Coarctation of the aorta and interruption of the aortic arch are rare complications. Tricuspid valvar regurgitation develops with great frequency over the lifetime of most patients, as does complete heart block. The aetiology of the condition is unknown, and is considered multi-factorial. Familial incidence is rare, with but one publication noting its occurrence.²⁹ The ratio of gender in those with usually

arranged atrial chambers is about 1.6 to 1, with males predominating.

CLINICAL PRESENTATION

The clinical presentation is influenced by the presence of the associated cardiac anomalies. Those with a large ventricular septal defect in the absence of obstruction to the morphologically left ventricular outflow tract obstruction will present with cardiac failure. Cardiac failure will also be seen in those with morphologically tricuspid valvar incompetence due to dysplasia of the valvar leaflets, often associated with marked displacement of the septal and mural leaflets into the morphologically right ventricular cavity, in other words producing Ebstein's malformation. Where there is severe pulmonary stenosis or atresia of the morphologically left ventricular outflow tract, the infant will be cyanosed, often having a ductal-dependent pulmonary circulation. Occasionally, there may be signs of complete heart block, either antenatally or in the immediate postnatal period, which can cause cardiac failure. When there is a large left-to-right shunt or severe tricuspid valvar regurgitation, sometimes together with complete heart block, then an infant may present with cardiomegaly in the first few days of life with cardiac failure, and may require inotropic and ventilatory support.^{28,30} The development of tricuspid regurgitation and morphologically right ventricular failure, however, may not occur until later in life.³¹ Those with a ventricular septal defect can also exhibit a moderate degree of obstruction within the morphologically left ventricular outflow tract. This combination provides balanced pulmonary and systemic circulations, with saturations of oxygen in the mid 80s, without cardiac failure. Rarely, those without associated cardiac anomalies can exhibit no clinical problems. In this setting, the abnormal segmental combinations can present as an incidental finding in an older patient, often with the development of complete atrioventricular dissociation. In some circumstances, the condition is brought to light when a right-sided heart is noted incidentally on a chest radiograph.

The physical findings are also determined by the nature of the associated cardiac abnormalities. Thus, there may be signs of cardiac failure, with failure to thrive, in those cases presenting in early infancy and requiring medical or surgical treatment. The cyanosed neonate will require construction of a systemic-to-pulmonary arterial shunt in the first few days of life. Signs of increasing tricuspid valvar regurgitation may be somewhat insidious, occurring over the first few years of life with the gradual onset of right ventricular dysfunction, and only then does cardiac failure become evident.³² Examination of patients of all ages will reveal the signs of either congestive cardiac failure or cyanosis.

INVESTIGATIONS

Electrocardiography

In those with usual atrial arrangement, the ventricular conduction system is disposed in mirror-imaged fashion. Thus, the activation of the ventricular septum is from right to left in a superior and anterior direction. This results in presence of Q waves in the right precordial leads, and absence of T waves in the left precordial leads, along with a reversal of the normal precordial pattern of the Q wave pattern (Fig. 39-19).³³ This pattern of electrical activation of the myocardium is

Figure 39-19 This electrocardiogram is from a boy aged 4 years, with usual atrial arrangement, a left-sided heart, moderate insufficiency of the left-sided atrioventricular valve, and mild pulmonary hypertension. Note the reversal of the pattern of the Q waves in the precordial leads, with positive T waves throughout these leads.

present in some three-quarters of patients.³⁴ The presence of conduction abnormalities and complete heart block is also frequent. The typical electrocardiographic pattern in those with usual atrial arrangement, therefore, can be summarised as left-axis deviation, reversal of the precordial progression of the Q waves, and prominence of the Q waves in leads III and aVF. QS complexes are seen in leads III and aVF, and over the right precordium.³⁵ These patterns will change when there is volume overloading or pressure overloading of either the right or left ventricle, and are mirror-imaged in those having mirror-imaged atrial arrangement.^{36,37}

Chest Radiography

Detailed evaluation of the chest X-ray has been superseded by non-invasive evaluation of the cardiac morphology by echocardiography. The plain chest X-ray, nonetheless, may reveal congestion of the lung fields, or plethora suggesting cardiac failure. Cardiomegaly may either be an indication of volume loading of the heart or of cardiac failure. The heart itself is often positioned in the middle or right side of the chest, with the apex pointing directly down or to the right. In those with mirror-imaged atrial arrangement, the heart is frequently found in the left side of the chest, with the apex pointing to the left. An unusual location of the heart is a further clue to the presence of congenitally corrected transposition.³⁸⁻⁴⁰ This finding, of course, is not a diagnosis in itself, but rather an indication for further investigation.

Echocardiography

Patients with congenitally corrected transposition are diagnosed nowadays echocardiographically, both antenatally and postnatally. Until very recently, the cross

sectional approach was standard, but three-dimensional echocardiography is now available for detailed cardiac analysis. This permits very accurate assessment of the cardiac morphology, without the need to make recourse to further investigations.⁴¹⁻⁴³ Detailed sequential segmental analysis is the pivotal investigation. This will show that the systemic veins drain to the morphologically right atrium, which is joined to the morphologically left ventricle. The connection of the morphologically left ventricle is then to the pulmonary trunk. The pulmonary veins will be identified joining the morphologically left atrium, which is connected to the morphologically right ventricle and thence to the aorta (Fig. 39-20). The morphologic nature of the left ventricle is identified on the basis of its smooth walls, and the presence of paired papillary muscles supporting the morphologically mitral valve. The morphologically right ventricle will be recognised on the basis of its coarse apical trabeculations, the presence of the moderator band, and attachments of the septal leaflet of the morphologically tricuspid valve directly to the septum. Associated lesions, such as ventricular septal defects (Fig. 39-21), different types of obstruction within the outflow tract of the morphologically left ventricle such as tissue tags or fibrous shelves (Fig. 39-22), and pulmonary valvar stenosis or atresia will clearly be seen. The morphology of the morphologically tricuspid valve must be studied with care. This can be markedly dysplastic, with displacement of the septal and inferior leaflets into the morphologically right ventricular cavity in those with associated Ebstein's malformation (Fig. 39-23). When there is marked dysplasia of the valvar leaflets, it is usual to see moderate-to-severe tricuspid valvar regurgitation on colour flow mapping (Fig. 39-24). Straddling and overriding of either the right- or left-sided atrioventricular valves should be identified if

Figure 39-20 The cross sectional echocardiogram, in four-chamber projection, shows the essential features of discordant atrioventricular connections. Note the reversed off-setting of the leaflets of the right-sided mitral and left-sided tricuspid valves (arrows). Morph. LA, morphologically left atrium.

present, taking care to exclude hypoplasia of either ventricle sufficient to militate against biventricular surgical repair. Sequential segmental analysis will also serve to identify rarer combinations found in some patients with discordant atrioventricular connections, such as those with double outlet right or left ventricles, or concordant ven-

triculo-arterial connections. The latter combination is of particular significance, since although the patients present with the features of transposition, the segmental combinations mean that an atrial redirection procedure is the corrective procedure of choice, placing the morphologically left ventricle as the pump to the systemic circulation.²⁰

Figure 39-21 The cross sectional echocardiograms, in four-chamber section, show a perimembranous ventricular septal defect (bracket) in the setting of discordant atrioventricular connections. Panel A shows the fibrous continuity between the leaflets of the pulmonary and left-sided tricuspid valves, while panel B shows the anterior and left-sided location of the aorta. LV, left ventricle; Morph, morphologically; RA, right atrium; RV, right ventricle.

Figure 39-24 Colour flow mapping shows severe regurgitation across the morphologically (morph.) tricuspid valve.

Figure 39-25 The angiogram shows a banded pulmonary trunk, the band having been placed to train the morphologically (morph.) left ventricle.

Cardiac Catheterisation and Angiography

These modes of investigation have become almost obsolete in the current management of either infants or older patients. They may be necessary in situations where there are multiple ventricular septal defects, which cannot clearly be seen using echocardiography. The investigation of pulmonary hypertension in older patients, and the evaluation and measurement of pulmonary vascular resistance, may be necessary to establish operability. Rarely, in those with pulmonary atresia, major aortopulmonary collateral arteries supply most of the blood to the lungs. The origin and course of these arteries can more clearly be shown with angiography. When anatomical repair is planned, such as the double-switch procedure, coronary angiography may be helpful in delineating the anatomy of the coronary arteries. When there has been prior construction of a systemic-to-pulmonary arterial shunt, or the pulmonary trunk has been banded to reduce the flow of blood to the lungs or to train the morphologically left ventricle (Fig. 39-25), haemodynamic and angiographic data is required to demonstrate the anatomy of the pulmonary arteries and to show whether the morphologically left ventricle has been adequately trained so that it can support the systemic circulation.⁴⁴

Computerised Axial Tomography and Magnetic Resonance Imaging

These modalities are now available non-invasively to evaluate the morphology and haemodynamics of patients with congenitally corrected transposition. To a large extent, their use depends on their availability at individual centres. In infants and small children, a general anaesthetic is usually necessary if these scans are to provide accurate data, but more modern systems, and faster computing power, may well provide accurate data without the requirement for

Figure 39-26 The magnetic resonance images show the results of the Senning operation as performed to redirect the atrial venous returns as part of anatomical correction. Panel A shows a short-axis cut and panel B an angulated cut producing a four-chamber section. Morph, morphologically; LV, left ventricle; RA, right atrium; RV, right ventricle.

anaesthesia. Magnetic resonance imaging is also of value in the post-operative situation to check the patency of the venous (Fig. 39-26) and arterial pathways subsequent to reconstructive surgery. The bedrock for evaluation of patients with congenitally corrected transposition of all ages, nonetheless, is echocardiography, with other modalities being used to fine-tune the diagnosis and haemodynamics.

Differential Diagnosis

It should now be always possible in all patients to make a clear diagnosis of congenitally corrected transposition and to identify all associated lesions. Some other lesions may still provide a problem. Distinction from corrected transposition can sometimes be difficult in those with discordant atrioventricular connections associated with other ventriculo-arterial connections, in those having left-handed ventricular topology in the setting of isomeric atrial appendages, in those having anterior and left-sided ascending aortas with normal atrial arrangement, and in those with anterior and right-sided aortas in the mirror-imaged situation. Appropriate echocardiographic interrogation, nonetheless, should identify these variations in morphology.

MANAGEMENT

The Morphologically Right Ventricle and Tricuspid Valve in the Systemic Circulation

The management of patients with congenitally corrected transposition would be relatively easy were it not for the morphologically right ventricle being responsible for pumping the systemic circulation. Physiological restoration of normal circulatory patterns can be restored by closing ventricular septal defects, if present, relieving any obstruction in the outflow tract to the pulmonary arteries, and repairing or replacing the morphologically tricuspid valve, while disturbances of atrioventricular conduction can be treated by placement of a pacemaker. If these procedures

are undertaken leaving the morphologically right ventricle pumping the systemic circulation, however, the ventricle may show signs of severe failure in infancy or later in life. On some occasions, the ventricle may sustain normal cardiac haemodynamics until the patient is well into old age, only then to fail. The causation of such morphologically right ventricular failure is poorly understood. Various explanations can be offered, such as volume loading or increasing tricuspid regurgitation, but it is as yet not known why some patients develop this problem and others do not.

In some neonates and infants, there is marked dysplasia of the leaflets of the morphologically tricuspid valve. The severe, or increasingly severe, tricuspid regurgitation thus produced creates a volume load on the morphologically right ventricle, which is then exacerbated by dilation of the valvar annulus and, hence, worsening cardiac failure. This produces a vicious circle. The strain on the morphologically right ventricle may be further exacerbated by the presence of volume-loading caused by deficient ventricular septation (Fig. 39-27). The morphologically tricuspid valve may itself initially be competent, but over the years can become regurgitant, this becoming worse with volume-loading and right ventricular dilation. It is unclear which patients might develop this complication. It seems fairly certain that, with severe dysplasia and displacement of the leaflets of the tricuspid valve towards the apex of the morphologically right ventricle, this creates a setting for tricuspid valvar regurgitation and ensuing cardiac failure. Increasing tricuspid regurgitation, nonetheless, can occur over time in patients who have a normally structured tricuspid valve. Since many patients tolerate well the tricuspid regurgitation for significant periods, along with a degree of morphologically right ventricular dysfunction, and can remain stable with medical management, it can be difficult to decide when to intervene surgically. Should surgical intervention with repair or replacement of the tricuspid valve be left too late, there is little chance of right ventricular functional recovery, with associated high operative risks. Thus, the timing

Figure 39-27 The chart shows the vicious circle of morphologically right ventricular failure, exacerbated in presence of a ventricular septal defect.

of intervention to achieve a good outcome is difficult in the group of patients who are relatively stable clinically.^{32,45–50}

It was shown in those with transposition and concordant atrioventricular connections that training of the morphologically left ventricle by banding the pulmonary trunk permitted a safe arterial switch to be performed, thus restoring the left ventricle to its role of pumping the systemic circulation.⁵¹ The same procedure has now been applied successfully in patients with congenitally corrected transposition (see Fig. 39-25), usually those having a degree of morphologically right ventricular failure and tricuspid valvar regurgitation. It has also been shown that banding the pulmonary trunk can sometimes reduce the amount of tricuspid valvar regurgitation by realigning the ventricular septum, pushing the septal leaflet of the tricuspid valve back into the right ventricle so that it apposes the other valvar leaflets and reduces the amount of valvar regurgitation. This reduction in valvar regurgitation reduces the volume loading of the morphologically right ventricle, helping to break into the vicious circle (see Fig. 39-27). Thus, banding in itself may be a therapeutic option, although more usually it is used to prepare the morphologically left ventricle for subsequent anatomical repair.^{52–54}

Medical Management

Medical management involves the usual modalities for cardiac failure, such as inhibition of angiotensin-converting enzymes, diuretics, and control of arrhythmias with pacing to raise the heart rate when necessary.

Surgical Palliation

Procedures to increase the flow of blood to the lungs, such as construction of systemic-to-pulmonary arterial shunts, either centrally or by the modified Blalock-Taussig option, or banding of the pulmonary trunk to reduce flow in those with ventricular septal defects and cardiac failure, can be used to stabilise patients until they are bigger and able to undergo more complex surgical correction.

Corrective Surgery

It is increasingly apparent that curative surgery is probably not possible. It is certainly possible to provide corrective surgery, either physiologically or anatomically,

but the patients always require careful follow-up, and often require other procedures, such as changes of valved conduits, repair of cardiac valves, and insertion of cardiac pacemakers should complete heart block develop. The reconstructed venous pathways may also become obstructed and require relief, after the atrial switch procedure.

Physiological Repair

Associated cardiac anomalies can be repaired with this approach, albeit that the morphologically right ventricle remains as the pump to the systemic circulation. As already discussed, ventricular septal defects, if present, can be closed, obstruction within the left ventricular outflow tract can be relieved by either resection or placement of a valved conduit, and the tricuspid valve, if leaking, can be repaired or replaced.

Usually the ventricular septal defect is perimembranous in position. It is typically approached through an incision in the right atrium, and then closed through the morphologically mitral valve. Some muscular outlet defects can be closed via the pulmonary trunk and the pulmonary valve. The conduction system passes in anterocephalad fashion around the pulmonary outflow tract. To avoid damaging the conduction system, either continuous or interrupted sutures are placed on the morphologically right ventricular margin of the defect superiorly, and from the morphologically left ventricular side of the margin inferiorly.⁵⁵

Relief of stenosis within the morphologically left ventricular outflow tract may require careful resection of accessory tissue, or open pulmonary valvotomy, but in general a valved conduit is placed from the morphologically left ventricle to the pulmonary arteries so as to relieve the obstruction. Incisions placed across the attachments of the pulmonary valvar leaflets, because of the disposition of the conduction system, will cause heart block. In order to avoid the conduction system, and the papillary muscle of the mitral valve, the ventriculotomy is placed towards the apex of the ventricle. Valved conduits will not last forever, and most will need to be changed. It is wise, therefore, to close the pericardium with a membrane to protect the heart during sternal re-entry at reoperations. Repair or replacement of the morphologically tricuspid valve sometimes has to be done as part of physiological repairs when there is severe tricuspid valvar regurgitation. It is fraught with problems of continuing cardiac failure, since often the morphologically right ventricle is failing by the time such surgery is entertained. In addition, particularly in younger patients where there is marked dysplasia of the valvar leaflets, repair can be extremely difficult, if not impossible. Under these circumstances, replacement may well be necessary.

Problems Associated with Physiological Repair

Many centres throughout the world have highlighted the problem of right ventricular failure following physiological repair. This deterioration in right ventricular function is usually associated with the development of tricuspid valvar regurgitation, which can occur within a few months of repair, or develop more insidiously over several years.^{32,45–50} It was such uncertainty regarding the longer-term outcome of physiological repair that led to the idea of restoring the

morphologically left ventricle to the systemic circulation, so-called anatomical repair.

Anatomical Correction

In this approach, the morphologically left ventricle is restored to pumping the systemic circulation either by combining atrial and arterial switch procedures, or else by performing the atrial switch along with ventricular rerouting. Where the pulmonary and systemic outflow tracts are unobstructed and possess competent and non-stenotic valves, the atrial switch is combined with an arterial switch procedure, the so-called double-switch operation (Fig. 39-28). Where there is pulmonary stenosis or atresia, usually in association with a large ventricular septal defect, the atrial switch is combined with tunnelling of the morphologically left ventricle to the aorta. A valved conduit is then placed from the morphologically right ventricle to the pulmonary arteries (Fig. 39-29).^{53,56-58}

In our unit, the double switch is performed under hypothermic cardiopulmonary bypass, with periods of low flow or circulatory arrest as necessary to achieve a clear operative field.⁵³ Other methods of cardiopulmonary bypass and cardioplegic techniques are equally applicable, and are used by other centres performing this type of surgery. Irrespective of the method used, it is important to ensure reliable myocardial protection. The procedures are long, with long myocardial ischaemic times. When performing the atrial switch, our preference is for the Senning procedure (see Fig. 39-27), sometimes with supplementation of the pulmonary venous atrium by incorporation of heterologous or homologous materials.^{59,60} The Mustard operation is equally applicable. Associated lesions are dealt with

in appropriate fashion, and then the arterial trunks are switched, together with the coronary arteries. Relocation of the pulmonary trunk may be achieved by transposing the pulmonary arteries anterior to the reconstructed aorta, or they may be left in posterior position. In general, if the aorta is more or less anterior to the pulmonary trunk, then the pulmonary arteries are relocated anteriorly. If the arterial trunks are more side-by-side, then we leave the pulmonary arteries behind the newly reconstructed aorta. At the end of the procedure, it is important to check on the reconstruction using transoesophageal or epicardial echocardiography, confirming the patency of the venous and arterial pathways as well as ensuring adequate ventricular function.

Ventricular Rerouting Combined with Atrial Redirection

The atrial switch is performed in the same manner as for the double-switch procedure. In most instances, in those suitable for ventricular rerouting, there is marked rightward rotation of the heart in those with usual atrial arrangement, and leftward rotation in those with mirror-imaged atrial arrangement, so that the ventricles come to lie anterior to the atrial chambers. This makes access to the atrial chambers more difficult when baffling the systemic venous pathways to the morphologically tricuspid valve, and the pulmonary veins to the mitral valve (see Fig. 39-27). Access to the morphologically tricuspid valve should reparative surgery be necessary can also be very difficult. An incision is made in the morphologically right ventricle, permitting creation of an intraventricular tunnel between the ventricular septal defect and the aorta. In creating this tunnel, care has to be taken to avoid any subaortic stenosis. The repair is completed by placing a valved conduit from the right ventriculotomy to the pulmonary arteries (see Fig. 39-29).^{56,61} Once the reconstruction has been performed,

Figure 39-28 The cartoon shows the steps involved in the so-called double-switch procedure.

Figure 39-29 The cartoon shows the end-result after an atrial redirection procedure combined with intraventricular rerouting of the ventricular septal defect to the aorta, and placement of a conduit from the morphologically (morph.) right ventricle to the pulmonary arteries.

echocardiographic evaluation in the operating room is again important to ensure that all the reconstructed pathways are unobstructed. We would strongly advise closure of the pericardium using a membrane, facilitating re-entry when the conduit needs to be changed.

Post-operative Management

The operative procedures are long. The median times of cardiopulmonary bypass in our unit have been around 2½ hours, with aortic cross-clamping lasting for more than 2 hours, and circulatory arrest lasting for almost three-quarters of an hour. It is often our practice not to close the sternum until 24 to 48 hours after completion of the operation, using inotropic support as necessary to maintain cardiac output. On occasion, extracorporeal bypass has been required for a few days to support the recovering myocardium.

Problems with Anatomical Correction

Perhaps surprisingly, infants in severe cardiac failure, with large ventricular septal defects and tricuspid regurgitation, have done well in our hands following the double-switch procedure, with none of these patients dying. Overall, in our own series of 54 patients, early mortality for anatomical repair was 5.6%, with 7 patients developing post-operative complete heart block. We have also lost two further patients thus far during follow-up. Regurgitation across the morphologically tricuspid valve has decreased in all those patients following anatomical repair in whom it was present prior to the operation. Such regurgitation has not arisen as a new problem during the period of follow-up. This is almost certainly due to the morphologically right ventricle working at lower pressures in the pulmonary circuit subsequent to repair. When anatomical correction is achieved using intra-ventricular rerouting, it is necessary, at some time, to change the conduit placed from the right ventricle to the pulmonary arteries, but despite the position of the conduit behind the sternum, such changes can be performed safely. Neo-aortic valvar regurgitation has been reported in other series, and in a small proportion of cases, it has been necessary to replace the aortic valve. Surgically induced complete heart block can be a problem, as in one-eighth of our patients, but can be managed by placement of a pacemaker.^{53,57} We have noted that the retrained morphologically left ventricle has a greater tendency to fail than the morphologically left ventricle that has been maintained at systemic pressures from birth.⁶² This is of concern, and emphasises the need for continuing surveillance of these patients. It seems likely that, over time, anatomical repair will prove a better option for the majority of patients. It is not possible, as yet, to select out patients who might better be managed with physiological as opposed to anatomical repair.

Alternative Approaches

In situations in which there is hypoplasia of the left or right ventricles, or overriding or straddling of the atrioventricular valves, it may not be possible to achieve biventricular repair. Conversion to the Fontan circulation is then warranted, and can have good outcomes.⁵⁰ Conversion can be divided into two stages, with initial construction of a superior cavopulmonary bidirectional shunt, followed by completion of the Fontan circulation after a delay of 1 or 2 years, usually with placement of an external non-valved conduit from the inferior caval vein to the pulmonary arteries. The results

of this approach thus far have been entirely satisfactory. Another alternative to the complex repairs may well be to maintain the pressure in the morphologically left ventricle at approximately half systemic pressure, preserving in this way the alignment of the ventricular septum, and ensuring that tricuspid regurgitation does not become a post-operative problem. This can be achieved by making limited resections of obstructions within the morphologically left ventricular outflow tract, or by placing valved conduits of smaller diameter from the morphologically left ventricle to the pulmonary arteries. When associated with construction of a bidirectional cavopulmonary shunt, this may prove a worthwhile approach, particularly when it is impossible to tunnel the ventricular septal defect to the aorta.⁶³

Conclusions

Over the long term, physiological repair of patients having congenitally corrected transposition or discordant atrioventricular connections, with repair of the associated cardiac anomalies, has proved an unsatisfactory strategy for management. Over the last 20 years, therefore, use of an anatomical repair, either by the double-switch procedure or by ventricular rerouting combined with atrial redirection, has become more popular. Although more complex in technical terms, this strategy has the advantage of being applicable with good outcomes to very sick patients, who are in marked cardiac failure with severe tricuspid regurgitation. The disadvantages are the need for continuing surveillance, valvar replacement or repair, and change of conduits. There is also a concern about ventricular failure, particularly in those patients that have undergone retraining of the morphologically left ventricle. It is unlikely at this time that we can see a way forward to providing a surgical cure for patients with congenitally corrected transposition. Whilst surgical intervention will hopefully prolong life, continuing problems almost certainly will arise which require reintervention and further surgery.

This thoughtful paper analyses physiological versus anatomical repair in patients with congenitally corrected transposition, and suggests ways of maintaining right ventricular function by maintaining left ventricular pressures and alignment of the ventricular septum in order to avoid late tricuspid valvar regurgitation by displacement of the septal leaflet.

Double Outlet Ventricle

JAMES L. WILKINSON, LUCAS J. EASTAUGH, and ROBERT H. ANDERSON

The concept of double outlet as a ventriculo-arterial connection has been well accepted for several decades. This is described elsewhere in this textbook (see Chapter 1). It may occur with each atrial arrangement, with any atrio-ventricular connection, and with all possible variations of ventricular morphology. The morphologic arrangement can then be further complicated by the presence of a host of associated defects, some common and some rare. The clinical picture is as inconstant as the anatomical permutations and associations would suggest. In this chapter, we review the combinations in which the outflow tracts arise from only one ventricle, but in the setting of hearts with two ventricles, and in which each ventricle possesses its own atrioventricular connection, in other words, those with biventricular atrioventricular connections. Origin of both arterial trunks from the same ventricle, of course, can also be found in the setting of univentricular atrioventricular connections, but these lesions are considered in the chapters of the book concentrating on the functionally univentricular arrangements (Chapters 31 and 32).

HISTORY

The first example of double outlet right ventricle known to us was described in 1793, by Mr Abernethy of St Bartholomew's Hospital, who commented that 'both ventricles, the left by means of an opening in the upper part of the septum ventriculorum, projected their blood into the aorta'.¹ Farre² regarded this case as being, in most respects, similar anatomically, and in its clinical history, to a number of other cases which were undoubtedly examples of what we would now describe as tetralogy of Fallot, albeit that Farre drew particular attention to the right ventricular origin of the aorta in the case described by Abernethy. The term double outlet right ventricle, however, did not appear until 1957.³ Prior to that, examples of hearts with both arterial trunks arising from the right ventricle were described as partial transposition since only the aorta was considered to be placed across the ventricular septum.⁴ Other hearts which would now be designated thus were included in the collections of Peacock,⁵ Von Rokitansky,⁶ Spitzer,⁷ and Abbott,⁴ generally under the terms partial transposition or complete dextro-position of the aorta.⁴ It is inappropriate at this point to revisit the tortuous semantic debate that has continued over the past century, and more, with regard to the use of the term transposition, particularly in relation to hearts with both great arteries arising from the right ventricle. Suffice it to say that, for our purposes, we consider discordant ventriculo-arterial connections to be the essence of

transposition (see Chapter 38). Transposition as thus defined, therefore, is mutually exclusive from double outlet right ventricle.

An equally tortured debate has surrounded the relationship between double outlet right ventricle and tetralogy of Fallot. It is a fact that the extent of right ventricular origin of the aorta is markedly variable in hearts having the phenotypic morphology of tetralogy of Fallot (see Chapter 36). In a proportion of such cases, therefore, the aortic valve will be supported predominantly by right ventricular structures. Indeed, cases of this type were included by Fallot himself in his original description of the lesion that now bears his name.⁸ As we have explained, however, we consider double outlet right ventricle to represent one form of ventriculo-arterial connection, rather than a malformation defined on the basis of phenotypic anatomy. There is also no question but that, in some hearts having the phenotypic morphology of tetralogy of Fallot, the larger part of the overriding subaortic outlet is supported within the right ventricle.^{9,10} Patients having such hearts will be described within this chapter. For quite some time, however, it was suggested that presence of complete muscular infundibulums supporting the entirety of the leaflets of both arterial valves was an essential part of the the diagnosis of double outlet right ventricle.¹¹ It was subsequently established that one of the most important principles of description of congenitally malformed hearts was that structures should be defined in their own right, and not on the basis of another feature which is itself variable.¹² On the basis of this principle, known as the morphological method, it is inappropriate to define double outlet ventricle, a specific form of ventriculo-arterial connection, on the basis of infundibular morphology, this latter feature being but one of the many variables complicating the morphology of the various entities grouped together because both arterial trunks arise in larger part from the same ventricle.

Double outlet right ventricle itself is but one part of the overall group of hearts to be described in this chapter. The other part, namely double outlet left ventricle, is very much rarer. Indeed, for quite some time distinguished morphologists and embryologists went on record as stating that double outlet from a morphologically left ventricle was an embryological impossibility.¹³ Description of a heart with both arterial trunks arising from the left ventricle in the setting of an intact ventricular septum proved beyond doubt that the entity existed.¹⁴ Since then, cases have tended to be described in isolation, rather than in large series, from either the pathological or clinical viewpoints.

PREVALENCE

Double outlet right ventricle is a rare cardiac malformation, accounting for fewer than 1% of all congenital cardiac defects. Although infrequent overall, it is sufficiently common for a number of authors to have accumulated large numbers of pathological, clinical or surgical cases. The more frequent variants of the anomaly are well documented, and present a familiar enough problem to the paediatric cardiologist and surgeon.

Double outlet left ventricle is a very much rarer malformation, albeit that the total number of published cases is now substantial. Indeed, it may be more frequent than has previously been recognised. It probably accounts for fewer than 5% of all hearts with double outlet ventriculo-arterial and biventricular atrioventricular connections. This would correspond to an incidence of fewer than 1 in 200,000 births.

MORPHOLOGY AND CLASSIFICATION

The literature relating to hearts in which both arteries arise in their greater part from the same ventricle is extensive, and includes descriptions of a bewildering variety of anatomic variations. So as to avoid confusion, in our review we focus attention, first, on the categorisation of the various malformations, and only then on the details of morphology, concentrating on the commoner, and more important, malformations.

Categorisation

A logical and step-by-step approach to diagnosis and classification proves of immense value when describing the hearts unified because both arterial trunks arise, in their greater part, from the same ventricle. Analysis, be it in the clinical or pathological situation, follows the same careful sequence that has been outlined in Chapter 1 (Table 40-1). Thus, as with any congenitally malformed heart, analysis starts with ascertainment of atrial arrangement and venous connections. Thereafter, the atrioventricular connections must be established with certainty. At the ventricular level, it is the anatomy of the connection between ventricular mass and great arteries that is the diagnostic feature, albeit that note is taken of the inter-relationships of the arterial trunks, the specific infundibular morphology, and the nature and severity of any obstructive problems in the

Figure 40-1 The cartoon shows the essential difference, when both arterial trunks arise from the same ventricle, in this case the right ventricle, between the interventricular communication and the hole closed by the surgeon so as to reconstitute the ventricular septum (green oval). Note that the muscular outlet septum is exclusively a right ventricular structure. The star indicates the crest of muscular septum.

subaortic and subpulmonary outflow tracts. The size, site, and morphology of the interventricular communication, which is categorised in the same way as any other hole between the ventricles (see Chapter 28), are also of great importance. In this respect, however, when both arterial trunks arise from the same ventricle (Fig. 40-1), the hole between the ventricles serves as the outlet for the other ventricle. Its most important feature, therefore, is its relationship with the subarterial ventricular outlets (Tables 40-2 and 40-3). Attention must also be paid to the integrity and function of the atrioventricular valves, especially the mitral valve, and to the presence of other associated cardiac defects, which are frequent (Table 40-4). It is neither practical nor desirable to use a rigid type of classification for the various malformations united simply because both arterial trunks arise, in their greater part, from the same ventricle. In our view, the categorisation of each case should be individualised, just as the medical and surgical management need to be tailored to cater to the particular problems of the individual patient. Certain anatomic variants in which both arterial trunks arise from the right ventricle, nonetheless, do occur with sufficient frequency to merit separate discussion. We commence our account, therefore, with definition and discussion of the commoner variants, as has

also been discussed in a review of double outlet right ventricle nomenclature as part of the Congenital Heart Surgery Nomenclature and Database Project.¹⁵

Double Outlet Right Ventricle

The commoner variants, in approximate order of frequency, are:

- Those with the interventricular communication in subaortic position, with the aorta spiralling from right to left relative to the pulmonary trunk, along with pulmonary stenosis, the so-called Fallot variant (see Fig. 40-2A)

Figure 40-2 The cartoons show the commoner variants of double outlet right ventricle. A, The variant with a subaortic defect, infundibular pulmonary stenosis, and the aorta to the right of pulmonary trunk, a variant also known as the Fallot type. B, The variant with a subpulmonary defect and parallel arterial trunks, also known as the Taussig-Bing type. C, The variant with a subaortic defect, and with the aorta to the right of the pulmonary trunk, but without pulmonary stenosis. The arrow indicates the path of blood from the left ventricle to the aorta with a subaortic defect.

- Those with the interventricular communication in subpulmonary position, with the aorta to the right of, and parallel to, the pulmonary trunk, the so-called Taussig-Bing variant (see Fig. 40-2B)
- Those with the interventricular communication in subaortic position, and with the aorta spiralling from right to left relative to the pulmonary trunk, but in the absence of pulmonary stenosis (see Fig. 40-2C)

Less common variants are:

- Those with the interventricular communication uncommitted, often described as non-committed, to either subarterial outlet, and with the aorta to the right of the pulmonary trunk, with either spiralling or parallel arterial trunks (Fig. 40-3A)
- Those with the interventricular communication in doubly committed position, with the aorta to the right of the pulmonary trunk, and with spiralling arterial trunks
- Those with the interventricular communication in subaortic position, but with the aorta to the left of the pulmonary trunk with parallel arterial trunks (Fig. 40-3B)
- Those with usual atrial arrangement and discordant atrioventricular connections, usually with the aorta parallel to and to the left of the pulmonary trunk (Fig. 40-3C) (see Chapter 39)
- Those with mirror-imaged atrial arrangement (Fig. 40-3D). Any of the previously mentioned variations may occur.
- Those with isomeric atrial appendages and, hence, mixed and biventricular atrioventricular connections (see Chapter 22)

Figure 40-3 The cartoons show other, less common variants of double outlet right ventricle. **A**, The variant with a non-committed defect. **B**, The variant with the aorta to left of pulmonary trunk, parallel arterial trunks, and pulmonary stenosis. **C**, The variant with discordant atrioventricular connections and usual atrial arrangement. **D**, The variant with mirror-imaged atrial arrangement and concordant atrioventricular connections.

Specific Anatomy of the Commoner Variants

Subaortic Interventricular Communication, Aorta to Right of Pulmonary Trunk, Spiralling Arterial Trunks, and Pulmonary Stenosis

There can be a complete muscular infundibulum supporting each arterial valve in this variant (Fig. 40-4), although fibrous continuity between the aortic and atrioventricular valves is found in a high proportion of cases (Fig. 40-5). The subpulmonary outflow tract is narrowed, with or without

Figure 40-4 In this specimen, both arterial trunks arise from the right ventricle, with each arterial valve supported in its entirety by a complete muscular infundibulum. There is pulmonary stenosis produced by a squeeze (red bracket) between the deviated outlet septum and anomalous septoparietal trabeculations, the hallmark of tetralogy of Fallot, but in this instance in combination with double outlet right ventricle. The yellow Y shows the septomarginal trabeculation.

Figure 40-5 This heart also has unequivocal double outlet right ventricle in association with tetralogy of Fallot, the red bracket showing the narrowed subpulmonary outflow tract, but in this instance with fibrous continuity between the leaflets of the aortic and mitral valves in the roof of the interventricular communication.

hypoplasia of the infundibulum (see Figs. 40-4 and 40-5). Often the valve is additionally involved. The obstructive lesions are similar to those seen in Fallot's tetralogy. The interventricular communication, cradled within the limbs of the septomarginal trabeculation, is perimembranous in four-fifths (see Figs. 40-4 and 40-5), having a muscular postero-inferior rim in the remainder. This feature has major surgical significance, since the atrioventricular conduction axis is not directly related to the margins of the defect in the presence of the muscular postero-inferior rim, being posterior to it, and hence less vulnerable at operation. In many cases, the aortic valve retains part of its connection within the left ventricle, but as long as most of the aorta is supported by the right ventricle, it is appropriate to diagnose the ventriculo-arterial connection as being double outlet (Fig. 40-6). Important associated lesions may include a restrictive interventricular communication, which in essence represents obstruction of the left ventricular outlet, this occurring in up to one-tenth of cases,¹⁰ and mitral stenosis.

With Subpulmonary Interventricular Communication

These hearts are usually described as the Taussig-Bing malformation, recognising the description of the index case in which the pulmonary trunk, which was unobstructed, lay to the left of the aorta and overrode an interventricular communication.¹⁶ In this initial heart, both arterial valves were supported by complete muscular infundibulums. There has subsequently been much discussion as to the most appropriate use of the term Taussig-Bing anomaly,¹¹ but in our opinion¹⁷ the term is best used for the spectrum of overriding of the pulmonary trunk in the setting of parallel arterial trunks, with the ends of the spectrum being either double outlet right ventricle (Fig. 40-7) or discordant ventriculo-arterial connections (see Chapter 38). The interventricular communication, again cradled within the limbs of the septomarginal trabeculation, opens beneath the pulmonary trunk because the muscular outlet septum is attached to the ventriculo-infundibular fold. A muscular postero-inferior rim, formed by union of trabeculation and

Figure 40-6 The cartoon shows how overriding valves are assigned to one or other ventricle. The short axis is viewed from the cardiac apex. According to the cord subtended by the plane of the ventricular septum relative to the overriding valvar orifice, it can be seen that the greater part of the aortic circumference (green surround of red circle) is supported by the right ventricle, with the lesser part (yellow surround) remaining in the left ventricle. The effective ventriculo-arterial connection is double outlet right ventricle.

Figure 40-7 This is an example of the so-called Taussig-Bing malformation, with double outlet ventriculo-arterial connections and with an interventricular communication which opens in a subpulmonary position. It is between the limbs of the septomarginal trabeculation (yellow Y) because the muscular outlet septum inserts to the ventriculo-infundibular fold. Note that the fold also fuses with the postero-caudal limb of the septomarginal trabeculation, producing a muscular postero-inferior rim to the interventricular communication which protects the atrioventricular conduction axis. In this heart, however, there is fibrous continuity between the leaflets of the mitral and pulmonary valves in the roof of the interventricular communication.

fold in two-fifths of cases, often separates the rim of the defect itself from the membranous septum (see Fig. 40-7). In three-fifths of cases, nonetheless, the defect extends posteriorly, becoming perimembranous (Fig. 40-8).

Double Outlet Right Ventricle with Subaortic Defect and No Pulmonary Stenosis

This malformation is similar in many anatomical respects to the anomaly with subaortic defect and pulmonary stenosis (compare Figs. 40-9, 40-4, and 40-5). As in the situation

Figure 40-8 In this example of a Taussig-Bing heart with double outlet right ventricle, the interventricular communication extends to become perimembranous. In this example, there are bilateral infundibulums supporting the leaflets of both arterial valves (stars). Note again that the interventricular communication is cradled within the limbs of the septomarginal trabeculation (yellow Y). This variant of double outlet is seldom associated with pulmonary stenosis. Aortic coarctation, in contrast, is a frequent association, and in autopsied cases is often seen in association with straddling of the mitral valve. The mitral valve can itself also be stenotic, but restriction of the interventricular communication producing left ventricular outlet obstruction is very infrequent.

Figure 40-9 This heart has double outlet right ventricle with subaortic interventricular communication, but without subpulmonary stenosis. Note that, despite the presence of bilateral infundibulums (stars), the interventricular communication is perimembranous because of the fibrous continuity between the leaflets of the mitral and tricuspid valves. The yellow Y shows the septomarginal trabeculation.

Figure 40-10 The heart again has double outlet with subaortic interventricular communication, but this time with fibrous continuity between the leaflets of the aortic and mitral valves in the roof of the interventricular communication. Note that in this heart there is a muscular postero-inferior rim to the interventricular communication (star). The defect itself remains within the limbs of the septomarginal trabeculation (yellow Y). Note that part of the aortic valve is attached within the left ventricle.

with a stenotic subpulmonary outlet, there can be bilateral infundibulums (see Fig. 40-9) or fibrous continuity between the leaflets of the aortic and mitral valves. When there are bilateral infundibulums, the arterial valves are usually side by side (see Fig. 40-9), but with fibrous continuity in the roof of the interventricular communication, the aortic valve is typically posterior and to the right of the pulmonary valve. The arterial trunks typically spiral as they exit from the heart. The interventricular communication is usually perimembranous (see Fig. 40-9), though it may have a muscular posterior margin (Fig. 40-10). When there is continuity between the leaflets of the aortic and mitral valves, the aortic root usually retains part of its connection with the left ventricle (see Fig. 40-10). In such instances, assignment of the overriding valve is made on the basis of the short axis of the root, not the long axis of the ventricular septum (see Fig. 40-6). Whilst the ventricular septal defect is often large in this group of cases, restrictive defects may be seen, which effectively produces obstruction to the outflow from the left ventricle, an important clinical consideration.

Other Anatomical Variations

As can be seen in the figures provided thus far, there is much individual variability within the malformations already described. This relates to the site, size and detailed morphology of the interventricular communication, the relationships of the arterial outlets to one another and to the septal defect, and to the frequent presence of additional malformations (see Tables 40-2, 40-3, and 40-4). With regard to the interventricular communication, although it usually extends to become perimembranous, irrespective

of the infundibular morphology, a muscular postero-inferior rim is present in a substantial minority of instances (see Table 40-3). Perimembranous defects may extend variably to open towards the inlet and trabecular portions of the right ventricle, as well as opening directly into one or other outlet. Restrictive defects, which produce obstruction to the outlet from the left ventricle, are uncommon, but when present are of obvious clinical and surgical importance. Multiple interventricular communications can be found on occasion.

Abnormalities of the atrioventricular valves are found in up to one-quarter of the hearts seen in autopsied series, and include mitral stenosis and straddling mitral valve. Obstruction to one or other of the arterial outlets occurs frequently. Pulmonary stenosis, when present, is similar to that seen in Fallot's tetralogy, but is infrequent in the setting of the Taussig-Bing heart. Obstruction of the systemic outlet is much more frequent in the latter setting, with interruption of the aortic arch in a significant proportion of these cases. Other major associated malformations include juxtaposition of the atrial appendages, totally anomalous pulmonary venous connection, and criss-cross atrioventricular connections. The frequent variations in coronary arterial anatomy are particularly important in the setting of the Taussig-Bing hearts, since these are now corrected surgically using the arterial switch procedure. Interatrial communications within the oval fossa are also frequent.

Less Common Variants

Non-Committed Interventricular Communication

In about one-tenth of cases seen in autopsied series, the interventricular communication is not directly committed to either arterial outlet. Such defects are usually perimembranous, and open primarily to the inlet of the right ventricle, often in the presence of a common atrioventricular valve (Fig. 40-11). Isolated muscular interventricular communications can also open directly to the inlet or apical parts of the right ventricle, and then also be non-committed (Fig. 40-12). Such non-committed defects are particularly important surgically, and require careful delineation of the relationships of the defect to the arterial outlets and to other structures within the right ventricle, especially abnormal leaflet tissue derived from the tricuspid valve which may interpose between the defect and the arterial outlets.¹⁸

Doubly Committed Interventricular Communication

In another one-tenth of cases seen in autopsied series, the interventricular communication is positioned so as to open directly into both arterial outlets (Fig. 40-13). As with the majority of the hearts already described, the interventricular communication is cradled between the limbs of the septomarginal trabeculation and is usually perimembranous, although it can have a muscular postero-inferior rim. If the muscular rim is present, it will protect the atrioventricular conduction axis. The essence of these hearts, however, is absence of a muscular outlet septum, with only a fibrous raphe interposing between the leaflets of the arterial valves. This means that both outflow tracts tend to override the crest of the muscular ventricular septum, and a spectrum exists between these hearts and double outlet from the left ventricle. Indeed, the hearts can be considered as showing double outlet from both ventricles (Fig. 40-14).¹⁹

Figure 40-11 The interventricular communication in this heart opens to the inlet of the right ventricle, and hence is non-committed, albeit that a track could be established surgically between the defect and the subaortic infundibulum, which in this instance is a complete muscular tube. There is a common atrioventricular junction. The *star* shows the muscular outlet septum. (Courtesy of Diane Debich-Spicer, All Children's Hospital, St Petersburg, Florida.)

Figure 40-12 The interventricular communication is again non-committed in this heart with double outlet right ventricle and bilateral infundibulums (*stars*), but in this instance because it is a muscular inlet defect. Note that, in this heart, the tension apparatus of the tricuspid valve interposes between the defect and both arterial outlets.

Consistent Variations in Morphology of the Overall Group

When previous accounts of the structure of the variants of double outlet are examined, the impression is often gained that, when the interventricular communication is in subaortic rather than subpulmonary position, it has

Figure 40-13 In this heart, the outlet septum is fibrous rather than muscular, and produces continuity between the leaflets of the aortic and pulmonary valves. In consequence, the interventricular communication, still between the limbs of the septomarginal trabeculation (*yellow Y*), and with a muscular postero-inferior rim (*star*), opens beneath both arterial outlets.

Figure 40-14 The cartoon shows how identification of the muscular structures surrounding the interventricular communication (*star*) in hearts with double outlet right ventricle identifies the potential danger areas during surgical correction.

moved relative to the muscular ventricular septum. To a certain extent, this must be the case, but when examined relative to the overall landmarks of the muscular ventricular septum, its location is remarkably constant.^{20,21} Thus, when the defect opens to the outlet of the right ventricle, be it subaortic subpulmonary, or doubly committed, then always it is found between the limbs of the septomarginal trabeculation. The variation in morphology depends upon the connection of the muscular outlet septum relative to the septomarginal trabeculation. When the septal defect is subaortic (see Fig. 40-4), then the muscular outlet septum is fused with the anterior limb of the trabeculation, as in tetralogy of Fallot. This fusion walls off the subpulmonary

outlet from the ventricular septal defect. When the defect is in subpulmonary position, in contrast, the muscular outlet septum is fused either to the posterior limb of the septomarginal trabeculation, or to the ventriculo-infundibular fold (see Fig. 40-7). This walls off the aorta from the septal defect and, almost always, produces a complete muscular subaortic infundibulum. The degree of squeeze between the muscular outlet septum and the ventriculo-infundibular fold determines the extent of subaortic obstruction. The smaller the subaortic muscular area, the more likely it is that there will be aortic coarctation or interruption. The characteristics of the doubly committed defect (see Fig. 40-13) are that, almost always, the outlet septum is fibrous rather than muscular, and the adjacent portions of the subaortic and subpulmonary infundibulums are absent. Such absence of the outlet septum, and incomplete formation of the subpulmonary infundibulum, is also a characteristic feature of the doubly committed and juxta-arterial ventricular septal defect found with concordant ventriculo-arterial connections (see Chapter 28). The interrelationships of the muscular structures around the interventricular communication (see Fig. 40-12) condition other important anatomic features of double outlet. Thus, the size of the ventriculo-infundibular folds determines the extent of the subarterial infundibulums. When the folds are extensive, then long infundibulums are found supporting both arterial valves (see Fig. 40-9). In contrast, when the fold is attenuated beneath each arterial valve, then there is atrioventricular-arterial valvar fibrous continuity (see Fig. 40-10), but still with double outlet ventriculo-arterial connection. It is then the relationship between the posterior limb of the septomarginal trabeculation and the ventriculo-infundibular fold which determines whether the ventricular septal defect is perimembranous (see Fig. 40-9) or has a muscular postero-inferior rim (see Fig. 40-10). All of these anatomical details are, nowadays, readily demonstrated using cross sectional echocardiography.

Double Outlet Right Ventricle with Intact Ventricular Septum

When the ventricular septum is intact, which can occur rarely in a patient with double outlet right ventricle, the left ventricle has no direct outlet, and in these circumstances is usually severely hypoplastic.

Subaortic Interventricular Communication with Left-Sided Aorta

The key point in diagnosing this variant is that, despite the aorta being left sided, the heart exhibits usual atrial arrangement with concordant atrioventricular connections. The lesions were of more significance when arguments raged concerning the significance of the so-called loop rule, left-sided aortas being presumed only to exist with left hand ventricular topology when there was the usual atrial arrangement. Nowadays there is no problem in defining with precision the atrial arrangement and the atrioventricular connections, and in recognising the left-sided location of the aorta. The interventricular communication is typically subaortic, although it can be subpulmonary or doubly committed. Infundibular morphology is also variable. The usual subaortic location of the interventricular communication makes surgical repair relatively easy,²² although the presence of a coronary artery passing anteriorly relative to the subpulmonary outlet can complicate the situation in the presence of pulmonary stenosis, which may be both valvar and subvalvar. When encountered, left juxtaposition

of the atrial appendages is frequent, as is straddling mitral valve.^{22,23}

Double Outlet Right Ventricle with Discordant Atrioventricular Connections

This complex malformation has been described in association with both usual and mirror-image atrial arrangements. When seen, many patients with usual atrial arrangement have their hearts placed in the right chest, while those with mirror-imaged atria have left-sided hearts. Pulmonary stenosis was present in four-fifths of the largest reported series,²⁴ with the interventricular communication being subpulmonary more frequently than subaortic. Despite the discordant atrioventricular connections, there was marked variability in the relationships of the great arteries, with the aorta to the left of the pulmonary trunk in only two-thirds of cases. This variant of double outlet right ventricle has much in common with congenitally corrected transposition, and is discussed further in Chapter 39.

Double Outlet Right Ventricle with Either Mirror-Imaged Atrial Arrangement or Isomeric Atrial Appendages

We have already made mention of double outlet right ventricle in the setting of mirror-imaged atrial arrangement. Very few cases have been reported, but the same variability must be anticipated as for double outlet right ventricle when found with usual atrial arrangement. Double outlet right ventricle is much more frequent in the presence of isomeric atrial appendages, being particularly common in the overall group of patients having isomeric right appendages. In the syndromes of isomerism, of course, variability occurs at all levels of the heart (see Chapter 22). This means that the complexity and multiplicity of the malformations seen in the presence of isomerism with double outlet right ventricle may be expected to be extreme. One combination in particular deserves mention, that of biventricular and mixed atrioventricular connections and a common atrioventricular orifice.²⁵ This combination is found with both right and left isomerism, and with either right hand or left hand ventricular topologies. The interventricular communication opens to the inlet of the right ventricle, and usually there are bilateral infundibulums. As shown in Figure 40-11, nonetheless, it is often possible to construct a tunnel between the interventricular communication and the subaortic outlet, so providing the associated malformations are not too severe, biventricular repair remains a possibility.

Double Outlet Left Ventricle

Because of the rarity of this malformation, pathological, clinical, or surgical series of any size have rarely been reported from individual institutions. Moreover, reviews of the subject, and reports of individual cases, have frequently included material relating to functionally univentricular hearts.²⁶⁻²⁸ The largest review of which we are aware collected a total of 100 cases, with biventricular atrioventricular connections in four-fifths. The reviews reveal that, as might be expected, double outlet left ventricle most commonly occurs in hearts with usual atrial arrangement and concordant atrioventricular connections, making up nine-tenths of the series. Discordant atrioventricular connections with usual atrial arrangement were noted in one-twentieth of cases, and mirror-imaged atrial chambers were reported in the remaining cases, albeit that no mention was made of isomeric atrial appendages. Variability, as with double outlet right ventricle, depends on the site of the interventricular

communication, its relationship to the subarterial outlets, and the relationships of the arterial trunks. Infundibular morphology has also varied dramatically, albeit that bilaterally deficient infundibulums are more frequently found with double outlet left ventricle than in any other situation. This arrangement, nonetheless, does not occur in the majority of cases, the commonest finding being a subpulmonary infundibulum with fibrous continuity between the leaflets of the aortic and mitral valves. Associated abnormalities are the rule rather than the exception. A particularly high frequency of obstruction in the pulmonary outflow tract is found when the interventricular communication is subaortic. Those with a subpulmonary defect have a high incidence of systemic obstruction, usually coarctation, with about half the reported cases being thus affected. As might be expected, there is a low incidence of pulmonary obstruction when the defect is subpulmonary. Anomalies of the atrioventricular valves occur in up to one-third of cases, and include hypoplasia, stenosis, straddling and Ebstein-like malformations. The tricuspid valve is more often abnormal than the mitral. Hypoplasia of the right ventricle is also a frequent finding. As with double outlet right ventricle, therefore, extreme heterogeneity exists. It is doubtful whether it is justifiable to seek to make groupings or categories. Each reported type is individually extremely rare, and is subject to a host of associated defects and problems. It is these features that dominate the clinical picture, and determine the surgical options.

In each case, therefore, the problem should be analysed in the same logical sequence required for any complex defect. Investigation and categorisation need to be individualised, with each patient having his or her defects systematically documented in terms of atrial arrangement, atrioventricular connection, morphology of the interventricular communication and its relationship to the outlets, arterial relations, obstruction to the ventricular outlets, atrioventricular valvar abnormalities, and other associated malformations.

MORPHOGENESIS

During early embryonic development, the outflow tract of the heart arises exclusively from the developing right ventricle. For the embryo, therefore, double outlet right ventricle can be considered the default option. Only as the ventricular septum closes does the subaortic outflow tract become connected to the left ventricle (see Chapter 3). In order for this process to occur normally, it is necessary that certain earlier cardiac developmental processes have taken place in their correct sequence. These include formation of the ventricular loop and the development, in appropriate orientation, of the primordiums of the components of the ventricular septum. Errors in these, and other, phases of early cardiac development may profoundly affect subsequent morphogenesis involving the orientation and calibre of the outflow tracts and the ventriculo-arterial connections.

In hearts with double outlet right ventricle, the only universal feature is failure of complete incorporation of either of the arterial outflow tracts into the left ventricle. In many cases, an additional feature is the persistence of a muscular infundibulum in both subarterial outlets, associated with lack of attenuation of the ventriculo-infundibular

fold in the area between the atrioventricular and arterial valvar leaflets. In these cases, atrioventricular-arterial valvar fibrous continuity is not found. In addition, the muscular outlet septum remains an exclusively right ventricular structure, being malaligned, to a greater or lesser degree, relative to the apical part of the muscular septum.

The fundamental cause of the embryological error or errors leading to double outlet right ventricle remains unclear. In the experimental situation, double outlet right ventricle has been created in chick embryos by placing a loop around the infundibulum prior to its septation, thus preventing it from migrating and attenuating in the normal sequence.²⁹ The relevance of these experimental data, however, to the naturally occurring malformation remains uncertain. It has now transpired that many genetically modified mice develop double outlet right ventricle, or else common arterial trunk arising exclusively from the right ventricle. It is also the case that examples are now encountered with the interventricular communication in both subaortic and subpulmonary positions.

This achieves significance, since it has long been recognised that, in terms of their pathological features, many hearts with double outlet right ventricle are very similar to specimens of Fallot's tetralogy, while others bear a strong resemblance to those having discordant ventriculo-arterial connections with ventricular septal defect. It was Lev and his colleagues³⁰ who first proposed the presence of a pathological continuum from, on the one hand, Fallot's tetralogy to double outlet right ventricle with subaortic defect and, on the other hand, from double outlet right ventricle with subpulmonary defect to discordant ventriculo-arterial connections with ventricular septal defect, a concept then supported by others who studied congenitally malformed hearts.^{31,32} All these workers took the view that these malformations were related to maldevelopment of the infundibulums, the experimental work now providing validation of this concept.

In double outlet left ventricle, both outflow tracts are incorporated into the left ventricle. This is associated with exaggerated leftward shift of the arterial valves in relation to the ventricular septum. While this is sometimes associated with attenuation of the infundibular muscle below each arterial valve, producing bilaterally deficient infundibulums, this is by no means the rule. Leftward shift of the arterial valves relative to the ventricular septum, therefore, is not dependent on absorption and shortening of the infundibulums.

PATHOPHYSIOLOGY

The pathophysiology of double outlet ventricle is complex, being determined by the site of the interventricular communication relative to the arterial outlets, the presence of obstruction to either the pulmonary or systemic outlet, the pulmonary vascular resistance, and the presence of other associated cardiac defects.

The overall effect is largely determined by the flow of blood to the lungs, the presence or absence of pulmonary hypertension, and the effect of streaming within the ventricle supporting the arterial trunks. An additional important factor may be the presence of associated aortic coarctation, which, as well as producing an increase in systemic afterload, is liable to lead to hypoperfusion of the

lower systemic segment after ductal closure, resulting in renal impairment and acute retention of fluids. This usually leads to severe symptoms and rapidly progressive cardiac failure in the neonatal period.

Flow of Blood to the Lungs

Pulmonary flow is related to the presence and severity of pulmonary stenosis, be it valvar or subvalvar, and to the level of pulmonary resistance. Pulmonary arterial pressure and resistance are frequently normal or low in the presence of significant stenosis. Pulmonary flow is then also restricted, sometimes to markedly subnormal levels. Diminished flow is inevitably associated with reduced arterial saturation of oxygen, though the degree of systemic hypoxia is also dependent on the effects of streaming. In the absence of pulmonary stenosis, the systolic pressure in the pulmonary trunk is usually equal to systemic pressure. Flow is then dependent on the level of pulmonary vascular resistance. The behaviour of the pulmonary vasculature, in the presence of pulmonary hypertension, is similar to that observed in the presence of other congenital cardiac defects. In the early months of life pulmonary resistance drops at a variable, though reduced, rate from the neonatal level. During this period, the flow of blood to the lungs increases progressively. Subsequently, sustained pulmonary hypertension leads to the development of obliterative pulmonary vascular disease,^{33,34} with rising pulmonary vascular resistance, until eventually flow may fall to subnormal levels. Increased flow tends to be associated with less severe systemic hypoxia though, again, the effects of streaming are important in determining the arterial tensions and saturations of oxygen.

Effects of Streaming

In the presence of a subaortic interventricular communication, left ventricular blood tends to be directed predominantly to the aorta when both trunks arise from the right ventricle. This results physiologically in a situation resembling that seen with a simple ventricular septal defect with concordant ventriculo-arterial connections. In the absence of pulmonary stenosis, little or no right-to-left shunting may be seen, with the blood in the aorta being almost fully saturated in many patients. When pulmonary stenosis co-exists, some right-to-left shunting is almost always found and the extent of this, and of the associated systemic hypoxia, is related closely to the degree of obstruction. The physiology, as also the morphology, in this situation tends often to resemble closely that found in Fallot's tetralogy. In a minority of patients with a subaortic defect, these effects of streaming are not seen, and in some the reverse may be the case, with lower saturation of oxygen in the aorta than in the pulmonary trunk.^{25,35}

When the interventricular communication is subpulmonary, the aorta is perfused preferentially with deoxygenated systemic venous blood. The physiology resembles that of transposition and, as in that condition, the degree of systemic hypoxia is dependent on the adequacy of mixing between blood in the systemic and pulmonary circuits. As the situation with double outlet tends to be associated with fairly good mixing in most cases, hypoxia may not be severe and the high flow of blood to the lungs seen in most

patients also militates against the development of severe hypoxia.

Streaming can be variable when the interventricular communication is either non-committed or doubly committed. In such cases, some degree of systemic hypoxia is almost invariable, and the main determinant of its severity is the degree of pulmonary stenosis.

Influence of Other Associated Defects

Mention has already been made of the serious effects which aortic coarctation may have on the pathophysiology. Many of the common associated defects may also affect the situation to a variable extent. Common atrioventricular orifice, and straddling mitral valve, probably reduce the effects of streaming, which are otherwise often seen. Hypoplasia, stenosis, or atresia of an atrioventricular valve may produce dramatic haemodynamic consequences, though mitral stenosis may produce surprisingly little effect if pulmonary blood flow is low due to associated pulmonary stenosis. A restrictive interventricular communication produces pressure loading of the left ventricle, which consequently becomes hypertrophied, but apart from elevated left ventricular pressure the haemodynamics are usually not greatly affected, unless the obstruction to flow from the left ventricle results in left atrial hypertension, with resulting pulmonary venous congestion and so on.

CLINICAL FINDINGS

Presentation

The clinical features of infants with double outlet ventriculo-arterial connection are extremely variable and may mimic those of many other defects. Those patients with double outlet right ventricle, subaortic defect, and pulmonary stenosis usually present a clinical picture which resembles that of Fallot's tetralogy. A systolic murmur is sometimes noted in the neonatal period, but the onset of cyanosis may be delayed for several months. Patients with double outlet right ventricle and subpulmonary defect, on the other hand, usually develop cyanosis in the neonatal period, though the cyanosis may not be severe. Cardiac failure, developing later in the first month of life or subsequently, with tachypnoea, dyspnoea, and failure to feed and thrive, compounds the picture. The appearance of severe cyanosis in the neonatal period is usually a reflection of the presence of severe pulmonary stenosis or atresia with very low flow to the lungs. Such a presentation is sometimes seen in those patients with the Fallot-type of double outlet, but is also seen in more complex defects, especially those with isomerism. Onset of symptoms of cardiac failure, but without cyanosis, at the end of the first month or in the second and third months of life, is typical of those cases with a subaortic defect and no pulmonary stenosis. This clinical picture resembles that of a large isolated ventricular septal defect.

Early onset of cardiac failure is particularly a feature of those cases with associated aortic coarctation or interruption of the aortic arch. A small proportion of patients do not present in early infancy, but are detected later in the first year of life, or rarely even later in childhood. Whilst some such patients may have features similar to a late presenting Fallot's tetralogy, others have evidence of severe pulmonary hypertension. They resemble more the child with a large

ventricular septal defect, pulmonary hypertension, and elevated pulmonary resistance who has survived without developing cardiac failure in infancy. Data from the Hospital for Sick Children in Toronto showed that the majority of patients with double outlet right ventricle in all categories presented in the first two months of life, except for those with a subaortic defect and pulmonary stenosis, who usually presented later.³⁶

The presenting features of double outlet left ventricle are similarly extremely variable. They do not permit distinction from double outlet right ventricle, or many other defects, on purely clinical grounds.

Physical Signs

The physical signs in double outlet ventricle vary with the clinical presentation and underlying pathology. Manifestations of cardiac failure in early infancy, with or without cyanosis, are usually indicative of high pulmonary flow and pulmonary hypertension. When such features appear in the first week or two of life, they are usually associated with major, or often multiple, associated defects such as aortic coarctation. Such infants usually have a hyperdynamic cardiac impulse with a parasternal systolic murmur of moderate amplitude, which often radiates fairly widely, particularly to the pulmonary area and the back. The second heart sound is usually loud, though this is often due to the aortic component, which, as in those with transposition, may be accentuated.

In the absence of cardiac failure an ejection systolic murmur varying between grades 2 and 4 of 6 may be audible along the left sternal border and in the pulmonary area, with radiation to the back. This is usually related to infundibular and/or valvar pulmonary stenosis. As in Fallot's tetralogy, the pulmonary component of the second sound is often inaudible. Cyanosis is variable, and may not appear for several months. An apical mid-diastolic murmur is occasionally heard and may reflect high pulmonary flow or associated mitral stenosis. A restrictive interventricular communication is associated with a harsh parasternal systolic murmur and a forceful apical impulse, on palpation, due to left ventricular hypertrophy. The murmur from a restrictive defect may be masked if there is associated infundibular stenosis.

Electrocardiography

Early reports³⁷⁻³⁹ of the electrocardiogram in double outlet right ventricle suggested that certain features were of predictive diagnostic value. These included a superior frontal plane QRS axis with a counterclockwise vector loop in the presence of right ventricular hypertrophy. This pattern was said to be particularly frequent in cases with a subaortic defect but without pulmonary stenosis. Delay of atrioventricular conduction, especially first-degree block, was found to be very common, and intraventricular disturbances of conduction, especially right bundle branch block, were also frequent. Some degree of left ventricular hypertrophy in the presence of severe right ventricular hypertrophy was also found in a high proportion of cases, and was right atrial hypertrophy.³⁹ Subsequent investigators,⁴⁰ however, were unable to confirm that these electrocardiographic features were of any great diagnostic value.

The most consistent electrocardiographic features in the commoner types of double outlet right ventricle are the presence of right ventricular hypertrophy, right-axis deviation, and the presence of an rR', qR, or rsR' pattern in right chest leads. The duration of the QRS complex is normal in most patients. Right atrial hypertrophy is common, and bi-atrial or pure left atrial hypertrophy is seen in a minority of cases. The presence of left atrial hypertrophy or left ventricular hypertrophy has not been shown to correlate well with the haemodynamics.⁴⁰ In two cases of our own, however, left atrial hypertrophy and diminished R waves in right chest leads were present in association with a restrictive ventricular septal defect and mitral valvar abnormalities.

Chest Radiography

Radiological features in double outlet right ventricle depend mainly on the associated malformations and are seldom of any diagnostic value. Atrial arrangement, as indicated by bronchial morphology on a penetrated or filter film, is usual in most instances. Cardiac position is variable, though the approximately nine-tenths of patients with the more common types have left-sided hearts. A right aortic arch was seen in up to one-third of cases with a subaortic defect and pulmonary stenosis,³⁶ and is occasionally present in other types.

Cardiomegaly of significant degree is, in general, associated with increased pulmonary flow. It is, therefore, an almost universal feature of cases with an unobstructed pulmonary outflow tract. Patients with pulmonary stenosis, on the other hand, frequently have little or no increase in cardiac diameter. Pulmonary oligoemia or plethora are again related to the presence or absence of significant pulmonary stenosis. The cardiac contour may mimic Fallot's tetralogy, large ventricular septal defect, or transposition with ventricular septal defect. No diagnostic characteristics are demonstrable. A straight right heart border is seen in some patients with left juxtaposition of the atrial appendages. The site and size of the interventricular communication have little influence on the radiological appearances.

Echocardiography

M-mode echocardiography⁴¹ was used in the early era of cardiac ultrasound to assess mitral-arterial valvar discontinuity and the degree of overriding of the arterial valve over the septum. Since such echocardiographic discontinuity can occur in a variety of other situations, including left ventricular dilation,^{42,43} and the exact connection of the arteries to the right or left ventricle is impossible to assess accurately, the inference that double outlet right ventricle might be present was frequently incorrect.

Cross sectional echocardiography has a vitally important role in the comprehensive investigation of the patient with double outlet right ventricle. Not only may the diagnosis of double outlet be made with a high degree of certainty, but the relationship of the interventricular communication to the arterial outlets, the presence of arterial outlet narrowing or obstruction, and the co-existence of important associated defects, especially those of the atrioventricular valves, such as common atrioventricular orifice or straddling mitral valve, may all be documented.

Figure 40-15 The echocardiogram in the long-axis view (*left panel*) is from a patient with the tetralogy type of double outlet right ventricle, with the subxiphoid view shown in the right panel. The aorta arises predominantly from the right ventricle, though the degree of overriding appears greater in the long-axis view. There is mitral-aortic fibrous continuity shown in long-axis view.

The diagnosis has been made on fetal echocardiography in an increasing number of cases in the last few years and is often fairly straightforward using views which permit assessment of the arterial outlets.⁴⁴ Using such techniques, accurate planning of surgical management and appropriate counselling of parents is often possible prior to delivery.

In the postnatal period, the diagnosis of double outlet right ventricle may be suspected in the long-axis view by demonstrating that both great arteries arise predominantly or entirely from the right ventricle, and that the only exit for the left ventricle is a ventricular septal defect.^{45,46} Assignment of the ventricular origin of each artery requires assessment in several different cuts, and the long-axis view can be misleading if used in isolation (*Fig. 40-15*). Discontinuity between the septal leaflet of the mitral valve and the leaflets of the arterial valves may be seen when present, but does not, in itself, establish the diagnosis, as it may be present in other malformations. Moreover mitral-arterial valvar continuity is characteristically present in Fallot's tetralogy, even when the aorta arises predominantly from the right ventricle. The degree of overriding of one or both great arteries over the ventricular septal crest can be assessed, using a combination of long-axis, short-axis,

apical and subcostal views. In most cases, the ventricular origin of each arterial trunk can be established with a high degree of accuracy, and true distinguished from spurious overriding. A combination of long-axis and serial short-axis views is also helpful,^{45,47} and subcostal short and long-axis scans (*Fig. 40-16*) have been used extensively.⁴⁸ Subcostal views are also helpful in analysing the relationships of the atrioventricular valves and their tension apparatus to the defect. Of particular importance in this respect, and particularly common, are abnormalities of insertion of the tricuspid valvar tension apparatus such that the pathway from the interventricular communication to one or both outflow tracts is impeded. This information may be of crucial importance to the surgeon. The views which give this information, however, may be misleading in assessing the extent of overriding of a great artery. This feature is probably better judged using parasternal long- and short-axis cuts.

The interrelationship of the great arteries and their relative sizes is usually readily demonstrable, as is the presence of valvar or subvalvar obstruction (*Figs. 40-16 and 40-17*). Particular questions which are of surgical relevance, and which can be answered by cross sectional echocardiography,

Figure 40-16 The echocardiograms show subxiphoid views in two patients with double outlet right ventricle with subpulmonary interventricular communications. The left panel shows a long-axis scan and demonstrates subpulmonary stenosis. In the right panel (short axis), the anatomy is that of the Taussig-Bing anomaly, with an overriding pulmonary valve and no obstruction to pulmonary flow, but mild subaortic stenosis.

Figure 40-17 The echocardiograms show short-axis subxiphoid views in two patients with double outlet right ventricle with side-by-side arteries. The left panel demonstrates subpulmonary stenosis, while in the right panel there is no obstruction.

include the anatomy of the outlet septum, the anatomy of the roof of the interventricular communication, the relationships of atrioventricular valvar tension apparatus to the septal defect, and demonstration of which arterial outlet is most closely adjacent to the defect.⁴⁸ In addition to these features, which may be difficult to define by other means such as angiocardiology, echocardiography is of particular value in establishing the presence of major atrioventricular valvar abnormalities, such as a common atrioventricular orifice or straddling of the mitral or tricuspid valve across the septum.⁴⁶ Other associated malformations, such as hypoplasia of the left or right ventricle, juxtaposition of the atrial appendages, coarctation of the aorta and interruption of the aortic arch, may also be demonstrable echocardiographically. Doppler echocardiography is primarily of value in assessing obstructive lesions and atrioventricular valvar regurgitation. Colour flow mapping is especially helpful in regard to the latter problem.

Cardiac Catheterisation and Angiocardiology

Cardiac catheterisation and angiography were, in the past, the mainstay of diagnosis of these malformations. With improvements in non-invasive imaging, especially echocardiography, the role of cardiac catheterisation has diminished, and many patients will now be referred for surgery without catheterisation. When catheterisation is performed, the investigator must keep in mind two particular objectives. The first is the anatomy of the ventriculo-arterial connection, along with the relationships of the interventricular communication. The second is to assess all surgically important aspects of the malformation. In most cases, if appropriate preliminary investigations have been performed, the atrial arrangement, atrioventricular connections and ventriculo-arterial connection will all be known prior to catheterisation. The bulk of the data required from cardiac catheterisation, therefore, relates to the surgically important aspects of the defect. In obtaining haemodynamic data, special attention must be paid to assessing any systolic pressure gradient between left and right ventricles, which would suggest a restrictive septal defect, or any diastolic pressure gradient across the mitral valve. It is essential to gain access to the left side of the heart, either

via the interventricular communication or at the atrial level, using trans-septal puncture if necessary.

Information concerning the relationship of the interventricular communication to the arterial outlets may be provided by the behaviour of the catheter, such as easy passage of a retrograde aortic catheter to the left ventricle suggesting a subaortic defect, or from an assessment of streaming. Haemodynamics resembling those of a large ventricular septal defect, or of Fallot's tetralogy, in both of which aortic saturation exceeds that in the pulmonary trunk, suggest a subaortic defect. By contrast, a higher saturation in the pulmonary trunk than in the aorta is usually indicative of a subpulmonary defect.

Measurement of pulmonary arterial pressure, and calculation of the flow and resistance, is mandatory in patients outside of infancy. The presence of pulmonary hypertension at systemic level, indicating absence of obstruction to the subpulmonary outlet, should always raise the suspicion of obstruction to the systemic outlet. A careful search should then be made for subaortic or aortic stenosis, and for aortic coarctation or interruption. The presence of pulmonary stenosis, on the other hand, makes it unlikely that any obstruction to the systemic outlet will be present.

Angiocardiology should include selective left and right ventriculograms (Fig. 40-18). The left ventriculogram should be carried out in a view designed to profile the ventricular septum, such as 45 degrees left anterior oblique inclination, with some craniocaudal tilt. The precise orientation must be assessed individually, and depends on the cardiac position and preliminary echocardiographic evidence. This view is intended to show the site and size of the interventricular communication or communications, and its relationship to the arterial outlets (Fig. 40-19). The presence of a common atrioventricular orifice, or overriding mitral valve, may also be demonstrated. The presence of mitral regurgitation may be assessed in the complementary right anterior oblique plane if biplane angiography is used.

Right ventriculography may be performed in a similar oblique projection, although frontal and lateral views may also be useful. This will normally demonstrate the relationship of the arterial outlets to one another, and the presence and nature of obstructive lesions in either outflow tract (see Fig. 40-18). The separation of the aortic valve from the

Figure 40-18 The left ventricular angiogram in left oblique projection (*left panel*) shows a muscular interventricular communication in addition to the subaortic defect. The right ventricular angiogram from the same patient, seen in antero-posterior projection (*right panel*), demonstrates infundibular stenosis of the tetralogy type.

Figure 40-19 The left ventricular angiogram in left oblique projection (*left panel*) shows an interventricular communication which appears to be subaortic, but which in reality is non-committed. The right panel shows a subpulmonary interventricular communication with streaming of left ventricular flow to the pulmonary trunk. The aorta fills very faintly in this angiogram.

mitral valve may also be assessed, usually using a left ventricular angiogram in oblique projections with appropriate crano-caudal angulation (Fig. 40-20).

In patients with unobstructed pulmonary flow, a selective aortogram is often desirable, profiled in frontal and lateral projections, to demonstrate or confirm the presence of aortic coarctation or interruption. Those with pulmonary stenosis may require selective pulmonary arteriography with 30 degrees craniocaudal tilt in the frontal projection to define the anatomy of the pulmonary trunk and its bifurcation. In all cases, the investigator must bear in mind the high frequency of associated malformations, and take whatever steps are necessary to define them or exclude them. In cases where radical reconstruction of the pulmonary outflow tract, with or without a conduit, or an arterial switch operation is contemplated, it may be desirable to define the coronary arterial anatomy by aortography, or by selective coronary arteriograms.

Computed Tomography and Magnetic Resonance Imaging

Even with conventional angiography and echocardiography, it may be difficult to determine the precise relationship of the great arteries to the interventricular communication.

Recent work with computed tomography and magnetic resonance imaging suggests that these modalities of investigation may provide useful additional information. The ability to generate cross sectional images in almost any spatial plane may be of considerable assistance in clarifying the anatomy of these complex hearts.^{49,50} Unfortunately intracardiac anatomy remains more difficult to assess in detail with these methods, and echocardiography, including the burgeoning three-dimensional modality, may continue to provide the most reliable means of assessment, at least in the short-term future.

DIFFERENTIAL DIAGNOSIS

As will be apparent from the foregoing description, the clinical picture, along with the radiographic and electrocardiographic features, are very variable and non-specific. Double outlet may mimic many cardiac lesions. Those forms that do not include pulmonary stenosis may, when acyanotic, closely resemble a large isolated ventricular septal defect. In the presence of cyanosis, the picture may simulate that of transposition with a ventricular septal defect, or other cyanotic defects with high pulmonary flow. Co-existing coarctation may lead to the early development of cardiac failure, producing a clinical picture which resembles other

Figure 40-20 The left ventricular angiogram, shown in left oblique projection in the left panel, and right oblique in the right panel, reveals mitral-aortic valvar separation.

variants of coarctation or hypoplastic left heart syndromes. The presence of pulmonary stenosis, on the other hand, is more often associated with presentation at a later age, and gives features similar to those of Fallot's tetralogy. In all cases, the differentiation depends on careful echocardiographic and angiographic delineation of the connections and relationship of the great arteries to the ventricles.

MANAGEMENT

Treatment of double outlet ventriculo-arterial connection is essentially surgical, including the palliative procedures which may be necessary after initial diagnosis. Other than for supportive measures, there is no place for medical treatment, although interventional catheterisation may have a role in the treatment of complications of surgical palliation or repair.

SURGERY

The surgery of double outlet right ventricle has posed a great challenge to the ingenuity and skill of cardiac surgeons the world over. In the early years of cardiac surgery, the nature of the malformation was not always recognised preoperatively or intraoperatively. In this setting, closure of the interventricular communication, without redirection of left ventricular blood to the aorta, led to some operative tragedies.⁵¹ Successful correction was first achieved in 1957.⁵² Since that time, a large number of surgical reports have appeared.^{24,52-64}

The surgical approach to the individual patient depends on the anatomic features present, and especially on the presence of complicating additional abnormalities. In more complex cases, corrective surgery may not be feasible. In those patients deemed unsuitable for correction, conversion to the Fontan circulation, or other palliative procedures, may be the preferred option. In the majority of patients, however, a biventricular repair is feasible. In our analysis of the series of patients undergoing surgery in Melbourne from 1978 to 1993,⁶⁴ we categorised the patients into complex and non-complex groups. Complex

patients had one or more isomeric appendages, discordant ventriculo-arterial connections, multiple interventricular communications, unbalanced ventricles, straddling or hypoplasia of an atrioventricular valve, a common atrioventricular valve, pulmonary atresia or other major pulmonary arterial anomalies. Those without any of these features made up the non-complex group.

In the early weeks of life, palliation may be required prior to subsequent correction. Patients with a subpulmonary defect, in whom the physiology resembles transposition, may benefit from balloon atrial septostomy. This is also worthwhile in those infants with severe left-sided obstructive lesions, such as mitral stenosis or atresia. Infants with severe pulmonary hypertension and congestive failure may require palliation with banding of the pulmonary trunk if primary correction is likely to carry high risks (see below). Conversely, infants with restricted pulmonary flow due to pulmonary stenosis may need construction of a systemic-to-pulmonary arterial shunt if primary correction is not considered either feasible or a satisfactory option at this age. Those infants with aortic coarctation or interruption will usually require urgent surgical relief of the obstructive lesion in the neonatal period, with or without simultaneous intracardiac repair. Banding of the pulmonary trunk may be considered desirable during the same procedure if early complete intracardiac repair is not possible.

Primary repair for those cases with a subaortic defect involves the placement of an intraventricular tunnel from the defect to the aorta, attaching the patch to the right ventricular outlet septum to restore septal integrity. Subpulmonary or valvar pulmonary stenosis may be relieved by infundibulectomy, valvotomy or enlargement of the outflow tract with a gusset. An external conduit may be used in cases where these methods are not appropriate. In such cases, operative mortality, in the modern era, is generally low.⁶⁵ Among 94 such non-complex patients having biventricular repairs in Melbourne since 1978, 4 died (4.2% mortality). Others⁵⁹⁻⁶² have reported a generally favourable experience with this subgroup of patients. Risks of total correction were initially considered to be significantly higher at younger age, but this was not found to be the case in one recent analysis.⁶⁵

By reason of concern on this score, nonetheless, some surgeons have preferred early palliation with banding of the pulmonary trunk or creation of systemic-to-pulmonary arterial shunts.⁶⁰ Other surgeons, however, report a low mortality except possibly in infants under 3 months of age. They recommend primary correction even in infancy.⁵⁹ This has been our preferred approach, as also in Boston.^{63,64} More complex anatomy in some patients with subaortic defects may complicate repair and increase the risks of operation. In the experience in Melbourne, a range of such complicating features were encountered (Table 40-5). Among 41 such complex patients, the hospital mortality rate after biventricular repair was 26.8%. This has led to our considering conversion to the Fontan circulation, or construction of cavopulmonary shunts, in these more complex patients, providing the haemodynamics are suitable.

In patients with subpulmonary septal defects, surgical results in the past were less good. In selected cases, it proved possible to construct an intraventricular conduit from the left ventricle to the aorta.⁶⁶⁻⁶⁸ In most, however, it is necessary to close the defect so that left ventricular blood is directed to the pulmonary trunk. This then necessitates an additional arterial switch procedure, or an atrial redirection operation. Atrial redirection in most instances was found to carry a high mortality.⁵⁹ For this reason, in the modern era, an arterial switch is preferable in almost all cases. It has been suggested that cases in which the great arteries are in an antero-posterior relationship are particularly suitable for the repair incorporating an arterial switch, whilst those with side-by-side arterial relationships may be more suitable for intraventricular repair.^{69,70} Others have employed an arterial switch procedure in both situations.⁷¹ Still other procedures have been attempted in some more complex cases. One such approach, the so-called REV procedure, involves sacrificing the pulmonary outflow tract in order to route an intraventricular baffle from the inter-ventricular communication to the aorta. The pulmonary bifurcation is then brought in front of the ascending aorta using a Lecompte manoeuvre, and is sutured directly to the upper edge of the ventriculotomy incision, using a pericardial patch or monocusp gusset to complete the anterior wall of the new outflow tract to the pulmonary arteries.^{72,73} This operation may be worth considering for patients with a subpulmonary defect with co-existing pulmonary stenosis, a combination which precludes an arterial switch repair. Another option in this situation is the use of a Rastelli-type repair incorporating insertion of an external valved conduit between the right ventricle and the pulmonary trunk.⁷⁴ We summarise the experience in Melbourne with subpulmonary defects in Table 40-6. The presence of associated pulmonary stenosis, and a range of other complicating factors, may prejudice a satisfactory biventricular repair but, in the absence of these complicating problems, most patients are suitable for an arterial switch procedure. The hospital mortality rate in non-complex patients submitted to biventricular repair was 3.1%, with 1 of 31 patients dying. This is no different from that experienced in non-complex patients with subaortic defects. Moreover, the presence of aortic coarctation or interruption did not impact on mortality at the time of repair, despite the fact that the arch was repaired at the same time as intracardiac repair in most cases. Over this period, we converted 10 children with subpulmonary defects to the Fontan circulation,

Total patients	22	2 (9.1%)

Patients with doubly committed ventricular septal defects are usually suitable for intraventricular repair, except when other major complicating issues are present. In our overall series of 352 patients, only 8 non-complex patients had this anatomy, and all could be corrected in biventricular fashion using an intraventricular patch (Table 40-7). There were two other complex patients, one with discordant atrioventricular connections and the other with a severely hypoplastic left ventricle. This type of defect was not identified as being a risk factor for death by Kirklin and colleagues,⁶⁵ and is probably as favourable as the subaortic defect for biventricular repair, though problems with subaortic outlet obstruction have occurred occasionally.⁷⁵

TABLE 40-7

SURGERY PERFORMED ON 10 PATIENTS WITH DOUBLY COMMITTED DEFECTS, INCLUDING 2 COMPLEX PATIENTS, FROM A COHORT OF 352 INFANTS OR CHILDREN WITH DOUBLE OUTLET RIGHT VENTRICLE, HAVING THEIR INITIAL PALLIATION OR REPAIR BETWEEN 1978 AND 2007 AT THE ROYAL CHILDREN'S HOSPITAL, MELBOURNE

Type of Surgery	Number	Hospital Deaths

Intraventricular repair	8	1
Total patients	8	1 (12.5%)
OTHER SURGERY (COMPLEX)		
Fontan (complex)	1	
Palliative (complex)	1	1
Total patients	2	1 (50%)

Non-committed defects, in contrast, may present difficulties. Selection of patients for biventricular repair as opposed to conversion to the Fontan circuit or cavopulmonary shunting depends on careful assessment of the interventricular communication and its relationship to the arterial outlets, as well as any associated problems. Of 80 such patients seen in Melbourne, 37 were submitted to biventricular repair using either an intraventricular baffle in 30, or in combination with an arterial switch procedure in the other 7. Of these, 4 patients died in hospital (10.8% mortality). We created the Fontan circuit or bidirectional cavopulmonary shunts in 33 patients, with 1 dying. The remaining 10 children were submitted only to palliative procedures, albeit with 7 deaths (Table 40-8).

Other options include the use of a tubular internal conduit from the left ventricle to the aorta, accompanied by insertion of a valved external conduit from the right ventricle to the pulmonary trunk,⁷⁶ or use of double external conduits.⁷⁷

TABLE 40-8

SURGERY PERFORMED ON 80 PATIENTS, 44 DEEMED TO BE COMPLEX, WITH NON-COMMITTED INTERVENTRICULAR COMMUNICATIONS, FROM A COHORT OF 352 INFANTS OR CHILDREN WITH DOUBLE OUTLET RIGHT VENTRICLE, HAVING THEIR INITIAL PALLIATION OR REPAIR BETWEEN 1978 AND 2007 AT THE ROYAL CHILDREN'S HOSPITAL, MELBOURNE

Palliation (band or shunt, etc.)	10	7
Total	80	12 (15%)

Additional risk factors identified by those undertaking surgical treatment of double outlet right ventricle have included atrioventricular valvar abnormalities such as straddling or a common atrioventricular orifice.⁶¹ The situation is further complicated for many with a common atrioventricular valve by the presence of right isomerism. This is itself associated with a wide range of other complicating anomalies which adversely affect the outcome (see Chapter 22). On the other hand, when isomeric atrial appendages are not present, an atrioventricular septal defect is usually amenable to repair with little increase in hospital mortality, but an increased risk of reintervention.⁷⁸ Patients with severe mitral or left ventricular hypoplasia, and those with supero-inferior ventricles with an inlet septal defect, have been regarded as inoperable.⁵⁹ This becomes less important if such patients are suitable for conversion to the Fontan circulation. Subpulmonary and non-committed defects were initially regarded as risk factors,⁶⁵ but this has become less significant in the current era. The need for placement of a transjunctional patch, or for an external valved conduit, have also been regarded as risk factors. Hence, the presence of pulmonary stenosis in itself may be an independent risk factor.

Multi-variate analysis of the earlier cohort of 193 patients treated in Melbourne⁶⁴ showed that the most significant anatomic features adversely affecting mortality were multiple interventricular communications and aortic interruption or coarctation. Multiple septal defects were particularly significant for those patients who had a biventricular repair. The site of a solitary interventricular communication did not have any significant effect on mortality in the series as a whole. Neither did the presence of pulmonary stenosis, an atrioventricular septal defect with common atrioventricular junction, or pulmonary atresia. Early age at the time of definitive surgery was associated with increased mortality, but only in the age group below 1 month. Those patients undergoing surgery prior to 1985 were also at greater risk, this effect being independent of the other identifiable variables. Analysis of the expanded series, now including 352 patients undergoing surgery between 1978 and 2007, no longer shows multiple septal defects as a risk factor, but this appears to reflect the fact that patients who are classified as complex are usually converted to the Fontan circulation rather than attempting biventricular repair. Our experience is in keeping with the other findings,^{63,65} showing that mortality has improved substantially in the recent era. Details of the subgroups of patients treated in Melbourne with common atrioventricular valves and with multiple ventricular septal defects are summarised in [Tables 40-9 and 40-10](#), respectively.

Apart from early mortality, late problems may also be significant, with a mortality rate of 21% reported by some⁶⁰ amongst patients with a subaortic septal defect. Most of these late deaths were related to arrhythmias. Residual haemodynamic problems have included residual defects, subpulmonary stenosis, and subaortic obstruction. Actuarial freedom from reoperation was less than 50% at 8 years for patients with non-committed defects and for those with subpulmonary defects.⁶³ By contrast, those with subaortic defects had a rate of freedom from reoperation better than 90% at 8 years. In those undergoing surgery in Melbourne,⁶⁴ site of the defect was not a variable which influenced the need for reoperation. In that data, freedom from either

death or reoperation was 65% at 10 years from the time of definitive operation. Apart from these problems, quality of life following repair has, in most cases, been excellent.

Additional Problems in the Surgery of Double Outlet Ventricles

In patients with restrictive interventricular communications, intraventricular repair must be accompanied by surgical enlargement of the defect. Alternatively, an extracardiac conduit can be placed from the left ventricle to the aorta, permitting the interventricular communication to be closed. The presence of complicating intracardiac anomalies, such as mitral stenosis, straddling of an atrioventricular valve, or a common atrioventricular orifice, may necessitate more extensive surgery involving valvar repair or replacement and so on.⁷⁹

Double outlet right ventricle with discordant atrioventricular connections is amenable to correction in some cases either by construction of an intraventricular tunnel to connect the morphologically left ventricle to the pulmonary trunk, or by use of an external valved conduit inserted from the left ventricle to the pulmonary trunk combined with

closure of the interventricular communication.²⁴ In the current era, use of the arterial switch procedure, combined with a Senning or Mustard operation, or, in the presence of pulmonary stenosis, a Rastelli type repair, also coupled with a Senning or Mustard repair, has been employed with success.⁸⁰ Whether this is a better approach than to proceed using the Fontan approach, or bidirectional cavopulmonary shunting, is debatable. Unfortunately, as with congenitally corrected transposition, there is a high incidence of heart block following surgical repair. This is almost certainly related to the abnormal disposition of the conduction system in patients with discordant atrioventricular connections.⁸¹

In our series of patients treated in Melbourne, 16 patients had discordant atrioventricular connections, one of whom was submitted to a biventricular repair. We adopted the Fontan route for 12, with no mortality, and 2 further children have been palliated with a bidirectional cavopulmonary shunt. In one additional patient, with complex anatomy, we proceeded with an aortic valvotomy and implantation of a pacemaker, but the patient died suddenly 2 years later. The other 15 patients are all alive.

Isomerism of atrial appendages was present in 39 patients, with 21 having right and 18 left isomerism. In this group, 26 had common atrioventricular valves, 8 underwent biventricular repair, and 23 were tracked towards Fontan palliation. Definitive surgery was not possible in 8. Overall, the presence of isomerism was a significant risk factor for early death, including those who reached definitive surgery.

Probability of Long-term Survival

Actuarial probability of survival following biventricular repair was estimated by one group⁶³ as being 81% at 8 years, which is similar to the earlier experience in Melbourne,⁶⁴ in which the probability was 81% at 10 years. Overall probability of survival, from the time of initial

surgery be it palliative or corrective, in the entire cohort undergoing surgery in Melbourne for this earlier period was calculated as being 76% at 13 years. It is noteworthy that those patients who were considered to be unsuitable for biventricular repair, and who were managed by a Fontan or cavopulmonary shunt procedure, have had a better record of survival in the short term, with a probability of 92% survival at 6 years. This earlier experience is now borne out by a review of our enlarged cohort of 352 patients (Figs. 40-21, 40-22, and 40-23). Those converted to the Fontan circuit had a 94% probability of survival at 10 years, compared with survival at 10 years after biventricular repair of 86%. This is amplified when comparing the complex patients who achieved definitive surgery, in whom survival probability was 78% at 10 years for those undergoing biventricular repair as compared with 94% for those who were converted to the Fontan circulation. Whilst the confidence intervals are not sufficiently tight, at 10 years, to show a clear difference, the actuarial analysis suggests that this difference increases with follow-up out to 20 years, though obviously late morbidity and mortality after the Fontan procedure may tend to reduce or reverse this difference in longer-term follow-up. Significantly the actuarial analysis of freedom from death or reoperation for all patients is much less optimistic, with only 28% of those undergoing biventricular repair being alive and free of the need for further operation at 20 years, as opposed to 60% of those converted to the Fontan circulation, although confidence intervals are wide in this analysis, and as yet do not demonstrate a significant difference (see Fig. 40-23).

Repair of Double Outlet Left Ventricle

Surgical repair of double outlet left ventricle follows similar lines to that for double outlet right ventricle.^{82,83} Cases with pulmonary stenosis are usually best dealt with by insertion of an external valved conduit from the right ventricle to the

Figure 40-21 The graph shows the survival of complex patients undergoing surgery in Melbourne after biventricular repair or conversion to the Fontan circuit, indicating better long-term survival for those managed with the Fontan procedure.

Figure 40-22 The graph shows survival for non-complex patients undergoing surgery in Melbourne who achieved biventricular repair.

Figure 40-23 The graph shows survival, and freedom from reoperation, for all patients undergoing surgery in Melbourne who either achieved biventricular repair or were converted to the Fontan circulation. Overall, freedom from reoperation appears superior in those with the Fontan circuit, but this barely achieves significance, as the 95% confidence intervals continue to overlap out to 20 years.

pulmonary trunk. Placement of an intraventricular patch to direct right ventricular flow to the pulmonary trunk and left ventricular flow to the aorta may be possible in some cases. Unfortunately, it appears that a high proportion of patients have significant right ventricular hypoplasia, or other major complicating anomalies, making either of the above operations difficult or impossible. In such patients, conversion to the Fontan circuit, or creation of a cavopulmonary shunt, is likely to produce higher earlier and medium-term survival than an heroic attempt at biventricular repair.^{26,84}

These reviews provide a useful overview of the results of surgery for double outlet right ventricle in the modern era.

Common Arterial Trunk

DANIEL J. PENNY and ROBERT H. ANDERSON

Common arterial trunk is a rare congenital malformation of the heart. As its name implies, its essential anatomical feature is the presence of an arterial trunk, which arises from the ventricular mass through a common ventriculo-arterial junction, giving rise directly to the systemic, pulmonary and coronary circulations. In most centres, surgical treatment, the only appropriate current therapeutic approach, is now performed routinely following only non-invasive pre-operative investigations in early infancy. Operative mortality is now low, although it may be increased in patients in whom there are associated abnormalities, for example, interruption of the aortic arch, or stenosis or regurgitation of the truncal valve. In most cases, the technique used for surgical correction includes placement of a conduit as part of the reconstructed pulmonary outflow tract. Because of this, after this form of surgery patients must be followed indefinitely in a centre which specialises in the care of those having congenital cardiac disease, as most will require procedures to address stenosis of the conduit in later life.

INCIDENCE

Common arterial trunk is a rare anomaly, occurring in 0.03 per 1000 live births according to data assembled from the New England Regional Infant Cardiac Program.¹ Among 906,646 live-born infants collected in the Baltimore-Washington Study, 4390 had congenitally malformed hearts, with 51 having common arterial trunk, so that this malformation occurred in 0.056 of every 1000 live births, and represented just over 1% of all instances of congenital cardiac disease.² A recent study showed that surgical treatment of common arterial trunk accounted for almost 1% of open heart procedures performed at the Royal Liverpool Children's Hospital between 1993 and 2005. The incidence of congenital malformations of the heart is known to be increased in the offspring of patients with common arterial trunk, being 6.6% in the offspring of those with uncomplicated lesions, and 13.6% of those with complex forms of the condition.⁴

ANATOMY

Of all the congenital lesions that benefit from being described in straightforward fashion, common arterial trunk is the most obvious. When described in terms of truncus, or various expansions of this term that implicate persistence of an embryonic condition, it is always necessary to provide a definition of the lesion as seen in the postnatal heart. Describing the entity as a common arterial trunk negates the need for further definition. A common trunk is one that arises from the ventricular mass through a common

ventriculo-arterial junction, and gives rise directly to the systemic, pulmonary and coronary circulations (Fig. 41-1).

Almost without exception, the common ventriculo-arterial junction is guarded by a common arterial valve,⁴ but by analogy to atrioventricular septal defect with common junction (see Chapter 27), it might be anticipated that the arterial valvar leaflets could be divided into separate orifices for the right and left ventricles, whilst still guarding a common junction. The latter situation is seen in the setting of the doubly committed and juxta-arterial ventricular septal defect (see Chapter 28), but such patients do not possess common arterial trunks. The pattern of branching of the common trunk itself can be complicated by various arrangements of the individual arteries within the systemic, pulmonary, and coronary arterial circulations. The presence of the common trunk, nonetheless, distinguishes the entity not only from those with doubly committed ventricular

Figure 41-1 This specimen is dissected to show the typical features of a common arterial trunk, exiting from the ventricular mass through a common ventriculo-arterial junction guarded by a common arterial valve, and supplying directly the coronary, systemic and pulmonary circulations. Note the dysplastic nature of the truncal valve.

Figure 41-2 In this specimen, the atretic and thread-like pulmonary trunk can be traced back to the ventricular mass. This specimen, therefore, has a solitary aorta with pulmonary atresia, rather than common arterial trunk.

septal defects with separate aortic and pulmonary valves, but also from the close cousins in which there is a window between the intrapericardial components of the aorta and pulmonary trunk, and also those patients in which a large patent trunk leaves the base of the heart in company with an atretic trunk, which can also be traced from its origin at the ventricular mass (Fig. 41-2).

One variant that can still give problems in terms of description, however, is when there is complete absence of the intrapericardial pulmonary arteries. In their time-honoured classification, Collett and Edwards⁵ included this variant as the type IV within their overall grouping. The trunk arising from the ventricular mass in this setting (Fig. 41-3), however, is best described as a solitary, rather than a common, trunk. This is because there is no way of knowing, had they been present, whether the intrapericardial pulmonary arteries would have originated from the arterial trunk or from the right ventricular outflow tract (Fig. 41-4). In terms of clinical presentation and treatment, such patients with a solitary arterial trunk have more affinities with tetralogy and pulmonary atresia (see Chapter 37) than with common arterial trunk.

A common arterial trunk, as we have defined it, is one form of single outlet from the heart. As a malformation involving the ventriculo-arterial junctions, it must be anticipated to co-exist with all possible segmental combinations. In almost all instances, nonetheless, there will be usual atrial arrangement, with concordant atrioventricular connections. Examples can be found in combination with discordant atrioventricular connections, or with absence of the right atrioventricular connection.⁶ While the atrioventricular junctions themselves are usually separate,

Figure 41-3 Unlike the specimen shown in Figure 41-2, in this heart there are no intrapericardial pulmonary arteries. The trunk arising from the heart, therefore, is best described as a solitary arterial trunk, since it cannot be determined with certainty whether the trunk was initially an aorta or a common trunk (see Fig. 41-4).

Figure 41-4 The cartoon shows that, had the pulmonary arteries been present in the heart illustrated in Figure 41-3, they could have arisen either from the heart, or from the arterial trunk itself (dotted lines). There is no way of knowing, therefore, whether the trunk was destined to become an aorta or a common trunk. Because of this uncertainty, it is best described as a solitary trunk. Patients with this arrangement, nonetheless, are best considered as a subset of those with tetralogy and pulmonary atresia.

and guarded by mitral and tricuspid valves, a common trunk can rarely be found in association with an atrioventricular septal defect and a common atrioventricular valve.⁷

In the presence of the common trunk, almost always the truncal valve is connected across the ventriculo-arterial junctions with both ventricles, the valvar orifice overriding the ventricular septal crest, and typically with its leaflets in fibrous continuity with the mitral valve in the left ventricle (Fig. 41-5). Such a biventricular connection necessitates the presence of a juxta-arterial interventricular communication. The defect is generally large. Its floor is the crest of the ventricular septum, reinforced on the right ventricular aspect by the limbs of the septomarginal trabeculation, or septal band, and its roof is the leaflets of the truncal valve. The cone of space subtended by the truncal valve has right and left ventricular margins, but it is usually the right ventricular margin that is considered to represent the

Figure 41-5 This long-axis section shows the truncal valve overriding the crest of the muscular ventricular septum with the valvar leaflets supported in both ventricles, but typically, as shown, in fibrous continuity with the leaflet of the mitral valve.

ventricular septal defect, and it is this space which is closed by the surgeon during repair.

In the majority of cases, fusion of the inferior limb of the septomarginal trabeculation with the ventriculo-infundibular fold along this right ventricular margin produces muscular discontinuity between the leaflets of the tricuspid and the truncal valves (Fig. 41-6).

In the absence of such fusion, there is continuity between the leaflets of the tricuspid and truncal valves, making the ventricular septal defect perimembranous (Fig. 41-7). When present, this muscular bar in the postero-inferior margin protects the specialised axis responsible for atrio-ventricular conduction. In most instances, there is a large distance between the coapting arterial valvar leaflets and the crest of the septum during ventricular diastole when the leaflets are closed. This space, however, may sometimes be reduced, or the leaflets may close directly on the septal crest (Fig. 41-8).

Some have described this latter arrangement as representing an intact ventricular septum.⁸ This is somewhat misleading because, even in this arrangement, a septal deficiency is seen at ventricular level when the truncal valve opens during ventricular systole. Furthermore, hearts are found when the ventricular septum is truly intact, the common trunk then arising in most instances exclusively from the right ventricle (Fig. 41-9). The ventricular septal defect can also be restrictive when the common trunk takes an exclusive origin from one or other ventricle. Such a restrictive ventricular septal defect is more likely to produce problems when the trunk arises exclusively from the right ventricle (Fig. 41-10).

Figure 41-6 The presence or absence of a muscular rim along the postero-inferior margin of the ventricular septal defect determines whether or not the defect is considered to be perimembranous. In this specimen, the ventriculo-infundibular fold fuses with the postero-inferior limb of the septomarginal trabeculation (SMT). The muscular bar thus formed (white asterisk) protects the atrioventricular conduction axis during surgical correction.

Figure 41-7 Unlike the heart shown in Figure 41-6, in this specimen the ventriculo-infundibular fold does not fuse with the postero-inferior limb of the septomarginal trabeculation. Instead, the postero-inferior margin of the defect is made up of fibrous continuity between the leaflets of the tricuspid and truncal valves, making the defect perimembranous, and putting at risk the atrioventricular conduction axis during surgical correction (red dotted line).

Figure 41-8 In this specimen, the dysplastic leaflets of the common truncal valve closed on the crest of the ventricular septum during ventricular diastole, the crest itself being thickened by fibrous tissue. An interventricular communication remains, nonetheless, during ventricular systole. Note the persistently patent arterial duct.

Figure 41-10 Although usually the truncal valve overrides the ventricular septal crest, as shown in Figure 41-4, occasionally the trunk can arise exclusively from one or other ventricle, here from the right ventricle. Note the completely muscular subtruncal infundibulum, and the potentially restrictive ventricular septal defect.

Figure 41-9 In this heart, in which there was absence of the left atrio-ventricular connection and hypoplasia of the incomplete left ventricle, a common arterial trunk arises from the dominant right ventricle, and the ventricular septum is intact. (Courtesy of Dr Andrew Cook, Institute of Child Health, University College, London, United Kingdom.)

The truncal valve has three leaflets in approximately two-thirds of patients. In most of the remaining patients, either two or four leaflets are seen guarding the common arterial orifice. The leaflets are almost always in fibrous continuity with the antero-superior leaflet of the mitral valve (see Fig. 41-5), but there can be a completely muscular subtruncal infundibulum, particularly when the common trunk arises exclusively from the right ventricle (see Fig. 41-10). Insufficiency of the truncal valve is not uncommon, and can be caused by thickened and dysplastic leaflets, or by prolapse of unsupported leaflets as a result of dilation of the ventriculo-arterial junction. Truncal valvar stenosis is relatively uncommon. When present, it is usually because the valvar leaflets are dysplastic.

The greatest anatomic variability is found in the pattern of the branching of the common trunk. The presence of a right-sided aortic arch, with mirror-imaged branching of the brachiocephalic arteries, is associated more often with common trunk, occurring in up to one-third of patients, than with any other congenital cardiac malformation.^{4,9} Hypoplasia of the aortic arch, with or without coarctation, is a particularly important associated finding, but is less frequent than complete interruption of the arch (Fig. 41-11).

Such interruption is one of the major subgroups recognised in the alpha-numeric system that was suggested for classification.¹⁰ When the arch is interrupted, the persistently patent arterial duct feeds the descending thoracic aorta and part of the brachiocephalic circulation, the precise proportion depending on the site of interruption. As with other forms of interruption of the aortic arch (see Chapter 46),

Figure 41-11 In this specimen, the systemic pathways are interrupted between the left common carotid and left subclavian arteries. The arterial duct feeds the descending aorta and the left subclavian artery. The probes are placed in the pulmonary arteries, which arise from the back of the common trunk. Note that the trunk itself arises almost exclusively from the left ventricle.

Figure 41-12 In this rare example of common arterial trunk, the pulmonary arteries arise directly from the left-sided truncal arterial sinus. (Image prepared and photographed by Dr Siew Yen Ho, Royal Brompton Hospital, London, and reproduced with her permission.)

retro-oesophageal origin of the right subclavian artery is frequently seen. Apart from those hearts with severe coarctation or interruption, or in which the pulmonary arteries are discontinuous, and one is fed through a patent duct, it is rare to find ductal patency co-existing with common arterial trunk, although it does exist (see Fig. 41-9).¹¹ While the state of the aortic arch is possibly the most significant clinical associated malformation, it has been the arrangement of origin of the pulmonary arteries, following the system proposed by Collett and Edwards⁵ that was traditionally used most frequently for numeric classification. The pulmonary arteries typically arise from the left posterolateral aspect of the common trunk, taking origin a short distance above the truncal valve, albeit that very rarely they can take their origin directly from a truncal arterial valvar sinus (Fig. 41-12).

In the more usual situation, it is the presence of a short confluent arterial segment that produces the type I identified by Collett and Edwards (Fig. 41-13). Alternatively, the right and left arteries can take separate origin from the posterior aspect of the trunk, producing the type II variant (Fig. 41-14), or very rarely from the right and left sides of the posterior aspect of the intrapericardial segment of the common trunk, this being the type III variant. In most instances, however, the morphology is intermediate, and many have suggested that this pattern should be recognised as type 1½. It is also possible to find examples in which only one pulmonary artery arises from the common trunk, the other being supplied initially through a duct that became ligamentous. In the clinical setting, this can present as

Figure 41-13 In this specimen, a short confluent pulmonary arterial segment interposes between the common trunk and the origin of the right and left pulmonary arteries. This is the so-called type I variant described by Collett and Edwards.

Figure 41-14 In this specimen, the right and left pulmonary arteries take separate origin from the leftward and posterior aspect of the common trunk. This is the so-called type II variant described by Collett and Edwards.

Figure 41-15 In this specimen, with a short confluent pulmonary arterial segment interposed between the common trunk and the origin of the right and left pulmonary arteries, the right pulmonary artery arises to the left of the origin of the left pulmonary artery. This is crossed pulmonary arteries.

unilateral absence of one pulmonary artery, but almost always the artery presumed to be absent is identified within the hilum of the lung. When this arrangement is found with common trunk, the discontinuous pulmonary artery initially fed by the duct is most frequently on the same side as the aortic arch. This is in contrast to the finding in patients with tetralogy of Fallot when one pulmonary artery is seemingly absent, since in this setting, the discontinuous artery is more frequently on the side opposite the aortic arch.

In some circumstances, the pulmonary artery feeding the right lung is to the left at its origin from the common trunk relative to the artery running to the left lung (Fig. 41-15). The two arteries then spiral as they extend to the pulmonary hilums. This entity is called crossed pulmonary arteries. As we have already discussed, in the original categorisation of Collett and Edwards⁵ there was also a type IV variant, which exists when the intrapericardial pulmonary arteries are completely absent. As we have described (see Fig. 41-2), this arrangement is better described as a solitary arterial trunk, since in the absence of the intrapericardial pulmonary arteries, it cannot be determined whether, had they been present, they would have arisen from the heart, giving solitary aortic trunk with pulmonary atresia, or from the arterial trunk itself, producing common trunk with pulmonary atresia. Irrespective of such speculative considerations, in clinical terms patients with absence of the intrapericardial pulmonary arteries present as a subset of those with tetralogy of Fallot with pulmonary atresia, rather than common arterial trunk. It is also possible for one pulmonary artery to arise directly from the ascending aorta, while the other takes its origin from the right ventricle. Some call this malformation

hemitruncus. This is incorrect since, of necessity, the hearts have separate ventriculo-arterial junctions guarded by separate aortic and pulmonary arterial valves. They cannot, therefore, be examples of common arterial trunk.

Anomalies of the origin and distribution of the coronary arteries are frequent.¹⁰ Unlike the situation when there are separate aortic and pulmonary valves, in which virtually without exception the coronary arteries arise from one or other of the aortic valvar sinuses adjacent to the pulmonary trunk, and usually both sinuses, there is no constant pattern of sinusal origin in the presence of a common ventricular outflow tract. Instead, the coronary arteries can arise from any of the truncal valvar sinuses, albeit that in most instances there are still two coronary arteries, with the left artery giving rise to anterior interventricular and circumflex branches. The arteries often arise close to a zone of apposition between the valvar leaflets, and origin above the sinutubular junction is quite common (Fig. 41-16). This can produce potential difficulties during surgical correction should the high origin be adjacent to the origin of the pulmonary arteries.

Knowledge of location of the atrioventricular conduction axis is also important when planning surgical repair. The sinus node and the atrioventricular node are normal in their location and structure. Having taken origin from the atrioventricular node, the penetrating atrioventricular bundle pierces through the central fibrous body, and the left bundle branch originates along the left ventricular septal endocardium (see Chapter 28). The right bundle branch travels within the myocardium of the ventricular septal crest, attaining a subendocardial course at the level

Figure 41-16 Note the origin of the left coronary artery above the zone of apposition of two of the leaflets of the tricuspid valve, but very close to the origin of the pulmonary arteries. The surgeon seeking to correct this specimen would need to take care not to damage the coronary arteries when removing the pulmonary arteries from the common trunk.

of the moderator band. In those hearts in which a muscular bar interposes between the attachments of the tricuspid and aortic valves in the postero-inferior margin of the septal defect, the membranous septum is intact behind the muscular tissue, and the atrioventricular conduction tissues are somewhat distant from the rim of the defect (see Fig. 41-5). In patients in whom the ventricular septal defect is perimembranous, in contrast, the conduction tissue passes directly along the left aspect of the fibrous postero-inferior rim of the defect (see Fig. 41-6). It is then at greater surgical risk. We have already mentioned most of the common associated cardiovascular anomalies found in the setting of common arterial trunk, including a right aortic arch, interrupted aortic arch, patency of the arterial duct, discontinuity of one pulmonary artery, coronary arterial anomalies, and incompetent tricuspid valve. A defect within the oval fossa has been noted in up to one-fifth of patients, persistence of the left superior caval vein draining to the coronary sinus in up to one-tenth, and an aberrant subclavian artery in between one-tenth and one-twentieth.¹² Partially anomalous pulmonary venous connection has also been reported.¹³

AETIOLOGY AND MORPHOGENESIS

Over the past decade, the evidence has accumulated that many cases of common arterial trunk result from a genetic defect. The evidence comes from interpretation of morphology, experiments in animals, studies on the role of

cells migrating from the neural crest in the development of the outlet components of the heart and the arterial trunks,¹⁴ and the discovery of deletions in chromosome 22q11 in patients with malformations involving the outflow tracts, often described as so-called conotruncal defects.^{15,16}

The morphology of common arterial trunk supports very strongly the notion that, during development, there has been failure of septation of the ventricular outlets and the outflow segment of the heart tube. It had been suggested that the entity represents failure of formation of the subpulmonary infundibulum, with the common arterial trunk in essence representing the aorta.¹² No evidence has accrued over the last decades to support this latter notion, but much has appeared to contradict it. From the morphological stance, specimens with common arterial trunk show no evidence of a blind-ending subpulmonary outflow tract, such as is seen in tetralogy with pulmonary atresia. It is this latter entity that provides the paradigm for underdevelopment of the subpulmonary outflow tract. In such hearts with tetralogy and pulmonary atresia, four-fifths of specimens have perimembranous ventricular septal defects. In contrast, in the setting of common arterial trunk, four-fifths of hearts have a muscular postero-inferior rim to the ventricular septal defect. Additionally, if the arterial root truly represented the aorta, then coronary arteries would be anticipated to arise in patterns comparable to those seen in the normal heart. This is rarely the case in the setting of common arterial trunk, where the origins and course of the coronary arteries are frequently bizarre.¹¹

Direct studies of cardiac development, on both normal and abnormal hearts, have always shown that the initially common ventricular outflow tract is separated by endocardial cushions, or ridges, to produce the intrapericardial arterial trunks, along with the arterial valvar leaflets and sinuses and their supporting ventricular outflow tracts.¹⁷ Failure of such separation during embryological development was demonstrated conclusively as producing common arterial trunk in an elegant study using Keeshond dogs published as long ago as 1978. This study¹⁸ showed that the cushions which normally divided the outflow segment of the heart failed to fuse in the setting of common arterial trunk, the concept subsequently being endorsed by further studies carried out by Bartelings and colleagues.¹⁹ Much work over the past 15 years has provided further evidence of the importance of the outflow cushions in dividing the initially common ventricular outflow tract, and has demonstrated an important role for cells migrating from the neural crest in populating these cushions (Fig. 41-17).

Other studies have shown that, when the migration of the cells from the neural crest is perturbed, the cushions do not develop properly, and one of the lesions produced is common arterial trunk.²⁰ This is in keeping with the results of selective inbreeding of the Keeshond dogs, which were used to study normal development.¹⁸ Using the same colony of inbred animals, a similar spectrum of malformations to that obtained subsequent to perturbation of the neural crest was observed.²¹ Many animals had common arterial trunk, but others had ventricular septal defects, or tetralogy of Fallot. Significantly, the pattern of inheritance was consistent with a defect at a single autosomal locus. The genetic basis for such malformations is further supported by observations made in the homozygous mutant *Spotch* mouse,

Figure 41-17 This section comes from a mouse in which the cells migrating from the neural crest are marked by a construct revealing the *Wnt1* gene, which is revealed by the blue colouration. The cells occupy both cushions, which are separating the distal outflow tract into the aortic and pulmonary channels. (Courtesy of Dr Sandra Webb, St George's Hospital Medical School, London, United Kingdom.)

in which a common arterial trunk arises exclusively from the right ventricle in many of the malformed embryos.²⁰ Common arterial trunk has been produced when there is deficiency of *sox4*, a gene which also normally populates the endocardial cushions of the developing outflow tracts.^{22,23} Some of the afflicted embryos in these experiments, however, had doubly committed ventricular septal defects rather than common arterial trunk. This is of particular interest, since as we have already discussed, the morphology of the outflow tracts is almost identical in the setting of a common arterial trunk (see Fig. 41-17) and in doubly committed defects, apart from the finding of separate aortic and pulmonary valvar orifices in the latter malformations. All of this is pertinent to findings in humans with microdeletions of chromosome 22q11.

The initial report of a family with a chromosomal translocation resulting in partial trisomy for chromosome 20 and partial monosomy for chromosome 22, with all patients having DiGeorge syndrome, and one having common arterial trunk, led to searching for microdeletions in the 22q11 region, first by high resolution banding,^{24,25} and then by fluorescent in situ hybridisation.²⁶ These investigations revealed that a majority of patients with DiGeorge syndrome have 22q11 deletions. As yet, however, no single gene has been found to be responsible for all cases, although the *TUPLE* gene has been implicated in some cases. It has been shown, nonetheless, that the DiGeorge syndrome is best considered as the severe end of a clinical spectrum. For a while, it was referred to as CATCH 22, with reference to the novel by Joseph Heller, and reflecting cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcaemia produced by deletions of 22q11. Experience showed that such usage was interpreted in pejorative fashion, and the term is now frowned upon. Be that as it may, nearly one-third of patients with non-syndromic defects involving the ventricular outflow tracts, and one-third of those with common arterial trunk, have been shown to have microdeletions in the DiGeorge critical region.²⁷ An association between common arterial trunk, and other

anomalies of the outflow tracts, and CHARGE syndrome (coloboma, heart disease, choanal atresia, retardation [mental and physical] genital hypoplasia, and ear anomalies) has also long been recognised. The anomalies of the outflow tracts found with CHARGE syndrome are much the same as in DiGeorge syndrome, except that tetralogy of Fallot and double outlet right ventricle predominate in the former, whereas, in the latter, common arterial trunk and interruption of the aortic arch proximal to the left subclavian artery are more common. It seems likely therefore, that chromosomal damage leads to deletions of 22q11, which, in some way, interferes with the migration of cells from the neural crest, and thereby causes damage to the third and fourth pharyngeal pouches. We have come a long way in understanding the morphogenesis of these lesions since the late lamented Robert Freedom and his colleagues²⁸ drew the attention of paediatric cardiologists to the association between anomalies of these pharyngeal pouches and congenital cardiac malformations.

It should not be thought, however, that all is now resolved. One-fifth of patients with terminal deletions of the long arm of chromosome 7 have been reported to have cardiac anomalies, including common arterial trunk.²⁹ In patients identified in the Baltimore-Washington Infant Study,² those with malformations of the outflow tracts showed no recurrences from 109 parents or siblings, in keeping with the findings of Nora and Nora,³⁰ who suggested a lower than usual recurrence rate of 1% for common arterial trunk, although subsequent studies were less convincing in this respect.³¹ Other studies have suggested an autosomal recessive pattern of inheritance.³² There are also other reliably documented reports of common arterial trunk in siblings,^{31,33,34} while two sets of three siblings have been documented with the lesion.^{35,36} Dizygotic twins concordant for common arterial trunk have also been described.³⁷ Patients with common arterial trunk, therefore, continue to be a fertile population in which to study the genetic background of congenital cardiac malformations.

DIAGNOSTIC FEATURES

Antenatal Diagnosis

It might be expected that common arterial trunk would be detected during the mid-trimester scan for fetal anomalies, which is routine in many countries. In practice, population-based studies demonstrate that the diagnosis may often be missed,^{38,39} presumably because the four-chamber view of the heart may appear to be normal on superficial examination. More detailed echocardiographic examination of the fetal heart, nonetheless, should reveal a ventricular septal defect. An arterial trunk that overrides the defect is the only outlet which arises from the ventricular mass.⁴⁰ Under ideal circumstances it will be possible to document the degree of regurgitation or stenosis of the truncal valve, and the course and integrity of the aortic arch can be delineated⁴⁰ (Table 41-1).

There are now a number of reports which document the outcomes for fetuses after such antenatal detection. Despite what we might now consider to be excellent outcomes from surgical repair, a significant proportion of parents will choose to terminate the pregnancy.^{40,41} A significant proportion of

TABLE 41-1

KEY DIAGNOSTIC FEATURES IN COMMON ARTERIAL TRUNK

Fetal echocardiogram	Four-chamber view	Ventricular septal defect with truncal override (may appear normal)
	Great vessels	Single arterial trunk Truncal regurgitation
Clinical examination	Aortic arch	Interruption
	Inspection	(?)Mild cyanosis Failure to thrive Tachypnoea
	Palpation	Bounding pulses Liver enlargement
	Auscultation	Normal first heart sound May have a single second sound (although not always) Ejection click Ejection systolic murmur (?) Diastolic murmur of truncal regurgitation
Electrocardiogram		Non-specific usually combined ventricular hypertrophy
Chest radiograph		Cardiomegaly Increased pulmonary vascular markings Narrow arterial pedicle
Echocardiogram	Parasternal long axis	Truncal origin Ventricular size and mural thickness Ventricular septal defect Velocity of interventricular shunting Truncal regurgitation
	Parasternal short axis	Morphology of truncal valve Mechanism of truncal regurgitation Origin of pulmonary arteries Stenosis of pulmonary arteries Origin of coronary arteries
	Apical four chamber	Ventricular origin of trunk Truncal regurgitation Truncal stenosis Function of atrioventricular valves
	High parasternal	Aortic arch Arterial duct Interruption of aortic arch
Cardiac catheterisation	Haemodynamics	Pressure measurement in right and left pulmonary arteries Pressure drop across truncal valve
	Oximetry	Pulmonary-to-systemic blood flow ratio
	Pulmonary vasodilator	To assess pulmonary vascular responsiveness
	Angiocardiography	Truncal injection to examine the degree of regurgitation Selective pulmonary angiogram Left ventriculogram to evaluate the size and location of septal defects

fetuses will have associated non-cardiac anomalies,⁴¹ with or without a deletion within chromosome 22.⁴²

Neonatal Presentation

The typical patient with common arterial trunk will present during the neonatal period, or in early infancy, with mild central cyanosis, a hyperactive precordium, and signs of increasing congestive cardiac failure. There will be difficulties in feeding, failure to thrive, often extreme tachypnoea, and hepatic enlargement. A wide pulse pressure, with bounding pulses, is to be anticipated. While a minor degree of hypoxaemia is common, obvious cyanosis is a feature of either raised pulmonary vascular resistance, or pulmonary stenosis. Once cardiac failure is established, the chest may bulge in consequence of the cardiomegaly.

At auscultation, the first heart sound is usually normal, while the second sound is accentuated. It might be anticipated that the second sound would always be single in the presence of a common arterial valve. This is not the case. In approximately one half of infants, there is close splitting of the second sound, documented by phonocardiography as well as by auscultation.⁴³ Possible explanations for this finding are asynchronous closure of the valvar leaflets, or production of a duplicate sound by vibrations within the arterial trunk. In most infants, there will also be a loud systolic ejection click, heard best at the apex, which coincides with the opening of the truncal valve. A systolic murmur is almost always heard, but can be of varying intensity and duration. Other findings often include an ejection systolic murmur of grade II or III heard maximally at the mid-to-upper left sternal border, or a harsh pansystolic murmur of

grade III or IV heard maximally at the lower left sternal border. Less common murmurs include the apical mid-diastolic one, which results from flow, and an early diastolic murmur heard maximally along the left sternal edge, indicating trun- cal valvar insufficiency. Rarely, the murmur may be contin- uous and heard not only over the precordium but also the back. This is indicative of pulmonary stenosis. Surprisingly, in perhaps one tenth of patients, no murmur is heard at all at the time of presentation. This indicates an absence of tur- bulence within the ventricles or their outflow tracts.

ELECTROCARDIOGRAPHY

Normal sinus rhythm is the rule, and conduction through the heart is similarly normal. The QRS axis as seen in the frontal plane is extremely variable and non-specific but is almost always directed inferiorly. The distribution of ventricular forces is also variable, reflecting the variability encountered in ventricular hypertrophy. The majority of patients showed evidence of combined ventricular hyper- trophy, with isolated right ventricular hypertrophy also a frequent finding.⁴⁴ It is unusual to find evidence of isolated left ventricular hypertrophy, or a normal pattern. There are, therefore, no specific electrocardiographic features for patients with common arterial trunk, except perhaps that inversion of the T waves is seen with frequency in the left precordial leads, probably reflecting the impaired coronary arterial diastolic flow.

RADIOLOGIC FEATURES

The chest radiograph shows significant cardiomegaly, together with an increase in pulmonary vascular markings (Fig. 41-18). The aortic arch is right sided in approxi- mately one-third of patients. This finding, in association with increased pulmonary vascularity, is strongly suggestive of common trunk. It may be possible to see an unusually high

Figure 41-18 Chest radiograph obtained from a four-week-old infant with common arterial trunk, demonstrating increased pulmonary vascular markings.

origin of the left pulmonary artery with no intervening con- fluent pulmonary arterial segment. Although the trun- cal root itself is dilated, the arterial pedicle tends to appear narrow simply because of its commonality. When flow of blood to the lungs is decreased, the heart is less enlarged, and the pulmonary vascular markings are closer to normal. Pronounced discrepancy between the vascular markings on the two sides suggests unilateral atresia, or absence, of one pulmonary artery. As with the electrocardiogram, there are no specific findings, but the association of right arch and plethora is highly suggestive of the diagnosis.

ECHOCARDIOGRAPHY

It is now possible in most instances to evaluate neonates and infants having common arterial trunk with such preci- sion that only cross sectional echocardiography is required prior to corrective surgery.⁴⁵ The goals of echocardiography are to define the ventricular origin and pattern of branching of the common arterial trunk, to determine the morphol- ogy and any functional abnormalities of the trun- cal valve, to exclude any stenosis at the origins of the pulmonary arteries, to distinguish a perimembranous ventricular sep- tal defect from one with a muscular postero-inferior rim, to exclude any abnormalities of the aorta, and to define all other associated lesions. In the majority of patients, tran- thoracic echocardiography will provide all of the diagnostic information.

The parasternal long-axis section of the left ventricle will usually show the common arterial trunk overriding the ven- tricular septum, with its valve forming the superior border of the ventricular septal defect (Fig. 41-19). This feature, of course, is lacking when the trunk has a univentricular origin. If the pulmonary arteries have a confluent segment, it will be seen arising posteriorly from the common trunk in this view. The leaflets of the trun- cal valve are frequently dysplastic and, occasionally, can prolapse, causing the ventricular septal defect to be restrictive. Indeed, as shown morphologically, the leaflets may occasionally coapt directly on the crest of the ventricular septum. Colour flow Doppler interrogation will demonstrate flow to the aorta from both the right and left ventricle, and will document any trun- cal valvar insufficiency, which can be predominantly or exclusively to either

Figure 41-19 Echocardiographic image from a parasternal window, demonstrating the long axis of the heart. There is a common arterial trunk (Tr) which overrides the crest of the muscular ventricular septum. LV, left ventricle, RV, right ventricle.

the right or the left ventricle. When the valve is stenotic, there is limited excursion of the leaflets. Turbulent flow distal to the truncal valve will then be evident on colour flow or continuous wave interrogation. The parasternal long-axis sections will demonstrate the expected fibrous continuity between the leaflets of the truncal valve and the truncal leaflet of the mitral valve (see Fig. 41-19), the degree of dilation of the left ventricle and the extent of biventricular hypertrophy. Restriction of the ventricular septal defect will be seen in this view. Continuous wave Doppler interrogation will then record a drop in pressure across the defect, which may either be from left to right or from right to left, depending upon the ventricular origin of the common trunk.

The parasternal short-axis section taken just above the level of the truncal valve demonstrates the pulmonary arteries as they arise from the common trunk. In the so-called type I variant of common trunk, a short pulmonary arterial segment arises from the left lateral aspect of the common trunk, and then divides into right and left pulmonary arteries (Fig. 41-20). Stenosis at the origin of the right or left pulmonary arteries, or pulmonary arterial hypoplasia, will be evident in this section. In the so-called type II pattern, the right and left pulmonary arteries arise from the posterior wall of the common trunk through separate but adjacent orifices (Fig. 41-21). In practice, it is often difficult to distinguish these patterns, even in postmortem specimens.

Figure 41-20 Echocardiographic image demonstrating the short axis of the arterial trunk (Tr). The right (RPA) and left (LPA) pulmonary arteries arise from a short common artery. There is laminar flow in both pulmonary arteries which are of normal calibre.

Figure 41-21 Echocardiographic image taken from a parasternal window demonstrating the separate origin of the right pulmonary artery (RPA). There is laminar flow within the pulmonary artery which is of normal calibre.

Figure 41-22 Image of the truncal valve, imaged from a parasternal window. In this patient the valve was functionally bicuspid.

In contrast, the type III variant is easily distinguished, the right and left pulmonary arteries arising from the common trunk via two widely separated orifices. Other rarer origins of the pulmonary arteries must be anticipated, including atresia or even absence of one pulmonary artery. The parasternal short-axis section will also identify the number of truncal valvar leaflets (Fig. 41-22). Discontinuity between the tricuspid and truncal valvar leaflets will be seen in this cut when there is a muscular postero-inferior rim to the ventricular septal defect, expected in four-fifths of patients.

The apical and parasternal four-chamber sections also demonstrate the large subarterial ventricular septal defect and the overriding of the truncal valve. Colour flow Doppler interrogation will usually demonstrate biventricular shunting across the defect. Any truncal valvar insufficiency will be evident in this view, while duplex scanning with continuous wave Doppler documents any systolic gradient should the truncal valve be stenotic. The diastolic drop in pressure between the common trunk and the ventricular mass can be demonstrated when there is valvar insufficiency. The drop in pressure identified across a stenotic truncal valve, however, will exaggerate the severity of stenosis. This is because the increased flow of blood to the lungs gives rise to a large left ventricular output. Gradients of up to 60 mm Hg as estimated with Doppler, therefore, will become insignificant after corrective surgery.

Although the parasternal long- and short-axis sections will demonstrate the pulmonary arteries arising posteriorly from the common trunk, the subcostal long-axis sections are unique in their ability to display most of the morphological features of common arterial trunk. The subcostal paracoronary sections demonstrate the ventricular septal defect, the nature of its postero-inferior rim, the overriding of the common trunk (Fig. 41-23), and the origin of both the ascending aorta and the pulmonary arteries (Figs. 41-24 and 41-25). Oblique sections may reveal not only the origins of the pulmonary arteries, but also the integrity of the aortic arch (Fig. 41-26). A right oblique section identifies the entirety of the proximal right pulmonary artery, whereas leftward rotation can be used to demonstrate the features of the left pulmonary artery. These sections also permit identification of any stenosis at the origins of the left and right pulmonary arteries, and will

reveal rare findings such as crossed origins of the pulmonary arteries.⁴⁶ Duplex scanning can be used to measure the drop in pressure across any identified stenoses. Anterior angulation demonstrates the morphology of the truncal valve, while colour mapping reveals the severity of truncal regurgitation (Fig. 41-27). Characteristically, interrogation using continuous wave Doppler identifies both systolic and diastolic flow immediately distal to the site of stenosis. Suprasternal sections can also be used to identify the origin of the pulmonary arteries from the common trunk. These cuts, in addition, will demonstrate any interruption of the aortic arch, the side of the aortic arch, and additional anomalies such as presence of an arterial duct or aortic coarctation. Retrograde diastolic flow is observed quite frequently in the aortic arch, reflecting the low diastolic pressure in the pulmonary arteries.

It is not unusual for interruption of the aortic arch to be associated with common arterial trunk, often in combination with significant dysplasia of the truncal valvar leaflets producing insufficiency and/or stenosis. Almost always the ascending aorta is relatively hypoplastic, being smaller than the proximal pulmonary arteries. The interruption can occur at any of the classical sites. At the time

Figure 41-26 Oblique image of the heart taken from a subcostal window, demonstrating the arterial trunk, the origin of the pulmonary artery from it and the integrity of the aortic arch.

Figure 41-27 Image of the heart taken from a subcostal window, with anterior angulation of the transducer. The origins of the right (RPA) and left (LPA) pulmonary arteries are widely separated and the origin of the left pulmonary artery is hypoplastic. Colour mapping demonstrates mild regurgitation of the truncal valve (*asterisk*).

of echocardiographic investigation, most neonates will already be receiving prostaglandins intravenously. Consequently, the arterial duct will be relatively large. While the presence of a patent arterial duct would lead one to suspect the presence of interruption of the aortic arch, ductal patency may rarely be present in association with a normal arch.⁴⁷ The high left parasternal echocardiographic section demonstrates the duct, and colour flow will then usually demonstrate the flow through it to be bidirectional. Pulsed Doppler interrogation reveals that systolic flow is from the pulmonary arteries to the descending aorta, albeit that, provided that the pulmonary vascular resistance is low, there will be reversal of flow during diastole. The suprasternal parasagittal sections will reveal the site of aortic interruption, if present, relative to the origin of the brachiocephalic, left common carotid and left subclavian arteries.

CARDIAC MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging is rarely used in the investigation of patients with common arterial trunk before surgery, as in most instances, cross sectional echocardiography provides adequate diagnostic information. Nonetheless, there may be some instances, for example in the examination of complex problems of the aortic arch or anomalies of the drainage of the pulmonary veins, where magnetic resonance may make a contribution to the pre-operative investigation. Such imaging makes a more significant contribution to the investigations of patients after surgery, when it permits the quantitative assessment of not only the performance of the right and left ventricles, but also of the severity of regurgitation of the neo-aortic and pulmonary valves, along with measurement of residual intracardiac shunts and imaging of the aortic arch.⁴⁸

CARDIAC CATHETERISATION AND ANGIOCARDIOGRAPHY

It is now possible to refer patients with typical non-invasive findings directly for corrective surgery. Should there be any doubt about any aspect of the presentation, however,

cardiac catheterisation should be performed, particularly if there is any suggestion of pulmonary vascular obstructive disease.⁴⁹

If catheterisation is to be performed, separate catheters should ideally be placed in each pulmonary artery, a systemic artery, the superior caval vein, and at least one pulmonary vein. Consumption of oxygen should be measured while the catheter in the superior caval vein is withdrawn to the inferior caval vein to obtain a second measurement of systemic venous oxygen. Then, with further manipulation, more values should be obtained to determine pulmonary venous saturation. The effect of administration of 100% oxygen, or pulmonary vasodilators, should be measured. Entry to the pulmonary arteries is achieved most readily by retrograde arterial catheterisation, looping the catheter in the truncal root so that it can then pass upwards into the pulmonary arteries.

Oximetry will reveal an increase in the saturation of oxygen in the pulmonary arteries, compared to the caval veins, indicative of a net left-to-right shunt (Fig. 41-28). Commonly, the saturation of oxygen in the pulmonary arteries may be lower than in the aorta, reflecting the streaming of blood preferentially from right ventricle to pulmonary arteries, and from the left ventricle to the aorta.^{9,13} Pulmonary venous saturations of oxygen cannot be assumed, because pulmonary oedema or chest infection can result in pulmonary venous desaturation.

Measurements of pressure will reveal, in the typical case, similar pressures in the right and left ventricles. There may be minor differences between the measurements in the two pulmonary arteries, and between the pulmonary arteries and the aorta, which may reflect streaming. Pressure differences may also reflect obstruction at the point of origin of pulmonary arteries from the aorta, or in one pulmonary artery. Such differences in pressure between the aorta and the pulmonary arteries were found in almost half of the patients studied by Calder and colleagues.⁹ Any differences in systolic pressure should be noted across the truncal valve. These were reported to occur in one third of the patients investigated by Calder and colleagues⁹ and varied from 10 to 60 mm Hg. Minor differences in pressure, nonetheless, are common and reflect excessive flow, rather than truncal stenosis.

Figure 41-28 Representative measurements of oxygen saturations (left hand panel, in percent) and pressures (right hand panel, in mmHg) obtained during cardiac catheterisation in a patient with common arterial trunk. There is evidence of a substantial left-to-right shunt, with the oxygen saturation in the pulmonary arteries, exceeding that in the caval veins. Nonetheless, the oxygen saturation in the aorta exceeds that in the pulmonary arteries, because of streaming. Pressures in the right and left ventricles are equal and there is no evidence of stenosis of the truncal valve. The pressure which was measured in the left pulmonary artery is slightly less and that in the right pulmonary artery and significantly less than that in the aorta, reflecting a stenosis of the origin of the right pulmonary artery.

Selective angiocardiology should consist, first, of injecting contrast medium into the truncal root, filming in frontal and lateral projections. Elongated right anterior oblique views show well the division of the aortic and pulmonary pathways from the trunk.⁵⁰ Rapid injections are necessary to avoid excessive dilution of the contrast medium by the torrential flow. Such an injection should demonstrate the anterior tilt of the truncal root,⁹ the origin of one or both pulmonary arteries from the ascending trunk, and the degree of truncal regurgitation. Exceptionally, the pulmonary arteries may be seen arising from the underside of the aortic arch,⁵¹ albeit that it is questionable in this setting whether the trunk itself is a common rather than a solitary structure. The arteries can also arise from other unusual sites, such as one of the truncal sinuses. An injection in the truncal root will usually demonstrate any interruption of the aortic arch, and should also reveal any unilateral absence of one pulmonary artery, an association found in between one-tenth and one-sixth of patients.^{9,13,52} If suspected, then a further descending aortogram, and selective injection(s) into collateral arteries, or even pulmonary venous wedge injections on the side of the absent pulmonary artery, should clarify whether the artery really is absent, or whether it originally derived its blood supply from an arterial duct. Abnormalities of the origins of the coronary arteries have been identified as a risk factor in one large surgical series of infants.⁵³ Although it was suggested that such abnormalities should be identified by coronary arteriography, or by echocardiography prior to surgery, there is no evidence as yet that such findings have reduced surgical mortality.

SURGICAL TREATMENT

Early attempts at surgical palliation involved banding the pulmonary arteries, either at the level of a confluent pulmonary arterial segment or separately for the right and left arteries. This procedure has now been almost completely abandoned, in favour of complete surgical repair. The first such complete repair of common arterial trunk, using a valved conduit to restore continuity from the right ventricle to the pulmonary arteries, was achieved at the Mayo Clinic in September 1967.⁵⁴

The operation begins with dissecting both pulmonary arteries down to their points of branching in the hilums of both lungs. The aorta is fully mobilised. The surgery is performed under hypothermic cardiopulmonary bypass. The degree of truncal incompetence is carefully assessed. Significant regurgitation may interfere with myocardial protection, irrespective of whether that is carried out by intermittent crossclamping or cardioplegia, which may make it necessary to inject cardioplegic solution into the coronary arteries or coronary sinus to achieve adequate protection. The pulmonary arteries are detached from the common trunk, taking care to avoid any coronary arterial origins. The defect in the aorta may be closed by direct suture, or with a small patch of polyester (Dacron) or polytetrafluoroethylene (Gore-Tex). If there is no confluent pulmonary arterial segment, access is improved by transecting the ascending component of the common trunk. The separate pulmonary arteries are excised with the interposed portion of trunk as a single button, and the ascending aorta is reconstructed as an end-to-end anastomosis. The ventricular septal defect is then closed with a patch in

Figure 41-29 Repair of common arterial trunk, without a conduit. **A**, The pulmonary trunk is anastomosed to the right ventricle. **B**, The anterior aspect of the anastomosis and pulmonary trunk is augmented with a monocusp.

such a way as to connect the remaining aortic component of the trunk with the left ventricle. Continuity between the pulmonary arteries and the right ventricle can often be established with the aorta crossclamped while the patient is being rewarmed. With adequate mobilisation of the pulmonary arteries, it should be possible to anastomose a homograft directly onto the right ventriculotomy without any prosthetic interposition.

As the availability of homografts may be limited, and in order to avoid the long-term problems of homograft stenosis, modifications to the procedure have been described which avoid their use. In one such modification, continuity between the right ventricle and pulmonary arteries is achieved without use of a conduit. This operation, originally described by Reid and colleagues,⁵⁵ and popularised by Barbero-Marcial and his colleagues,⁵⁶ involved a direct anastomosis between the pulmonary arteries and the right ventricle, with the anterior aspect of the anastomosis being augmented with a monocusp or pericardial patch (Fig. 41-29). The Brazilian series as initially reported involved seven infants aged from 2 to 9 months. Of these patients, one died early, but no late deaths were reported. The monocusp valve seemed to function well, as judged echocardiographically, but was frequently regurgitant. This novel approach was then used by others, albeit with limited success.^{57,58} More recent reports suggest that, in the longer term, the requirement for surgical revision of the pulmonary outflow tract may be reduced in some patients when this approach is used.⁵⁹ Thus, the actuarial freedom from either late death or need for further surgery in those patients who survived the early postoperative period was approximately 90% at 10 years. In a series⁶⁰ reported from Birmingham, in the United Kingdom, it was observed that mortality, both early and in the medium term, was similar in patients who underwent repair using a direct anastomosis, compared to those in whom a valved conduit had been used. The freedom from reintervention to the right ventricular outflow tract, however, was greater in those having direct anastomosis, being 89% at 10 years, compared to those in whom a conduit had been used, with only 56% requiring no further intervention. Thus, while this approach may have some benefits in terms of reducing the requirement for further surgery because of stenosis of the pulmonary outflow tract, further studies will be required

to examine the impact of the pulmonary regurgitation, which is common after this type of modification.

An alternative solution to overcome the limited supply of homografts has been to use alternative types of conduit. Although a number of different types of conduit have been used, there has been considerable recent interest in the Contegra conduit (Medtronic, Inc, Minneapolis, Minnesota), a heterologous bovine jugular venous graft which contains a trileaflet venous valve. It is available in sizes as small as 12 mm, making it potentially ideal for reconstructing the right ventricular outflow tract in neonates and infants. There have been recent concerns, nonetheless, with respect to the development of accelerated stenosis in the distal part of the conduit, particularly when small sizes are used. Thus, in one series, 15 of 21 conduits with a diameter of 16 mm or less were noted to be significantly stenosed within 1 year of implantation.⁶¹

Regurgitation of the truncal valve remains a significant challenge. In general regurgitation of even a moderate severity should be dealt with conservatively. Where severe regurgitation exists, often resulting from prolapse of a rudimentary leaflet of the truncal valve, the valve needs to be repaired, or rarely replaced.⁵⁸

Successful surgical correction can also be achieved when the aortic arch is interrupted. The original successful repair, described by Gomes and McGoon,⁶⁰ left the duct in place to supply blood to the descending aorta. This, of course, can only be done after the age of a year or so, when there is no chance of ductal closure. Because of this, this technique is now rarely used. In younger patients, the duct and all ductal tissue must be excised. The entire thoracic aorta, the pulmonary arteries, the head and neck vessels, and the duct must then be thoroughly mobilised, so that the ascending and descending parts of the aorta can be joined. Surgery is performed using profound hypothermia and circulatory arrest, with snaring of the head vessels, or alternatively by utilising the technique of continuous cerebral perfusion.⁶⁰ It has been suggested that, if the arch can be advanced and the anastomosis performed without using a patch to augment it, the requirement for reintervention may be reduced.⁶²

OUTCOMES AFTER SURGERY

Historically, surgical repair of common arterial trunk has been associated with high mortality. Thus, the Pediatric Cardiac Care Consortium reported a mortality rate of 44% for patients who underwent surgery between 1985 and 1993.⁶³ More recent population-based audits continue to report significant mortality in this group of patients. The publication from the Centers for Disease Control⁶⁴ reported an early mortality rate of 20.5%. The mean stay in hospital for these patients was 28.9 days, with an average cost to the hospital of approximately US\$57,000.

Recent publications from single institutions, in contrast, demonstrate that surgical repair can be undertaken with low perioperative risk. Brown and coworkers⁶⁵ reported an early mortality rate of 17% for patients undergoing surgery between the years 1978 and 2000. The median age at the time of surgery was 76 days. This report highlighted the contribution of associated cardiac anomalies, such as interruption of the aortic arch, or stenosis of the truncal valve, to perioperative mortality. These anomalies were

Figure 41-30 Probability of freedom from reintervention for patients ($n = 142$) who underwent insertion of right ventricular-to-pulmonary artery conduit between January 1990 and December 2000 at The Royal Children's Hospital Melbourne. For the 53 patients with common arterial trunk, the actuarial freedom from reintervention was $21 \pm 7\%$ and $11 \pm 6\%$ at 5 and 8 years after surgery respectively.

associated with a perioperative mortality of 29%, compared to 9% for patients without these complicating factors. The main problem in the medium term related to the conduit placed between the right ventricle and pulmonary arteries, such that by 7 years, the freedom from reoperation was only 64%.⁶⁶ A series of patients who underwent surgery at a median age of 10 days between 1992 and 1999 has recently been reported.⁶⁷ Early mortality was 5%, and 92% survived at one year and beyond. The risk of death was higher in patients who weighed less than 2.5 kg. Again, the main reason for further surgery in the medium term was stenosis of the conduit, which needed to be replaced in almost half of all patients by the age of 3 years. Very similar outcomes were reported for patients undergoing surgery at a median age of 28 days from 1995 and 2000, for whom mortality early after surgery was 3.4%, and freedom from reintervention for conduit stenosis was 50% at 6 years.³ For patients who underwent surgery for common arterial trunk at the Royal Children's Hospital in Melbourne,⁶⁸ the freedom from reintervention was only 21% at 5 years after surgery (Fig. 41-30).

Although replacement of the conduit between the right ventricle and the pulmonary arteries has become the definitive method to relieve obstruction, transcatheter angioplasty has been reported in a number of series, with variable outcomes (Fig. 41-31). Of the 142 patients who underwent cardiac surgery which incorporated a conduit between the right ventricle and the pulmonary arteries at the Royal Children's Hospital at Melbourne between January 1990, and December 2000, transcatheter dilation of the conduit was undertaken in 15 patients. Of these, the procedure was deemed to be successful in only 4 (27%). Of the 9 patients with common arterial trunk in whom the intervention was performed between 1.1 and 8.2 years after surgery, it was considered to be successful in only 1.⁶⁹ There are a number of reports, nonetheless, which suggest that percutaneous implantation of stents may result in significant immediate haemodynamic improvement, and in some patients may prolong the lifespan of the conduit by several years.⁷⁰ Stents have been placed successfully in one recent series of patients.⁷¹ Of these patients, 8 remained free

Figure 41-31 Transcatheter dilation of conduit stenosis. **Left panel**, A right ventriculogram demonstrates a significant stenosis of the conduit. **Middle panel**, Inflation of the balloon revealed a waist at the site of the stenosis was relieved by further inflation. **Right panel**, At the end of the procedure, a repeat ventriculogram demonstrated partial relief of the stenosis.

from a second intervention, although 20 required a further procedure between 6 and 44 months after the initial insertion of a stent. The authors suggested that implantation of stents is likely the procedure of choice for patients with a discrete stenosis of the conduit placed from the right ventricle to the pulmonary arteries. The recent development of the valved stent by Bonhoeffer and coworkers from Great Ormond Street Hospital in London may be particularly useful in this group of patients.

As emphasised, interruption of the aortic arch is an important risk factor in patients with common arterial trunk. Reports of small numbers of patients from single centres demonstrate excellent surgical outcomes. A recent report from the Congenital Heart Surgeons Society demonstrated survival rates of only 44% at 6 months after surgery for those patients with associated interruption of the aortic arch.⁷⁰ Patients in whom repair of the aortic arch had been undertaken as an initial and isolated procedure had a particularly high mortality. There was an additional late phase of hazard, with survival rates at 10 years being only 31%. In addition, there was an ongoing requirement for further surgery to either the aortic arch or the right ventricular outflow tract. Regurgitation of the truncal valve occurred in almost half of all patients.

RECOMMENDATIONS FOR LONG-TERM FOLLOW-UP

Common arterial trunk is a condition for which continued follow-up is recommended by those having special expertise in the care of adults with congenital cardiac disease.^{72,73} The main issue of significance in the care of the adult after surgery for common arterial trunk relates to the fate of the conduit which has been interposed between the right ventricle and the pulmonary circulation. Untreated, significant obstruction to the conduit may result in problems in right ventricular performance, exercise tolerance, and arrhythmia, and may place the patient at risk of cardiac failure. Although it has been recommended that contact sports are avoided, there should be no other restriction to exercise if haemodynamics are good.⁷⁴ In general, pregnancy is tolerated well,⁷⁴ although it is likely that the presence of right ventricular dysfunction increases maternal

risk.⁷⁴ As discussed earlier, there is a risk of recurrence in offspring, in particular when there is known deletion with-in chromosome 22.

This recent publication from the Congenital Heart Surgeons Society examines the difficulties in the treatment of interruption of the aortic arch in association with common arterial trunk.

The Arterial Duct: Its Persistence and Its Patency

LEE N. BENSON

'All these arrangements are marvellous, without any question. But we have to consider that it exceeds all expectations how soon the occlusion of all these openings takes place'.

HISTORICAL CONSIDERATIONS

When Siegal¹ re-examined the original Greek text, he pointed out that Galen was familiar with many aspects of the fetal circulation, even though he did not realise that blood circulated. Galen understood that fetal blood was aerated in the placenta, and that blood was diverted away from the liver by a short vessel connecting the portal to the inferior caval vein. He also knew that blood passed through the oval foramen to bypass the right ventricle, and reach the left side of the heart directly. He realised, nonetheless, that some blood still entered the right ventricle and pulmonary trunk, from whence it was shunted into the aorta through a special fetal channel, thereby bypassing the lungs. The quotation at the head of the chapter, taken from Siegal,¹ provides a clear indication of Galen's understanding of the dramatic readjustment of the circulation at birth.

It is Botallo, nonetheless, with whose name we usually associate the persistently patent arterial duct. In fact, Botallo described postnatal patency of the oval foramen! It was by a series of misinterpretations, and careless translations, that his name became, quite unjustifiably, attached to the arterial duct.² William Harvey, who was a pupil of Fabrizio d'Acquapendente in Padua for 2 years, synthesised previous detailed descriptions of fetal cardiac anatomy from his mentor in his own writings. His genius resided in proposing the concept of active circulation of the blood. He was well aware of the large size of the arterial duct prior to birth, and the fact that blood flowed through it from right to left during fetal life.³ Harvey³ was incorrect only in his belief that flow of blood to the lungs was completely lacking in the fetus. Subsequently, Highmore, a friend of Harvey, described closure of both the oval foramen and the arterial duct as occurring with the onset of respiration, believing the arterial duct to collapse as a consequence of blood being diverted to the lungs.⁴ Since then, several ingenious theories have been put forward to explain closure of the duct, all being based on postmortem appearances, and all invoking mechanical factors.⁵ It was Virchow⁶ who first suggested that the closure results from contraction of its mural smooth muscle, while Gerard⁷ introduced the concept of two-stage closure, in which functional constriction is followed by anatomical obliteration. Thanks to Huggett,⁸ we came to understand the role of oxygen in effecting functional closure by muscular contraction.

As early as 1907, in an address to the Philadelphia Academy of Surgery, John Munro had suggested surgical ligation of the persistently patent arterial duct.⁹ After an interval of 31 years, the first attempt at surgical closure was made in a 22-year-old woman with bacterial endocarditis.¹⁰ Unfortunately, although the patient survived the surgery, she died a few days later from complications of the infection. As a result, it was Robert Gross, of Boston, who first successfully ligated a patent duct, in a 7-year-old child with intractable heart failure.¹¹ He thereby introduced an amazing era of progress in the surgery of congenital malformations of the heart. No historical review of the arterial duct, however brief, would be complete without recognising the importance of Gibson's exquisite description of the murmur that typifies its persistence,¹² notwithstanding the fashion in which Gibson's initial account has subsequently been misquoted.¹³

NOMENCLATURE

From time to time, authors have argued that the terms patent and persistent are redundancies that should be avoided when describing the arterial duct. In my view, this oversimplifies the situation, and both terms retain their value. Persistence implies that the duct is present after the time of its expected closure and, therefore, distinguishes a pathological from a physiological state. The concept of patency remains useful in the perinatal period, especially in the premature infant in whom the term can be used to signify a duct that is functionally open, as opposed to one that is functionally closed, but retains the potential to reopen.

THE NORMAL FETAL CIRCULATION

About two-thirds of the fetal cardiac output originates from the right ventricle, with only 5% to 10% passing through the lungs.^{14,15} As such, the majority of right ventricular output passes through the arterial duct into the descending aorta, and its presence is essential for normal fetal development, permitting right ventricular output to be diverted away from the high-resistance pulmonary circulation. Premature constriction or closure may lead to right heart failure, resulting in fetal hydrops.¹⁶

EMBRYOLOGY AND PATHOGENESIS

During early fetal development, five arterial arches link the aortic sac with the paired dorsal aortas, although all arches are never present simultaneously (Fig. 42-1).

The arches are numbered 1 through 6, albeit that there is no evidence to support the existence of the purported fifth

Figure 42-1 The cartoon shows the presumed arrangement of the arteries percolating the pharyngeal arches of the developing embryo. They are numbered 1 through 6, and are bilaterally symmetrical, although the purported fifth arch has never been recognised in normal embryos. They take their origin from the aortic sac, and come together in bilateral dorsal aortas, which join together to form the descending aorta. The subclavian arteries (arrows) are derived from the seventh intersegmental arteries, and initially arise distally from the dorsal aorta, needing to migrate cranially to reach their definitive positions.

Figure 42-2 The cartoon shows the primitive system of double arches proposed by Edwards to explain vascular rings and slings. The arches persist on both the right (R) and left (L) sides, uniting posteriorly to form a neutral descending (desc.) aorta. Each arch gives rise to subclavian (SA) and common carotid (CA) arteries, along with an arterial duct, which joins the appropriate pulmonary artery (PA). The aortic sac and outflow tract have divided to form the aorta and the pulmonary trunk (PT). The double arch surrounds the tracheo-oesophageal pedicle (OE, T).

arch, even though some congenital malformations are interpreted on the basis of its persistence. The initial symmetrical arrangement does, however, provide the basis for the pattern of the hypothetical double arch proposed by Edwards¹⁷ to explain vascular rings and slings. This bilaterally symmetrical arrangement, with paired brachiocephalic arteries and arterial ducts (Fig. 42-2), is usually transformed to the configuration seen in postnatal life by the disappearance of some arterial segments, and realignment of others (Fig. 42-3).¹⁸

The normal duct develops from the dorsal portion of the left sixth arch. From their inception, the sixth arches are associated with the developing lungs. The arteries feeding the developing lungs develop within the anterior wall of the mediastinum, and take their origin of the floor of the aortic sac, which initially feeds also the bilateral arteries of the sixth arches (Fig. 42-4).

When the developing arterial segment is divided to form the intrapericardial components of the aorta and pulmonary trunk, the sixth arches, originating from the caudal part of the aortic sac, are placed in continuity with the pulmonary channel. A significant event in the appropriate connection of the pulmonary arteries with the intrapericardial pulmonary trunk is the obliteration and disappearance of the right sixth arch. On the left side, the arch persists as the arterial duct, with the pulmonary arteries left in continuity with the channel from the pulmonary trunk to the left sixth arch (Fig. 42-5).

The hypothetical double arch system devised by Edwards¹⁷ is able to explain all developmental anomalies of the aortic arch, including those associated with an abnormally situated duct, be the duct patent or represented by the arterial ligament. The various possibilities are discussed in Chapter 47, including those in which there is persistence of both sixth

Figure 42-3 With normal development, the right arch and right duct regress, leaving a left arch feeding the descending aorta, an arterial duct on the left side, and the brachiocephalic artery (BCA) giving rise to the right common carotid and subclavian arteries. Abbreviations as for Figure 42-2.

Figure 42-4 The image shows a reconstruction of the developing arteries of the pharyngeal arches in a mouse on the 12th day of development. It is viewed from above, looking down on the arterial pole of the heart, with the aortic sac and the developing intrapericardial arterial trunks shown in green. The pulmonary arteries are not seen, but already the right sixth arch is beginning to regress. (Courtesy of Dr Sandra Webb, St George's Medical University, London, United Kingdom.)

Figure 42-5 This reconstruction shows the appearance of the arteries percolating through the pharyngeal arches on the 13th day of development in the mouse. The pulmonary arteries are now seen originating from the floor of the aortic sac (green), which feeds the left sixth arch. The right sixth arch has already regressed (star), although its remnant is still visible. (Courtesy of Dr Sandra Webb, St George's Medical University, London, United Kingdom.)

arches, producing bilateral arterial ducts. Such circumstances are rare, and are always associated with intracardiac anomalies. Typically the ducts supply discontinuous pulmonary arteries in the setting of tetralogy of Fallot with pulmonary atresia, albeit that bilateral ducts can also be found in association with isolation of a subclavian artery.¹⁹ The arterial duct does

not always persist on one side. Its absence was first described as a postmortem finding in 1671, being seen in a grossly malformed infant with an extrathoracic heart and tetralogy of Fallot described by Nicolas Steno.²⁰ Absence of the duct is a typical finding in the syndrome of tetralogy of Fallot with so-called absent pulmonary valve and dilated pulmonary arteries.²¹ It was thought that absence of the duct, and hence absence of any overflow, explained the dilated pulmonary arteries, but the pulmonary arteries can be dilated even when the duct is present and patent (see Chapter 36). The duct is also absent in approximately three-quarters of patients with a common arterial trunk. Absence of significant flow through the duct in the presence of a larger aortopulmonary connection permits the duct to disappear early in fetal life. In more complex varieties of common arterial trunk, however, such as those with so-called absence of one pulmonary artery, or those patients with an associated interruption or atresia of the aortic arch, patency of the duct is essential to maintain both the systemic and pulmonary circulations (see Chapter 41).

A number of teratogens are known to influence the development of the duct, including rubella, alcohol, amphetamines, and the anticonvulsant hydantoin, with the duct being most sensitive from 18 to 60 days of gestation.²² Absence of the duct has been induced experimentally in chick embryos by the administration of agonists of β -adrenoceptors, leading to the suggestion that the teratogenesis is mediated by cyclic AMP.²³

ANATOMY

The Arterial Duct and Its Normal Closure

In the fetus, and in the neonate prior to its closure, the arterial duct is a short and wide vessel of variable length. It connects the pulmonary arteries to the lesser curve of the arch of the aorta, terminating at the point of transition from the isthmus to the descending aorta, distal to the origin of the left subclavian artery (Fig. 42-6).

Figure 42-6 The image shows the arrangement of the arterial trunks at the time of birth. The duct is the direct continuation of the pulmonary trunk, and is larger than the right and left pulmonary arteries (RPA, LPA). The duct joins with the isthmus of the aortic arch, with both pathways continuing as the descending aorta. The aorta gives rise to the brachiocephalic (BCA), left common carotid (LCA), and left subclavian (LSA) arteries.

Figure 42-7 This view through a left thoracotomy shows the relationship of the left recurrent laryngeal nerve to the persistently patent arterial duct (arrow). The pulmonary arterial end of the vessel is covered by a reflection of the pericardium. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

Patency is maintained by the relatively low fetal oxygen tension²⁴ and cyclooxygenase-mediated products of arachidonic acid metabolism, primarily prostaglandin and prostacyclin,²⁵ whose levels are high because of production by the placenta and decreased metabolism in the fetal lungs. Produced both locally, in ductal tissue, and circulating, these mediators cause vasodilation through interaction with prostanoid receptors.

Prior to birth, the duct is very much the direct continuation of the pulmonary trunk, with the left and right pulmonary arteries taking origin as smaller branches from the trunk. Posteriorly, the duct is related to the left main bronchus, while anteriorly it is crossed by the vagus nerve. This gives off the left recurrent laryngeal nerve, which encircles the duct before ascending behind the aortic arch into the neck (Fig. 42-7). In terms of its microscopic structure, the duct is a muscular artery endowed with an intima, media and adventitia, differing markedly from the adjacent pulmonary trunk and aorta (Fig. 42-8). While the media of the aorta is composed mainly of circumferentially arranged elastic fibers, the media of the duct consists largely of spirally arranged smooth muscle cells, some with circular and others with longitudinal orientation,²⁶ with an increased content of hyaluronic acid. The intimal layers are thicker than those of the adjoining vessels, and contain increased amounts of mucoid substance.²⁷ In the newborn, the tissues are rather loosely arranged, with a well-defined internal elastic lamina that may be single or focally duplicated, with small interruptions encountered regularly. No collagen is seen in the media by light microscopy, but abundant material that stains positively for acid mucopolysaccharides is observed between the muscle and elastic laminas. Electron microscopy reveals fine collagen fibrils lying between adjacent lamellas of smooth muscle cells and elastin. During

Figure 42-8 The microscopic section, stained using the trichrome technique, shows the markedly different aspect of the muscular walls of the arterial duct compared to the fibroelastic walls of the aorta and pulmonary trunk. Note the intimal mounds within the ductal lumen.

the second half of gestation, the smooth muscle cells show decreasing evidence of secretory activity, and increasing maturation of their contractile elements.

It is known that vessels cannot close by isolated contraction of circularly arranged muscle,²⁸ so coincident shortening of the less abundant longitudinally arranged muscle fibres is critical to effective closure. The duct is innervated mostly by adrenergic fibres, supplying largely the adventitia and outer media, with cholinergic fibres being extremely sparse or totally absent.²⁹ Vessels are also found in its walls that may have a role in fuelling contraction at birth.²⁶ Some degree of hyperaemia of these vessels is common in newborn infants.

There is controversy with regard to the structure of the intimal layers during fetal life. Eccentrically placed intimal cushions, or mounds composed of smooth muscle and elastic tissue, have been described by many authors, with suggestions made that the formation of these mounds precedes normal ductal closure subsequent to birth. It is questionable, however, whether the intimal cushions are produced during normal fetal maturation. When account is taken of the high flow of blood through the fetal duct, it is difficult to conceive that prominent protrusions of intima into the lumen could exist without inducing turbulent flow and a bruit. No such bruit is heard in the undisturbed ducts of fetal lambs at term. Furthermore, in many of the studies suggesting the presence of intimal cushions, the tissues have usually been subjected to one or more perturbations, such as relatively slow fixation, mechanical stimulation, or cessation of circulation with loss of intraluminal distending pressure. On this basis, the existence of intimal cushions as prenatal structures has been challenged. In a series of experiments,³⁰⁻³⁴ Hornblad and colleagues showed that, independent of the degree of closure, the lumen of the duct remained round, was without deformation, and showed no evidence of formation of mounds. Mural thickness increased at the time of closure, while the internal elastic lamina became corrugated, especially in the mid-portion of the vessels. A decrease in the lumen was associated with accumulation of endothelial cells within the lumen. They concluded that closure was aided by passive central displacement of endothelial and inner medial cells, but that no part of the medial layer was prepared prenatally for this process.³⁰⁻³⁴ These findings endorsed earlier studies in the human, which suggested that the cushions appeared as a normal reparative reaction to distending forces during fetal life.³⁵

At birth, the vessel unequivocally constricts with the abrupt increase in oxygen tension inhibiting ductal smooth muscle voltage-dependent potassium channels, resulting in an influx of calcium and ductal constriction.³⁶ Levels of prostaglandin and prostacyclin fall because of metabolism in the functioning lungs, and elimination of the placenta. The intimal thickenings, or cushions, become irregular ridges protruding into the lumen, running mainly lengthwise. By their extrusion, they exert traction on the media, causing disorganisation and formation of mucoid lakes (see Fig. 42-8). Anatomical obliteration follows functional closure. The process begins with necrosis of the inner wall, followed by the formation of dense fibrous tissue. The lumen is progressively obliterated by a process of fibrosis, probably representing organisation of mural or occlusive thrombus. Eventually, the duct becomes converted into a fibrous strand, the arterial ligament, which may become calcified. Anatomical obliteration may take several weeks to complete. About two-thirds of ducts are normally obliterated by the age of 2 weeks,³⁷ and almost all by 1 year.

The Persistently Patent Arterial Duct

As stated above, in normal circumstances all ducts should be converted to an arterial ligament within the first year of life, with two-thirds closing in the initial 2 weeks. Some ducts, however, never close. These are the channels best described as showing persistent patency. Gittenberger-de Groot³⁸ found the internal elastic lamina to be intact in some, but not all, of persistently patent ducts studied histologically, along with a sparsity of intimal cushions (Fig. 42-9). Bakker³⁵ had noted similar findings, describing them in terms of aortification. The duct, if persisting as a patent structure, joins the pulmonary arteries to the descending aorta in the fashion seen in the neonate (Fig. 42-10). The channel itself can vary markedly in its width (compare Figs. 42-11 and 42-12). The duct can also vary considerably in its shape. Study of a large number of angiograms from patients with persistently patent ducts undergoing interventional closure at the Hospital for Sick Children, Toronto³⁹ showed that the most frequent pattern was to find a constriction at the pulmonary end of the duct. This pattern was seen in

Figure 42-9 This histological section is through the walls of a persistently patent arterial duct. Note the intact internal elastic lamina, and lack of intimal mounds. (Courtesy of Dr Siew Yen Ho, Imperial College, London, United Kingdom.)

Figure 42-10 The dissection shows the course of a persistently patent arterial duct. As expected, it follows the course of the channel seen at birth (see Fig. 42-6).

Figure 42-11 In this persistently patent arterial duct, the lumen of the channel is relatively narrow (arrow).

two-thirds of cases. In just under one-fifth, a constriction was found at the aortic end of the duct, and in just under one-tenth, the lumen was unrestricted. In just under one-twentieth, there was a constriction at both ends, whilst the remaining patients showed bizarre patterns not lending themselves to classification (Fig. 42-13).

In the past, persistently patent arterial ducts were often the nidus for infectious endocarditis, but this complication is now extremely rare in developed countries. Ducts could also become aneurysmal and elongated (Figs. 42-14

Figure 42-12 In this persistently patent duct, the lumen of the anomalous channel is wide (arrow). (Compare with Fig. 42-11.)

Figure 42-14 This duct has become elongated and aneurysmal.

and 42-15), but this is also now a rare finding, as is ductal rupture.

EPIDEMIOLOGY

The factors responsible for persistent ductal patency beyond the first days of life are not fully understood. An increased incidence is seen in the premature neonate due to physiological factors more related to prematurity rather than an inherent abnormality of the duct.⁴⁰ In infants born at term, persistent patency occurs sporadically, but there is increasing evidence that genetic factors, or prenatal infection, play a role in many children. The estimated incidence lies between 1 in 2000 and 1 in 5000 live births.^{41–43} Persistent patency of the duct accounts for about one-eighth of all congenital cardiac malformations. The most extensive study from a relatively homogeneous population was that performed by Carlgren,⁴³ when he charted the incidence of congenital cardiac disease to children born in the Swedish City of Gothenburg. Persistent ductal patency was the

third most common lesion identified, representing about 0.04% of live births. If children with the so-called silent duct are included, found incidentally by echocardiography performed for another reason, the incidence may be as high as 1 in 500.⁴⁴ A significantly higher incidence of ductal patency is also seen in infants born with low weight, patency being found in almost half of infants weighing less than 1750 g at birth, and up to four-fifths of those weighing less than 1200 g (see also Chapter 11).

Genetic Factors

Unlike premature infants as noted above, in whom persistent ductal patency is more often due to developmental immaturity, in the infant born at term there is likely a structural abnormality. There is also an increased frequency in several genetic syndromes, such as those with defined chromosomal aberrations, examples being trisomy 21, 14q- and 4p- syndrome, single-gene mutations such as Carpenter's syndrome and Holt-Oram syndrome, and

Figure 42-13 The variation in morphology of the arterial duct noted from angiograms taken prior to interventional closure at the Hospital for Sick Children, Toronto.³³

Figure 42-15 A lateral angiogram of a child with an elongated aneurysmal duct taken before transcatheter occlusion.

X-linked mutations such as incontinentia pigmenti. Although most cases of persistent patency are sporadic, many are also believed to be due to a multi-factorial inheritance pattern, with a genetic predisposition and an environmental trigger that occurs at a vulnerable time.⁴⁵ Females predominate in a ratio of greater than 2:1. The mode of inheritance appears to be autosomal recessive with incomplete penetrance.⁴⁶ In a family having one sibling with a patent duct, there is about a 3% chance of a persistent duct in a subsequent offspring,⁴⁵ and a higher risk to the offspring given one affected parent, some 45 times greater than the that for the general population. The risk to further children in sibships where two children have been affected is probably in the order of 10% and increases with each affected child.

Infection and Environmental Factors

Maternal rubella during the first trimester of pregnancy, particularly in the first 4 weeks, is associated with a high incidence of a persistently patent arterial duct.^{49–50} The histology resembles that of a very immature duct, with an extensive subendothelial elastic lamina, thought to retard anatomic sealing.⁵¹ Additional environmental factors have been reported associated with persistence, such as in fetal valproate syndrome,⁵² or after thalidomide.⁵³ A patent arterial duct may be more likely to be found in infants born at high altitude.⁵⁴

PATHOPHYSIOLOGY

Persistent patency results in shunting of blood from one side of the circulation to the other, the volume of flow depending on the length and internal diameter of the duct,

and on the systemic and pulmonary vascular resistances. As pulmonary resistance is usually much lower than systemic, the flow is from the aorta to the pulmonary trunk. Hence, flow to the lungs is increased, and results in left atrial and left ventricular overload. If the duct is widely patent, flow depends entirely on the ratio of resistances. Right ventricular failure may occur in the presence of a large duct with pulmonary hypertension or pulmonary oedema, and an elevated left atrial pressure. In most patients, the duct is partially constricted, and the major factor limiting flow. Under these conditions, pulmonary arterial pressure is normal or only mildly elevated. Symptoms and clinical findings are largely determined by the magnitude of the shunt.

Clinical Features

Most patients are asymptomatic, the lesion recognised with detection of the characteristic murmur. Occasionally, there may be a history of prematurity or asphyxia during birth. Children with large shunts may fail to thrive, experience difficulty with feeding during infancy, and frequently suffer recurrent infections of the upper respiratory tract. Occasionally, congestive heart failure develops.

Physical Examination

There is retarded growth in about one-third of children. They are acyanotic in the absence of complicating factors. The peripheral pulses are easily palpable, with a rapid upstroke and decay. There is a widened pulse pressure, with lowering of the diastolic component. Arterial pulsation in the neck may be prominent in those with large shunts. Precordial examination reveals an active cardiac impulse, with the forceful cardiac apex displaced to the left. When the shunt is small, the only abnormal finding may be the murmur. The continuous, or machinery, murmur of the uncomplicated persistent duct is best heard in the left infraclavicular area, although it is occasionally maximal at the third left interspace. Gibson's¹² description of the murmur is quoted by Tynan¹³: 'It begins quite obviously after the commencement of the first sound. It is continued during the latter part of that sound and the whole of the short pause. It persists throughout the second sound and dies away gradually during the long pause. The murmur is distinctly rough and thrilling in its character. It begins, however, somewhat softly, and increases in intensity to reach its acme just about, or immediately after, the incidence of the second sound, and from that point wanes until its termination. The second sound can be heard to be loud and clanging and when carefully analysed it is the pulmonary part of that sound which is accentuated'. Turbulent flow through the duct itself causes the murmur. Additional murmurs may be present due to increased flow across the aortic valve, producing an ejection systolic sound, and across the mitral valve, giving a diastolic murmur with loud onset. The systolic component of the continuous murmur may be transmitted into the neck, may be associated with a thrill in the second left intercostal space, or may increase in intensity during inspiration due to a fall in pulmonary vascular resistance. Many patients with loud continuous murmurs also have multiple clanging sounds. These are relatively localised to the pulmonary area, and are most frequent in

the second half of systole, corresponding to the period of peak flow within the duct. Neill and Mounsey⁵³ attributed these sounds to the turbulence caused by the head-on collision of opposed flow from the duct and the right ventricle, and named them eddy sounds. These auscultatory findings are only for an uncomplicated persistent duct in a child. It should be remembered that these features may differ in infancy, or be altered by the development of complications.

Investigations

Electrocardiogram

Patients with an isolated persistent arterial duct usually have some electrocardiographic evidence of left atrial and ventricular hypertrophy, reflecting volume overload of the left heart. Occasionally, the electrocardiogram may show combined ventricular hypertrophy, or, if the duct is small, be entirely normal. The electrical axis is usually normal, and deviation to the right, with right atrial and/or right ventricular hypertrophy, suggests the presence of additional defects or pulmonary hypertension. The electrocardiographic changes are less predictable in infants and clinically less helpful.⁵⁴ Prolongation of the PR interval, which disappears or decreases after closure, has been observed in about one-fifth of cases.⁵⁵ Atrial fibrillation may develop in adult life.^{56,57} When the shunt is large enough to equalise the systemic and pulmonary arterial pressures, biventricular hypertrophy is likely to develop. With the onset of pulmonary vascular disease, the predominant findings will be those of right ventricular hypertrophy.

Chest Radiography

The chest film may be normal in patients with a small shunt. Cardiomegaly is present in those in whom flow to the lungs is close to twice systemic flow or greater. Increased pulmonary vascular markings are seen, with an obvious bulge of the pulmonary trunk at the left border of the cardiac silhouette. The aorta is also prominent. Both it and the pulmonary trunk tend to enlarge with age. Enlargement of the left atrium is usually present, and reflects increased pulmonary venous return due to the left-to-right shunt. Increased pulmonary vascularity may be more marked on the right, as is often seen with other left-to-right shunts (Fig. 42-16). The duct may calcify, although this complication is more common when the vessel is closed rather than patent. The aortic end of the duct, the ductal ampulla, may be seen on the chest radiograph, and can be demonstrated angiographically during the first week of life. These findings may be modified, especially if pulmonary vascular disease develops.

Figure 42-16 The left panel is a chest radiograph from a patient with small ducts. Note the minimally increased pulmonary vascularity. The right panel shows another child with a larger ductal communication. There is increased pulmonary vascularity and cardiomegaly.

Echocardiography

Persistent patency beyond the neonatal period is readily diagnosed from the characteristic clinical features. Cross sectional echocardiography will help rule out other structural cardiac malformations. The duct can be imaged throughout its length using a high left parasternal view,^{58,59} allowing evaluation of ductal size, and the presence of tissue within the lumen, indicating imminent closure. In preterm infants, imaging may be difficult due to emphysematous lungs from high ventilatory pressures. A subxiphoid view can then be used. Characteristic diastolic flow in the pulmonary trunk identified by Doppler interrogation increases the confidence of diagnosing ductal shunting.

Flow through the duct can be quantified by analysis of Doppler tracings of diastolic flow in either the left pulmonary artery or the descending aorta. Colour flow Doppler techniques have been more useful in revealing ductal patency. This is, at present, the most sensitive method for detecting and semi-quantifying ductal flow⁶⁰ (Fig. 42-17). Qualitatively, the presence of bidirectional, or pure right-to-left, shunting is specific for elevated pulmonary arterial pressures.^{61,62} In children with high pulmonary vascular resistance, with a low-velocity Doppler signal or right-to-left flow, the duct may be very difficult to demonstrate by colour flow imaging, even if it is large. Associated findings such as septal flattening, unexplained right ventricular hypertrophy, or high-velocity pulmonary regurgitation should prompt an investigation for a patent duct. Contrast echocardiography may also be helpful in this setting, identifying microbubbles in the descending aorta in

Figure 42-17 The echocardiogram (high left parasternal view) shows a large duct in a newborn (left panel). Note the proximity to the left pulmonary artery. The middle panel shows colour flow Doppler mapping, with mild turbulence confirming the presence of flow (orange colour) entering the pulmonary trunk (orange coloured pattern). The right panel is a spectral Doppler trace showing the direction, timing, and velocity of flow in the duct. MPA, main pulmonary artery; LPA, left pulmonary artery.

Figure 42-18 Lateral arteriograms outlining various ductal anatomies.

consequence of ductal right-to-left shunting, but not in the ascending aorta. Additionally, using colour flow mapping, Doppler measurements of velocity can be used to estimate pulmonary arterial pressure.^{63–65} M-mode studies provide an assessment of left atrial and ventricular size, which gives some idea of the magnitude of the shunt. In children with a small duct, the chambers are usually of normal size, although mild left atrial and/or left ventricular enlargement may be seen. In children with a moderate or large duct, the left atrium and ventricle are enlarged. Echocardiography is probably most valuable in the diagnosis of ductal patency in the premature infant. It will be discussed further in that section.

Recent echocardiographic studies using colour flow Doppler have further identified the presence of small ductal communications in the absence of any typical murmur of patency, this degree of shunting giving uncharacteristic soft vibratory systolic murmur or no murmur at all.^{44,66,67} These findings have a significant impact on estimates of the incidence of ductal patency and the risk of endocarditis.

Cardiac Catheterisation and Angiography

Most cardiologists would not consider catheterisation a necessary diagnostic procedure for children with typical clinical findings. If it is undertaken, it is usually possible to probe the duct from the pulmonary trunk, and to pass a catheter through the vessel and down the aorta. When the catheter apparently crosses a duct, but then turns in a headward direction, the alert investigator should consider the presence of an aortopulmonary window. The size of the shunt may be difficult to quantify by oximetry because it is difficult to obtain a truly representative sample distal to the site of shunting. Pulmonary arterial pressure is usually normal or slightly elevated. The duct can be visualised by selective aortography with injection of contrast media in the last part of the aortic arch (Fig. 42-18).

Therapeutic catheterisation, however, is currently the treatment of choice for most children and adults with a patent duct. In this regard, complete haemodynamic assessment is important prior to attempting closure, particularly in the adult. In patients with an elevated pulmonary arterial pressure, assessment of pulmonary vascular resistance and its response to vasodilating agents may be helpful in determining suitability of closure. Assessment of haemodynamics during temporary test occlusion with a balloon catheter may also be a helpful manoeuvre in assessing advisability of closure in marginal cases.

Angiography defines the anatomy. Such detailed assessment is essential before attempting closure so that the proper device and size can be chosen. Important features include the minimal diameter, usually at the pulmonary arterial end; the largest diameter, usually at the aortic ampulla; the length of the duct; and its relationship to the anterior border of the tracheal shadow, the latter helping to guide positioning of the device.³⁹ Other imaging modalities are available to confirm the presence of ductal patency. Radionuclide scanning can be used to detect the presence of shunting, but anatomic localisation is lacking. Magnetic resonance imaging provides anatomic detail,⁶⁷ and is particularly useful in the setting of unusual ductal geometry, and in those with associated abnormalities of the aortic arch (Fig. 42-19).^{68,69} Examples include the patient with a ductal aneurysm

Figure 42-19 Volume rendered magnetic resonance image showing the anatomy of the aortic arch in an infant with hypoplastic left heart syndrome. Ductal anatomy (duct = DA), and its relationship to the ascending aorta (AAO, arrow) and left subclavian artery (LSCA) are clearly understood. LPA, left pulmonary artery.

presenting as a mass in the chest, the duct associated with a vascular ring, a right aortic arch, or cervical arch. With velocity encoding of cinemagnetic resonance signals, patterns of shunting can be detected.^{70,71} In the adult, computed tomography can assess the degree of calcification, an important feature if surgical closure is considered. In general, however, the simpler technique of cross sectional echocardiography with colour flow Doppler provides sufficient anatomic and haemodynamic detail to define the anatomy and its variations, and points the way to proper management.

Diagnostic Problems

Other causes of a continuous murmur may create confusion. The venous hum often causes difficulty to the inexperienced auscultator. This noise, which can be loud, is usually best heard in the supraclavicular fossa, and while audible bilaterally, it is usually louder on the right. A venous hum, when loud, may be transmitted below the clavicle, and may be misdiagnosed as being from a patent duct. This error can be avoided by exerting pressure over the root of the neck, turning the head to the side, or laying the child down. These manoeuvres readily obliterate the venous hum, while having no effect on the murmur generated by ductal flow. An aortopulmonary window rarely causes a continuous murmur similar to that of persistent ductal patency. More typically, however, the communication is large, and does not cause a continuous murmur. Even with careful aortography, this condition may be misdiagnosed. Echocardiography should now help to avoid this error. Major aortopulmonary collateral arteries, pulmonary arteriovenous fistulas, and collateral arteries associated with coarctation, all cause continuous murmurs. These seldom cause diagnostic problems because of the general clinical picture and the location of the murmur. Other causes of continuous murmurs heard in the chest include ruptured sinus of Valsalva, peripheral pulmonary arterial stenosis, common arterial trunk, coronary artery fistulas, the supracardiac form of totally anomalous pulmonary venous connection, mitral atresia, surgically created systemic-to-pulmonary arterial shunts, and rarely anomalous origin of the left coronary artery from the pulmonary trunk. Prolapse of an aortic valvar leaflet into a ventricular septal defect may also simulate persistent patency of the duct. Most, if not all, of these potential pitfalls can be avoided by careful clinical evaluation and good echocardiography.

NATURAL HISTORY

Like most congenital cardiac malformations, reliable information about the natural history of untreated patients with a persistently patent duct is non-existent. Available data stems from the short period of time which elapses between the condition being diagnosed with any frequency and to its being relieved by an operation. Campbell⁷² attempted an overview of the natural history, based on his own extensive clinical experience and on the literature. Inevitably, such calculations tend to over-emphasise the number of patients who experience events, be they favourable or adverse, and underestimate

the number of patients with an asymptomatic and undetected duct.

Spontaneous Closure

By definition, a persistent duct is one that remains open beyond 3 months in an infant born at full-term. Delayed closure in premature infants, or that occurring within the first 3 months, is therefore excluded from consideration in this section. Campbell⁷² analysed four series of patients in which 11 examples of spontaneous closure occurred over 1842 patient-years, giving a rate of 0.6% per annum. Several of the examples, however, were based on quite tenuous clinical impressions. In none was catheterisation performed before and after the event. The figure calculated by Campbell is almost certainly an overestimate. He did not suggest that surgery should be delayed except, perhaps, in patients with small shunts and signs that the duct was already closing. Few cardiologists would now agree even with these exceptions.

Effect on Life Expectancy

By combining four series, consisting mainly of unselected schoolchildren with a persistent duct, Campbell deduced a mortality rate of 0.42% per annum during the first two decades. Thereafter, he calculated mortality rates per year as 1% to 1.5% in the third decade, 2% to 2.5% in the fourth, and 4% for each subsequent year. These calculations indicate that one-third of patients with a persistent duct die by the age of 40, in contrast to less than one-twentieth of the normal population. Many of the figures are based on data obtained in the era before antibiotics were available. As infective endocarditis is a major cause of death, the impact of antibiotics must also be taken into account. These figures agree fairly well with age at death as reported in necropsy series. Abbott,⁷³ for example, found the mean age at death, having excluded those who died in infancy, to be 30 years, and in another series, the mean age was 36.5 years.⁷⁴ Despite this agreement, the fact remains that calculations from autopsy series, and from clinical series, are extrapolations from rather small numbers. They undoubtedly exaggerate the adverse aspects of the natural history.

COMPLICATIONS

The important complications of persistent patency of the duct include congestive heart failure, infective endarteritis, pulmonary vascular disease, aneurysmal formation, thromboembolism, and calcification.

Congestive Heart Failure

Congestive heart failure resulting from an isolated persistent duct develops either in infancy or during adult life. Infective endarteritis may rarely precipitate heart failure during childhood. Heart failure in infancy usually has its onset before the age of 3 months. A delayed normal fall in pulmonary vascular resistance may cause the left-to-right flow to increase progressively. The clinical picture is initially that of left heart failure, with tachypnoea and pulmonary oedema. Ultimately, signs of right heart failure appear

with hepatomegaly. Although initially there may be a good response to diuretics, this is seldom maintained and closure is advisable. Infants born at term do not respond to indomethacin when over 3 months of age. The occasional occurrence of sudden death in infants treated medically further encourages a policy of early intervention. Amongst adults, there used to be a group with cardiomegaly and features of left ventricular overload and strain. Such patients now are rare in countries with well-developed systems of health care, as it is unlikely their lesion would have escaped detection. Congestive heart failure may also occur as a terminal event in patients in whom severe pulmonary vascular disease complicates a persistently patent duct. If so, transcatheter closure appears to be the treatment of choice.

Infective Endarteritis

Infective endarteritis in a patient with an uncomplicated persistent duct is uncommon in childhood, and appears to be prevented by surgery or catheter-based embolisation. In the era preceding antibiotics, and interventional or surgical treatment, it was a major cause of death, accounting for almost half of all deaths in several pooled autopsy series.⁷³⁻⁷⁵ Campbell⁷² calculated an infection rate of between 0.45% and 1.0% per annum for patients after the first decade. The first line of treatment should be with antibiotics, following the recommendations as established by the American Heart Association, with surgery or embolisation delayed until sterilisation is completed. Occasionally, this proves impossible, in which case surgery or occlusion should be performed under continuing antibiotic therapy.⁷⁶ Vegetations are usually found at the pulmonary arterial end of the duct, and may give rise to recurrent pulmonary embolisation, with the clinical picture suggesting recurrent pneumonia. In developing nations with limited access to health care, infective endarteritis associated with the persistently patent duct continues to be a significant health issue.⁷⁷ Infection may cause some examples of ductal aneurysms, especially those occurring postoperatively. While two cases of endarteritis on a clinically silent and non-hypertensive duct have been reported, the anticipated high incidence of the silent duct has little implications for treatment.^{44,78,79}

Pulmonary Hypertension and the Persistent Duct

Although the pulmonary arterial pressure is usually normal, or only slightly elevated, in patients with persistently patent ducts, occasionally it is raised sufficiently to modify the physical findings. The implications of pulmonary hypertension secondary to an increased flow, as opposed to that caused by increased resistance are markedly different and the two situations should be clearly differentiated.

When the duct is widely patent, and pulmonary vascular resistance is low, systolic pulmonary arterial pressure equals systemic systolic pressure, and blood flow to the lungs is several times greater than that in the systemic circuit. The pulmonary arterial diastolic pressure may equal or be slightly lower than that in the aorta. These patients usually experience severe congestive heart failure, with failure to thrive and recurrent respiratory infections. Their electrocardiogram shows combined ventricular hypertrophy, while the chest radiograph reveals cardiomegaly with marked pulmonary plethora. The echocardiogram

will reveal enlargement of the left heart chambers. Such patients respond poorly to medical therapy, and the correct management is to eliminate the shunt. Successful ligation or catheter occlusion usually restores pulmonary arterial pressure to normal. There appears to be little risk of subsequent pulmonary vascular changes in this group of patients.

Some individuals respond to pulmonary venous distension, and to the left atrial enlargement secondary to high pulmonary blood flow with reflex pulmonary vasoconstriction partially protecting themselves against the full effects of unrestricted ductal flow. If studied haemodynamically, these patients will be found to have a moderate left-to-right shunt, with pressure in the pulmonary circulation at systemic levels, with or without a high pulmonary capillary wedge pressure. Pulmonary arterial pressure usually falls with administration of oxygen, or in response to pulmonary vasodilators. Successful elimination of the shunt usually restores pulmonary arterial pressure to normal. Fixed and high pulmonary vascular resistance may result from progressive structural changes in patients who originally had large left-to-right shunts and normal pulmonary vessels. Alternatively, it may exist from birth.^{80,81} Civen and Edwards⁸² suggested that patients in this category represent a form of persistence of the fetal pulmonary circulation. As yet, there is poor understanding of the factors which initiate and maintain the progressive pulmonary vascular damage.

It is instructive to follow the clinical changes that accompany the rise in pulmonary vascular resistance. Initially, the pulmonary diastolic pressure approaches systemic levels, decreasing diastolic flow across the duct. As flow diminishes, the diastolic component of the continuous murmur becomes attenuated and eventually disappears. At this stage, the patient has a pansystolic murmur. With a further increase in resistance, systolic pressures begin to equalise, systolic flow diminishes, the systolic murmur shortens, and eventually it also disappears. Concurrent with these changes, the second sound becomes closely split or even single, and there is accentuation of the pulmonary component. The clinical findings become those of severe pulmonary hypertension, with marked right ventricular hypertrophy and a loud, often palpable second pulmonary sound; a pulmonary ejection click is almost always audible. The second sound is loud and difficult to split. A high-pitched early diastolic murmur, the Graham Steel murmur of pulmonary regurgitation, may be added to these sounds, as may a pansystolic murmur of tricuspid regurgitation when right heart failure supervenes. Equalisation of pressures with balanced resistances also brings reversal of the direction of flow through the duct, the magnitude of the flow increases concomitant with the rise in pulmonary vascular resistance. In some patients, it is possible to recognise differential cyanosis, the blue discolouration being confined to the lower body, and with clubbing of the toes but not the fingers. Unless there is differential cyanosis, it is not possible to recognise a duct clinically in patients with severe pulmonary hypertension and high pulmonary vascular resistance. The diagnosis will depend on cardiac catheterisation and angiography, or cross sectional echocardiography and colour flow Doppler studies.

Until heart failure develops, the chest radiograph shows at most mild cardiomegaly, with marked prominence of the

pulmonary arterial segment (see Fig. 42-16B). Right-axis deviation, right atrial hypertrophy, and right ventricular enlargement are usually evident in the electrocardiogram. In some cases, however, a picture of combined, or even left, ventricular hypertrophy may still be seen. It is impossible to calculate accurately the risk of progressive pulmonary vascular disease in patients with a large persistent duct. Surgical treatment has been available almost as long as clinical recognition. The information in terms of natural history necessary to answer the question is not available, nor would such a study now be feasible. Campbell⁷² did not address this problem in his calculations, although there are several reports in the literature concerning this complication.⁸³⁻⁸⁵ These are based, however, on selected groups of patients and overemphasise the frequency of the problem. Nor do they all distinguish adequately between pulmonary hypertension with high flow and true pulmonary vascular disease. The presence of pulmonary hypertension secondary to structural changes within the pulmonary vasculature increases the risk of closure, especially once there is right-to-left shunting, with a reported mortality in more than half of a small group of such patients.⁸³ The complication should be largely avoided by early recognition and treatment of the hypertensive duct. In patients with pulmonary vascular resistance greater than 8 Woods units per meter square, lung biopsy has been recommended to determine candidacy for closure, but unfortunately it may not be fully predictive of outcome.⁸⁶ Such patients may be haemodynamically worse after closure with the development of suprasystemic pulmonary arterial pressure, low cardiac output, and right ventricular failure. Patients have been described, nonetheless, with severe histological changes consistent with irreversible pulmonary vascular disease, which resolves completely after closure of the duct.⁸⁷ In the occasional patient who escapes early detection, cardiac catheterisation with a vasodilator challenge may be useful in determining the extent of pulmonary vascular changes, and their potential for reversal.

Aneurysm of the Duct

True aneurysm of the duct is rare. It manifests in two distinct forms. The first presents at or shortly after birth,^{88,89} the so-called spontaneous aneurysm of infancy⁹⁰ (Fig. 42-20). The second form presents in childhood or later life.^{91,92} Recent studies suggest that the incidence may be as high as 8%.⁹³ The true incidence remains unknown, as the definition is not precise, and many aneurysms detected by fetal or neonatal echocardiography resolve spontaneously, without clinically apparent sequels. About one-quarter of patients will have an underlying disorder, such as trisomy 21 or 13, Smith-Lemli-Opitz syndrome, type IV Ehlers-Danlos syndrome, or Marfan's syndrome.⁹⁰ Ductal closure usually begins at the pulmonary arterial end of the vessel, and if closure at the aortic end fails to occur, it becomes in effect an aortic diverticulum under systemic pressure. While formation of such a diverticulum is common, it is less clear why this occasionally progresses to aneurysmal formation. Structural abnormalities are possibly present in the aortic, but not the pulmonary end of the duct, such as those associated with collagen vascular disorders. Sepsis may be involved in the pathogenesis of some cases in infancy. A diverticulum arising from the pulmonary trunk

is also common. Usually, the type found in infancy is asymptomatic, and may not be uncovered until autopsy for death from other causes. It presents as a tumour-like left-sided mediastinal mass. In one-fifth of cases, rupture or embolism leads to death. Dissection and infection may also occur. Regression can occur, presumably due to thrombosis and organisation, but progressive enlargement, or the onset of hoarseness because of damage to the recurrent laryngeal nerve or left bronchial obstruction, is an indication for surgical excision. In view of the frequency of life-threatening complications, prompt surgical removal is advisable. Percutaneous occlusion of the aneurysm has not been established, but a potential approach is placement of a covered stent in the aorta to exclude the aneurysm and occlude the duct.⁹⁴ Aneurysm of the duct is even more uncommon in adults.⁹⁵ The duct may be patent at both ends, but is usually closed at the pulmonary arterial end.⁶⁹⁻⁹⁸ Possible pathogenic mechanisms include arrested closure, with persistence of an aortic diverticulum, delayed spontaneous closure of the pulmonary arterial end, infective arteritis and external trauma in a patient with a persistent duct,⁹⁹ or even coil occlusion of a preexisting patent duct.¹⁰⁰ Aneurysm of the duct should be considered in the differential diagnosis of adult with unexplained mediastinal masses seen on chest radiography. The diagnosis can be confirmed by aortography or by computerised tomography.^{101,102} Like the pattern seen in infancy, the high incidence of rupture, embolisation, and effects of pressure suggest that surgical excision is advisable. Surgical ligation may itself be followed by aneurysmal formation,^{95,103} often associated with recanalisation.

Thromboembolism

Thrombosis of the duct as a source of neonatal embolus was first described in 1859.¹⁰⁴ Several cases, mostly fatal, have since been noted.^{105,106} Early diagnosis can provide an

Figure 42-20 The antero-posterior retrograde aortogram shows a ductal aneurysm. Note the associated moderate aortic insufficiency.

opportunity for successful intervention, which may include thrombectomy, heparin, and resection of infarcted tissue.

TREATMENT

Once the diagnosis of uncomplicated persistent patency of the arterial duct is established, elimination of the shunt should be recommended by catheter occlusion or surgery, even when the shunt is small. The justification for closure of small communications resides in the prevention of infective endoarteritis, coupled with an extremely low procedural morbidity and mortality. As noted above, in the setting of the so-called silent duct, there is little clinical evidence to justify any intervention or recommendation to prescribe coverage against subacute bacterial endocarditis. In the occasional patient who develops congestive heart failure, excluding those patients to be discussed below in the context of prematurity, drugs should be administered to combat the failure, but only until intervention can conveniently be arranged.

Surgical Intervention

In 1939, Robert Gross performed the first successful ligation of a persistent arterial duct in a 7-year-old girl.^{11,107} The duct is usually approached through a left posterolateral incision, using the third interspace in infants, and the fourth space in children over 1 year. Uncommonly, the duct is on the right side, especially in the presence of a right aortic arch. It must then be approached from the right. The duct may be ligated or divided. The relative merits of each procedure continue to be hotly debated by surgeons. Excellent results have been reported using both procedures. The incidence of clinically apparent recanalisation with ligation is about 1%,^{108–111} albeit that echo-Doppler studies have detected flow after ligation in clinically silent ducts, suggesting the incidence of residual flow to be higher.¹¹² Large ducts exceeding 7 to 10 mm in diameter, or those associated with pulmonary hypertension, are generally divided. Mortality reported from a large experience extending over 25 years for closure of the uncomplicated duct was no more than 0.2%,¹¹³ with a figure of 0.5% cited in another series.¹¹⁴ Once the safety of the operation was established in older children and adults, it was natural for surgeons to attempt closure in infancy,¹¹⁵ with Mustard already in 1951 reporting successful ligation in 4 infants.¹¹⁶ Many surgeons then demonstrated the ease with which the duct could be ligated, even in those born prematurely.¹¹⁷ In most units, surgical ligation is now reserved for those premature infants who have failed an adequate course of indomethacin, or when there are contraindications to its administration (see below). Such surgical ligation can be done at bedside. The need for accurate anatomical definition prior to intervention in the premature infant must be underscored.¹¹⁸

Complications are uncommon. Injury to the laryngeal nerve injury can occur occasionally, but is usually temporary,¹¹⁹ although it can be permanent. Rarely, a false aneurysm may develop, prompting urgent surgical reoperation after ligation.¹²⁰ Damage to the phrenic nerve has also been reported, occurring most frequently in the premature infant. Chylothorax can also occur. Inadvertent

ligation of the distal left pulmonary artery occurs infrequently. This is a hazard when the duct is large and the recurrent laryngeal nerve has an unusual course. Ligation of the descending aorta can occur, especially when the duct is approached from a median sternotomy. Signs of aortic coarctation may also be unmasked after ductal ligation.¹²¹ This is a constant hazard in the premature infant. Abnormal findings after ductal ligation, such as decreased femoral pulses or declining urinary output, should prompt rapid re-evaluation.

Video-assisted thorascopic closure without thoracotomy has been a recent innovation, first reported by Laborde and his colleagues.¹²² Clinical evidence of successful closure was found in all, although two attempts were necessary in two patients. Damage to the recurrent laryngeal nerve occurred in one, while four suffered pneumothorax. Increasing experience with the procedure has reduced the incidence of complications. Continued experience has shown this approach to shorten hospital stay, and to provide a cost-effective, safe and rapid technique compared to open thoracotomy.¹²³ Results are comparable to transcatheter closure.^{124,125} Recently developed for the neonate and infant, a transaxillary muscle sparing thoracotomy provides excellent exposure for ductal division, produces less postoperative pain, and achieves an acceptable cosmetic result.¹²⁶

Closure in the Catheterisation Laboratory

The percutaneous methods for closure were pioneered by Portsman and colleagues,¹²⁷ who reported use of a conical Ivalon plug in 1967, with an umbrella-type device subsequently being used in 1979 by Rashkind and Cuaso.¹²⁸ Both these implants required large sheaths for introduction, and were often associated with residual shunting. In 1992, the use of spring coils was reported,¹²⁹ and due to the technical simplicity of insertion, this has become a widely used technique for closure for small-to-moderate sized ducts. In the ensuing years, a number of devices and techniques have been developed to close larger ducts.

As a result, transcatheter closure has become the treatment of choice for most children and adults with patent ducts. In particular, percutaneous techniques offer considerable advantages over surgical closure for patients with a calcified ductal wall, with or without increased pulmonary vascular resistance, since the latter often necessitates cardiopulmonary bypass.

The essentials of the technique, regardless of the implant used, are to place a catheter or delivery sheath across the duct from either the pulmonary artery or the aorta, and position the implant in the duct. Several techniques have been developed to stabilise the coils during delivery, as non-detachable Gianturco coils could migrate or assume unacceptable configurations or positions.^{130–133} Varieties of detachable coils are now available, which allow control of positioning prior to their release (Fig. 42-21).

The Nit-Occlud (Produkte für die Medizin AG, Köln, Germany) is a spring coil specifically designed for ductal embolisation.¹³³ The design is biconical, in contrast to the cylindrical Gianturco coil (Fig. 22-22). The Amplatzer Duct Occluder (AGA Medical, Plymouth, MN) is a plug-like design made of Nitinol wire woven into a mesh in the shape of a mushroom (Fig. 22-23). This device can be

Figure 42-21 The left panel shows a detachable Gianturco coil used for ductal occlusion. Note the Dacron fibers, which promote thrombosis, along its length. The other panels show retrograde lateral aortograms before and after occlusion with such a spring coil.

effective in larger ducts.¹³⁴ The device has a detachable cable allowing repositioning or retrieval as necessary. A modified Amplatzer Duct Occluder designed so that the retention skirt has an angle and concavity to fit the aortic end has now been used in clinical practise, and a double retention disc design is now available for clinical use.¹³⁵ Other devices currently in use, or under investigation, include a modified buttoned device, and the wireless patch developed by Sideris and associates.¹³⁶ Given the variety of ductal configurations and sizes, it is apparent that no individual device will be optimal for closure in all patients. The availability of a variety of implants enhances the capability to close the majority of lesions.

The results of transcatheter occlusion have been excellent. Complete closure rates at follow-up exceed 90% to 95% in most studies.¹³⁷ Because of modifications in design, development of new techniques, and increased skill of operators, rates of complete closure have improved significantly over time.¹³⁸ Serious complications of transcatheter closure are rare. The most common complication is embolisation of the device, which was relatively

common early in the experience with coils. Embolised coils can be retrieved, but even when they cannot, adverse consequences are rare. Other potentially important complications are disturbance to flow in the proximal left pulmonary artery or descending aorta from a protruding device, haemolysis from high-velocity residual shunting, femoral arterial or venous thrombosis related to vascular access, and infection.

Regardless of technique of closure, the clinical diagnosis should be confirmed non-invasively prior to catheterisation by colour Doppler echocardiography, with particular emphasis placed on the presence of associated lesions which could complicate the procedure, such as azygous continuation of the inferior caval vein, presence of an additional lesion which requires surgical intervention, or the presence of pulmonary vascular disease. Special attention should also be directed to the transverse arch and isthmic region to exclude unsuspected coarctation. The procedure is ideally suited for patients weighing more than 6 kg. In smaller infants because of the risk of the size of the implant and difficulties in positioning, left pulmonary

Figure 42-22 Pictured in the left panel is the Nit-Occlud PDA occlusion device, with its biconical configuration. Note the reversed winding on the proximal end. The middle and left panels show lateral aortograms before and after occlusion with the device. (Modified from Schneider DJ, Moore JW: Patent ductus arteriosus. *Circulation* 2006;114:1873–1882).

Figure 42-23 The Amplatzer Duct Occluder is shown in leftmost panel. Note the mesh-like weave retention disc that is placed in the aortic end of the duct, as shown in the middle two panels, and the control cable. The right panel shows the newest design (Duct Occluder II, AGA Medical Corporation), with two retention discs, designed to avoid embolisation.

arterial stenosis or aortic obstruction may occur. There is considerable variation in procedural details as practiced amongst centers, such as the use of coincident arterial cannulation, the number and type of angiograms, and so on. The majority of procedures, however, can be performed in an outpatient setting, with discharge on the afternoon of insertion.

PATENCY OF THE ARTERIAL DUCT IN THE PREMATURE INFANT

During the last four decades, there has been a marked increase in premature delivery in many, but not all, developed countries. While the reasons for this are obscure, the increase has been met by the development of neonatal intensive care units and, more recently, units for pregnancies considered to be at high risk. The art and science of caring for the extremely premature infant have developed to the point where survival of infants weighing no more than 500 g is not uncommon.

Pathophysiology

There are several factors which tend to prevent closure of the arterial duct in the immature infant, as both the sensitivity to oxygen and the action of prostaglandin are age dependent,¹³⁹ and the relaxant mechanism of prostaglandin is more active in the immature duct.^{140,141} The type and duration of ventilatory support, drug therapy, phototherapy, blood transfusions and diuretics undoubtedly account for the wide variations in incidence reported from different institutions.

The pulmonary vascular resistance is lower in the premature than the full-term child due to the rapid increase in number of muscularised pulmonary vessels. The vessels of the immature lung also constrict less for a given stimulus than at term. Constrictive stimuli include hypoxia, acidaemia, and possibly circulating vasoactive peptides and prostaglandins, frequent co-morbidities in the respiratory distress syndromes. These factors render the immature infant especially liable to develop left-to-right shunting when the duct remains patent. Systemic vasoconstriction, so often a feature of the sick premature infant, may further encourage the shunt and exacerbate the respiratory distress syndrome.¹⁴² The immature infant is further handicapped by its reduced cardiac reserve. The increased volume overload secondary to a left-to-right shunt produces an inordinate rise in left ventricular end-diastolic pressure, and a concomitant rise in pulmonary venous pressure. With a large left-to-right shunt through the duct, systemic diastolic pressure falls, compromising the flow through the coronary arteries, which, combined with a shortened diastole because of tachycardia and raised ventricular end-diastolic pressures, predisposes to subendocardial ischaemia. Systemic hypoxia secondary to pulmonary problems, combined with a reduced capacity to carry and deliver oxygen due to anaemia and fetal haemoglobin, further impairs myocardial function, and both are reflected in ischaemic changes in the electrocardiogram frequently seen in the sick premature infant. Other important circulations, such as those of the gut, kidneys, and brain, may be compromised by the haemodynamic changes related in part to the diastolic runoff from the

aorta into the pulmonary arteries, with the duct an aetiological factor in necrotising enterocolitis, and cerebral haemorrhage.

Clinical Features

The clinical picture of patency of the duct in the premature infant depends on the size of the left-to-right shunt, on the maturity of the heart and lungs to adjust to the increased volume load, and on the presence of other pathologies, which may obscure the more typical findings. As many premature infants have respiratory distress syndrome, the use of surfactant will modify the clinical expression of ductal shunting by influencing pulmonary vascular resistance. The presence of a significant duct can often be difficult to recognise even by experienced clinicians, and echocardiography is of great value. Three distinct patterns of clinical presentation may be observed.¹⁴³

Absence of Pulmonary Disease

These infants generally have birth weights exceeding 1500 g. Smaller infants may be encountered, nonetheless, whose mothers may have received steroids, or themselves received surfactant. Sometime a systolic murmur is detected in the first week of life. This becomes louder and longer as pulmonary vascular resistance falls, and eventually spills into early diastole. The murmur is best heard in the second and third left interspaces. It is associated with accentuation of pulmonary closure, with the typical continuous murmur as heard in older children usually not being present. If the shunt becomes large, the precordium becomes hyperactive, the pulse pressure wide, and the peripheral pulses bounding. An apical third sound may also occur associated with a diastolic flow murmur. If the left ventricle fails, tachycardia and tachypnoea develop, and moist sounds can be heard in the chest. Apnoea and bradycardia may complicate severe left ventricular failure. Hepatomegaly may only develop late. Most infants in this group do not develop massive shunts, and can be managed by simple medical means. The duct closes spontaneously in the majority at an age approximating to full-term. These older infants tend to respond less well to indomethacin than more immature infants do.

Infants Recovering from Lung Disease

Left-to-right ductal shunting may develop in infants recovering from respiratory distress syndrome. Usually they weigh between 1000 and 1500 g. Most probably the duct is patent from birth, and left-to-right shunting only develops during recovery when pulmonary vascular resistance falls. At this time, increased administration of fluids may further aggravate the loading effects of the shunt on left ventricular function. Many of these infants are still maintained on mechanical ventilators, or continuous positive airway pressure, when shunting first develops. Because of this, the initial systolic murmur may be difficult to detect. Often the clinical findings are quite labile. If the shunt increases, the murmur becomes more obvious. Like the first group, it may eventually spill into diastole. Other signs of a large shunt may be present, including bounding pulses, a hyperdynamic precordium, and tachycardia. This group of patients tends to be more immature, and to develop left ventricular failure with relatively smaller shunts. Ventilatory status may deteriorate so that higher concentrations of oxygen and increased pressure or rate settings are required

to counter a deteriorating status of the blood gases. Apnoeic episodes and bradycardia are common.

Infants with Lung Disease

This group tends to include the most immature infants with birth weights below 1000 g. These patients are usually ventilator-dependent, and the development of a left-to-right ductal shunt in these patients is associated with increasing requirement for ventilator support and deterioration of the status of the blood gases. Murmurs may be difficult to hear, and occasionally a very large duct may be silent. Signs of a large left-to-right shunt may occur, but left ventricular failure is often difficult to differentiate from signs due to pulmonary disease or sepsis.

Investigations

Neither the electrocardiogram nor the chest radiograph is particularly helpful in making the diagnosis of a significant duct in premature infants. The electrocardiogram may show left ventricular hypertrophy in the group without lung disease, especially if the shunt is substantial and has been present for some time. In the other two groups, right ventricular predominance is more usual. As mentioned, ischemic changes may also be present. The chest radiograph may show cardiomegaly with increased pulmonary blood flow. Often the heart is not obviously enlarged, and pulmonary changes due to flow or failure are difficult to differentiate from those due to primary pulmonary problems.

Echocardiography

Persistent patency of the duct after the neonatal period is readily diagnosed by its characteristic clinical features. In premature infants, however, especially those with respiratory distress syndrome, the recognition of significant shunting across a patent duct can be difficult. Cross sectional echocardiography and Doppler flow studies are invaluable in determining the presence of a duct, its shunting pattern, size and response to therapy. Additionally, it is essential in ruling out other structural malformations prior to intervention. Indeed, patients with severe ventilator-dependent respiratory distress syndrome may have a large ductal shunt, which may be entirely silent due to lack of turbulent flow within the vessel. Cardiomegaly may also be absent, especially in infants who are fluid-restricted.

Management

Because many ducts will eventually close in premature infants, there has been an understandable reluctance to advise aggressive intervention as soon as a significant left-to-right shunt is recognised. The presence of a ductal shunt, however, has been implicated in the pathogenesis of bronchopulmonary dysplasia, and as a factor in the duration of ventilator support. This increased risk of chronic lung disease has led many to advocate early and effective treatment. Early experience with surgical ligation demonstrated that congestive heart failure could quickly be controlled, although mortality and morbidity from the respiratory distress syndrome remained high. With further surgical experience, mortality directly due to the operation has been reduced to less than 1%. Some centers have advocated, and successfully performed, surgery in the nursery, thereby avoiding the hazards of transport to and from the operating room.

Once the role of E-type prostaglandins in maintaining ductal patency during fetal life was established, pharmacologically induced closure using indomethacin was soon reported in the premature infant.^{144,145} Transient renal insufficiency and mild gastrointestinal bleeding are the main side effects. Despite its widespread usage, questions remain concerning proper dosage, duration of treatment, and optimal timing of administration. The major determinants of success are gestational and postnatal age. In general, initial management includes maintenance of an appropriate level of haemoglobin, ventilatory support, diuretic therapy, and restriction of fluids. The trend is to earlier closure, either by medical or surgical means. In ventilated infants weighing less than 1000 g, administration of indomethacin has been associated with improved outcomes,¹⁴⁶⁻¹⁴⁸ even in the absence of large left-to-right shunts. In contrast, in infants weighing more than 1000 g, outcomes are unaltered, and treatment with indomethacin should be restricted to those with signs of a significant shunt.¹⁴⁴⁻¹⁴⁹ Once the problem is recognised, intake of fluid should be restricted, and furosemide given in a dose of 1 mg/kg. Digoxin is of dubious benefit in this situation. If the shunt remains large after 24 hours, indomethacin should be given, preferably intravenously although nasogastric administration can be successful. Extreme prematurity, very low birth weight, and advanced conceptional or postnatal age are all factors, which reduce the chances of successful closure using indomethacin. Renal and/or hepatic insufficiency, serious hyperbilirubinemia, or problems with coagulation are contraindications to its use. If the duct persists or recurs, a second course of indomethacin should be administered. Dosages are largely selected on an empiric basis. The initial dose is 0.2 mg/kg, while subsequent dosages depend on age at time of initial treatment. If the patient is less than 48 hours of age, the subsequent two doses are 0.1 mg/kg; if the patient is aged from 2 to 7 days of age, 0.2 mg/kg; and if the patient is greater than 7 days, 0.25 mg/kg. The rate of reopening is highest in the very premature, occurring in one-third of those weighing less than 1000 g and in less than one-tenth of those weighing 1500 g. If there is no response to indomethacin, surgical ligation should be undertaken.^{149,150}

Indomethacin-induced closure of the duct is followed by immediate and progressive clinical improvement, with a decrease in requirements for oxygen and in mean airway inflation pressure during mechanical ventilation. Lung compliance has been shown to improve after both surgical ligation and medical closure with duration of ventilation, length of hospitalisation, and the costs of medical care reduced by early treatment.¹⁵¹⁻¹⁵³ The use of prophylactic indomethacin in infants without a duct may decrease the incidence of intracerebral complications but its use in this setting is controversial.¹⁵⁴ Such therapy has not been shown to reduce length of stay, oxygen need, or mechanical ventilatory duration nor the incidence of bronchopulmonary dysplasia.^{147,155,156} Reversal of indomethacin-induced ductal closure by administration of prostaglandin, in the presence of ductal-dependent cardiac malformations, has been possible.¹⁵⁷

Surgical ligation of the persistent duct in premature infants was first reported in 1963.¹⁵⁸ As with indomethacin, surgery has been associated with a decreased need for ventilatory support, and reduced hospital stay,^{157,159}

particularly in infants weighing less than 1500 g.^{150,161} Surgery can be safely carried out in the neonatal intensive care unit to avoid the stress of transportation to the operating theater. While ligation has been the traditional approach, recently video-assisted thorascopic techniques have been proved successful.^{162,163}

Overall mortality remains high, but more often is related to continuing respiratory distress, intracranial haemorrhage, necrotising enterocolitis, or coagulopathy, rather than the therapies themselves.¹⁵² Many questions remain unanswered concerning the true impact of a large left-to-right ductal shunt on the course and outcome of prematurity and respiratory distress syndrome. In a large multi-centre trial, one-third of infants with a significant duct had spontaneous closure, while indomethacin induced closure in seven-tenths of infants treated. There was no difference in the rate of closure if indomethacin was given immediately on diagnosis, or after 48 hours of intensive medical therapy. Rates of death were identical in patients treated with indomethacin early, with indomethacin given late, or with surgery, being about 13% overall in each group.¹⁶²⁻¹⁶⁴

Infiltration of Formalin, Balloon Dilation, Implantation of Stents, and Bioengineering of the Arterial Duct

Rudolph and colleagues¹⁶⁵ described a technique of subadventitial formalin infiltration of the wall of the duct designed to maintain long-term patency of the vessel in patients with duct-dependent cardiac malformations in whom surgery was either inadequate or not feasible. It was shown, however, that infiltration of formalin did not ensure ductal patency even for a short time.¹⁶⁶ The technique was abandoned in favor of infusion of prostaglandin E₁.

Percutaneous balloon dilation has also been proposed as a method to maintain ductal patency.¹⁶⁷ Temporary patency can be achieved, but abrupt closure, thrombosis, or rupture can occur, making this a less reliable means of assuring patency. Except for special instances, this technique has not been pursued clinically.

To provide a mechanical scaffold for the ductal wall, resistant to the constrictive forces of ductal closure, Coe and Olley¹⁶⁵⁻¹⁶⁸ proposed the implantation of endovascular stents. This approach, using either self- or balloon expandable stents, has had expanding clinical application. The implantation in anatomically uncomplicated ducts, such

as in pulmonary atresia, critical pulmonary stenosis or the hypoplastic left heart syndrome (Fig. 42-24), has been encouraging.¹⁶⁹⁻¹⁷² Use in more complex situations, such as occur in tetralogy with pulmonary atresia, however, can be technically difficult.¹⁷³ With innovative approaches to deliver the implant, such as cut-down of the carotid arteries, transvenous through a ventricular septal defect, or after radio-frequency-assisted balloon dilation of an atretic pulmonary valve, the procedure can be performed even in ducts which originate from the undersurface of the aorta or are tortuous. Largely, application has been advanced through improved design of the stents, such as flexible balloon platforms or systems with lower profiles, or taking advantage of the potential of drug-eluting implants to alter the vessel reactivity, thus reducing in-stent stenosis. Recently, at the Hospital for Sick Children in Toronto, Lee and colleagues investigated the use of rapamycin-coated stents implanted into the ducts of small newborn pigs (unpublished data). The mean luminal diameter of bare metal implants compared with the drug-eluting stents was smaller by 32% and 42% at 4 and 6 weeks, respectively, by inhibition of neointimal formation (Fig. 42-25). While the role of stents in the management of infants with complex ductal dependent lesions has yet to be fully defined, such studies are very promising.

Bioengineering of the Arterial Duct for Therapeutic Gain

Novel methodology is emerging for maintaining ductal patency into the postnatal period to sustain life and allow surgical intervention of duct-dependent cardiac malformations. Very recently, maintenance of ductal patency was described through surgical transfection of fetal lambs.¹⁷³ By targeting the ductal smooth muscle cells with an expression vector encoding a decoy mRNA of the fibronectin message, it proved possible to sequester the protein which binds, thereby preventing upregulation of fibronectin and arresting intimal cushions. This approach both emphasises the importance of fibronectin to the process of ductal closure and identifies a new therapeutic modality and target. While fet surgery is likely not feasible in the clinical setting, an alternative approach of targeting chemotherapeutic agents given by systemic infusion to different vascular beds by unique peptide zip codes, may offer bright therapeutic avenues.¹⁷⁴ Recently at the Hospital for Sick Children in

Figure 42-24 The left panel shows an infant with hypoplastic left heart syndrome awaiting cardiac transplantation. The duct became stenotic and unresponsive to prostaglandin. Here, a pulmonary arterial angiogram depicts a stent placed transvenously across the duct to relieve the stenosis. In the right panel, an aortogram is seen after implantation of a stent in an infant with pulmonary atresia and intact septum who was prostaglandin dependent.

Figure 42-25 Movat pentachrome staining of the arterial duct ($\times 400$ magnification). The upper right panel shows the spontaneously contracted duct in seven-day-old piglet. The upper left panel shows the duct, stented with a bare metal stent and immediately harvested. The lower six panels show examples of stented ducts representative of the bare and drug-eluting stent groups. Note that there is negligible difference in lumen patency between the drug-eluting stent and bare metal stent at 2 weeks but increased luminal compromise in the bare metal stent group at 4 and 6 weeks compared with the drug-eluting stent.

Toronto, Humpl and colleagues investigated percutaneous postnatal transfection of a vector containing the gene for prostaglandin into ductal tissue, resulting in prolonged patency.¹⁷⁵

These studies identifying and characterising the cellular and molecular mechanisms involved in ductal patency and closure have advanced our understanding of this developmentally programmed fetal vessel. The impact of these advances extends beyond the scope of ductal remodeling, as they have provided insight into the pathogenesis of occlusive vascular disease processes, which utilise similar pathways. This work has also positioned the field towards further advances associated with the development of safe therapeutic measures to maintain ductal patency for infants with cyanotic congenital heart disease, ultimately translating into improved care and clinical outcome.

Techniques non-pharmacological methods to maintain ductal patency have attained prominence in treatment strategies for the infant with ductal dependent pulmonary or systemic blood flow. These reports discuss the implantation of endovascular stents to palliate such lesions.

- Mason CA, Bigras JL, O'Blenes SB, et al: Gene transfer in utero biologically engineers a patent ductus arteriosus in lambs by arresting fibronectin-dependent neointimal formation. *Nat Med* 1991;5:176–182.

- Humpl T, Zaidi SH, Coe JY, et al: Gene transfer of prostaglandin synthase maintains patency of the newborn lamb arterial duct. *Pediatr Res* 2005;58:976–980.

These two reports apply molecular methods, developed from an understanding of ductal vascular biology to maintain ductal patency. While neither has attended clinical application, research following these approaches will improve our methods to control ductal patency.

Pulmonary Stenosis

GRAHAM DERRICK, PHILIPP BONHOEFFER, and ROBERT H. ANDERSON

This chapter will discuss pulmonary stenosis, where it exists as an isolated finding. Where pulmonary stenosis exists as part of a more complex anomaly, such as tetralogy of Fallot, the reader is directed to the complete descriptions found in the relevant chapters.

GENETICS, EMBRYOGENESIS AND INCIDENCE

Genetics

The first descriptions of pulmonary stenosis were recorded by Giovanni Baptista Morgagni, of Padova in Italy, in 1761.¹ This lesion is now known to be common, and comprises about one-tenth of all congenital cardiac malformations.

The incidence of pulmonary stenosis in the United Kingdom or North America is about 0.4%. The rate of familial recurrence, however, is considerably higher, at up to 4%, suggesting that a proportion of cases at least are linked to a genetic basis. Further investigations within families have supported this hypothesis, suggesting that pulmonary stenosis can be caused by a single gene defect with or without additional abnormalities within the phenotype. Clearly there are a number of genetic abnormalities involved. At the time of writing, a search on the Online database for Mendelian Inheritance in Man² for variants of pulmonary or pulmonic, stenosis, or valve stenosis, revealed 92 reports for conditions including pulmonary stenosis where Mendelian inheritance is suspected. Of these, the locus for a genetic abnormality, be it a point gene mutation, deletion or aneuploidy, were confirmed in two-thirds of the results, whilst the remaining third of the reports were of cases with Mendelian or suspected Mendelian inheritance. Perhaps the most frequently presenting patients with a genetic basis for their pulmonary stenosis are patients with Noonan's or Williams' syndromes.

Non-genetic factors have also been implicated. For instance, the congenital rubella syndrome, now very rarely seen because of adequate immunisation and prenatal maternal screening, includes severe peripheral pulmonary arterial stenosis.

Embryology

The precise embryology of the development of the pulmonary valve in the human, indeed both ventricular outflow tracts, is not fully understood. Because of the obvious constraints of studying human embryological development, other species of embryo have formed the basis of the understanding of embryology. The most common models have been proposed based on sequential

sections and stains of the developing chick embryo or chick-quail chimera. Difficulties also exist because of differing nomenclature used between the groups studying the lesions.

As we have explained in Chapter 3, the heart develops as a tubular structure with a solitary lumen when the embryo is 20 days old, differentiating into a sequential pulsatile pump by 28 days. By 30 days, partial separation has occurred, creating a chambered structure with interatrial and interventricular communications. Remodelling of the outflow tract produces two vessels, each with its own arterial valve. The tissues of the outflow tract are derived from different sources. The cardiac mesenchyme contributes to the myocardium and some of the endothelium, with other endothelial contributions from migrating cells of the non-cardiogenic regions of the lateral plate and head mesenchyme. Initial septation is produced by ingrowth of mesenchyme, derived from the neural crest, into the cushions developing throughout the outflow tract. These cushions then fuse with each other, and also with the back wall of the aortic sac between the origins of the arteries supplying the fourth and sixth aortic arches. This process achieves separation of the intrapericardial components of the aorta and the pulmonary trunk. The proximal part of the outflow tract remains encased in a sleeve of outflow myocardium. It is division of the distal part of this persisting muscular outflow tract, again by the cushions packed with cells from the neural crest, which produces the primordia of the developing aortic and pulmonary valves. It is the outflow cushions themselves, by a process of cavitation, that are remodelled at their distal ends to produce the leaflets and sinuses of the valves. The role of cells derived from the neural crest is demonstrated by ablation of the neural crest itself, which results in failure of septation, and a persistent common arterial trunk. Tissue derived from sources other than the neural crest also plays a role in differentiation and separation of the ventricular outflow tracts, and the origin of this tissue is still not known.³ The reader is directed to a complete review of the literature and discussion of the role of tissues derived from the cardiac neural crest in the development of the cardiac outflow tracts provided by Waldo and colleagues.⁴

The proximal portions of the left and right pulmonary artery branches derive from the caudal portion of the aortic sac, which also feeds the arteries of the sixth pharyngeal pouches. The distal portion of the right sixth branchial arch regresses completely, while the distal portion of the left branchial arch persists as the arterial duct, and latterly the ligament of the arterial duct. The peripheral pulmonary vasculature, distal to the origin of the branches of the

pulmonary trunk, derives from the postbranchial pulmonary vascular plexus, which develops in close relationship with and alongside the developing lung buds.

Incidence

Pulmonary stenosis is the second most common congenital cardiac malformation. In a large prospective study of all live born infants, including also data from autopsies of stillborn infants,⁵ the total incidence of congenitally malformed hearts was 6.6 per 1000 live births. Of these, pulmonary stenosis accounted for 5.8%. Half of all congenitally malformed hearts include pulmonary stenosis as a component of the defect.

MORPHOLOGY

As far as stenosis within the pulmonary outflow tract is concerned, obstruction at valvar level is by far the most common lesion. Understanding completely the mechanisms responsible for stenosis mandates a clear appreciation of normal valvar anatomy.⁶ At present, such understanding is constrained by varying use of the term annulus to describe the structure of the normal valve. Paradoxically, it is only when the valve is stenotic that the attachments of the leaflets approximate to an annular arrangement.

The Normal Pulmonary Valve

The essence of normal valvar anatomy at the ventriculo-arterial junction is the suspension of the leaflets in semilunar fashion within the sinuses of the pulmonary trunk. The key feature is that the hinges of the leaflets cross the anatomic ventriculo-arterial junction. The arrangement is best seen when the normal outflow tract is spread open, having already removed the leaflets (Fig. 43-1). The dissection

Figure 43-1 The normal pulmonary outflow tract has been opened and spread to show its full width, the leaflets of the pulmonary valve having been removed. The dissection shows how each leaflet is attached distally at the sinutubular junction, but proximally to the muscular infundibulum. The semilunar line of attachment of each leaflet, marking the haemodynamic ventriculo-arterial junction, crosses twice the anatomic junction between the wall of the pulmonary trunk and the muscular infundibulum, leaving triangles of fibrous wall (*vertical hatching*) as part of the ventricle, but sequestering crescents of musculature (*horizontal hatching*) as parts of the valvar sinuses.

Figure 43-2 The cartoon shows the effect of the hingeline of the valvar leaflets (one shown in purple) crossing the anatomic ventriculo-arterial junction. Triangles of arterial wall are incorporated into the ventricular outflow tract to the level of the sinutubular junction, while crescents of muscular infundibulum are sequestered at the base of each valvar sinus.

shows that each leaflet is attached at its two extremities at the sinutubular junction, whilst the basal attachment is supported by the musculature of the subpulmonary infundibulum. True anatomical rings can then be identified at the level of the sinutubular junction, and also at the anatomic ventriculo-arterial junction, this latter structure being the locus over which the fibroelastic walls of the pulmonary trunk are supported by the muscular subpulmonary infundibulum. A third ring can then be constructed by joining together the basal attachments of the leaflets, but this latter ring is a geometric construction, rather than an anatomic reality. The semilunar line of attachment of each of the leaflets, which marks the haemodynamic ventriculo-arterial junction, crosses the anatomical junction between the muscular infundibulum and the pulmonary trunk in two places. Because of this, crescents of muscular infundibulum are incorporated at the base of each pulmonary sinus, while three tapering triangles of fibrous pulmonary truncal wall extend beyond the anatomical ventriculo-arterial junction as parts of the ventricular outflow tract, reaching to the level of the sinutubular junction (Fig. 43-2).

In this normal arrangement, the free edge of each leaflet is appreciably longer than the cord of the sinus that supports it, thus permitting the three leaflets to fit snugly together when closed so as to produce a competent valvar orifice. It is the semilunar nature of suspension of the leaflets, therefore, that permits competent closure and unobstructed opening of the valve, with the zones of apposition between the adjacent leaflets extending in triradiate fashion from the centroid of the valvar orifice to the sinutubular junction at its periphery (Fig. 43-3).

Pulmonary Stenosis

It is fusion of the adjacent leaflets along their commissures, or zones of apposition, which is the essence of valvar stenosis. The fusion along the zones of apposition is typically uniform. It begins peripherally, so that the valvar orifice is narrowed to a central opening. The more the fusion extends towards the centre of the valve, the narrower will be the central opening, and the more severe will be the valvar stenosis.

Figure 43-3 The cartoon shows the idealised arrangement of the pulmonary valvar leaflets seen from the arterial aspect. The free edge of each leaflet is longer than the cord of the sinus supporting it (red dotted line), permitting the leaflets to close together snugly along their zones of apposition (red arrows), which are attached peripherally at the sinutubular junction (stars), and meet at the valvar centroid (red circle).

When stenosis of a trifoliate valve is mild to moderate, the opening has a triangular configuration (Fig. 43-4).

In contrast, in the most severe forms which produce typical neonatal critical stenosis, the extent of fusion is sufficient to leave only a central pin-prick opening. In this so-called domed stenosis, the central part of the dome tends to be smooth, with evidence of the fused zones of apposition

Figure 43-4 This moderately stenotic valve is shown having removed the pulmonary trunk and photographing the specimen from the arterial aspect. The zones of apposition of the leaflets are fused from their peripheral attachments (stars) towards the centroid of the valvar orifice (red arrows). This produces a narrowed central orifice. Note the tethering of the leaflets at the sinutubular junction.

Figure 43-5 In this critically stenotic valve, the valvar dome is smooth, with evidence of the fused zones of apposition seen only at the margins of the valve.

seen to varying degrees as peripheral raphes with tethering at the sinutubular junction (Fig. 43-5).

When the critically stenotic valve is opened, then because of the obliteration of the zones of apposition between the leaflets, there is also a reduction in the extent of their semilunar hingeing, so that the line of attachment within the pulmonary root achieves a more circular configuration (Fig. 43-6). This is the annular paradox, where ring-like attachments become evident only when the valve is malformed. In this respect, it should also be noted that, although it is frequent to describe the orifice of the normal pulmonary valve in terms of the annulus, the diameter usually measured in this fashion by the echocardiographer is at the level of the virtual basal ring (Fig. 43-7).

As we have already demonstrated, when such a normal valve is opened, it is the semilunar attachments of the leaflets which dominate the picture. An attachment approximating to a ring is never seen unless the valve is stenotic (see Fig. 43-6).

In some instances, it is possible to identify four raphes, suggesting that the valve itself initially had four leaflets. Indeed, quadrifoliate non-stenosed pulmonary valves are by no means unusual, and were discovered as incidental benign lesions once in each 250 postmortems by Becker.⁷ The incidence of a bifoliate, or bicuspid, and stenosed pulmonary valve is reported to be between 7% and 17%, diagnosed with echocardiography or by the surgeon. Archives of autopsied hearts, including our own, have not replicated such a high incidence.⁷⁻¹⁰

The typical lesion producing pulmonary valvar stenosis, therefore, is uniform fusion of the peripheral zones of apposition of a trifoliate valve, leaving a central aperture. Usually this arrangement is associated with some degree of thickening at the union of the zones of apposition with the sinutubular junction, this arrangement being described surgically as tethering (see Fig. 43-4). Accentuation of such tethering can produce marked narrowing at the sinutubular

Figure 43-6 The cartoon shows the arterial view of a valve such as shown in Figure 43-5 to the left hand, and the arrangement of the opened root to the right hand. The fusion of the leaflets produces a more circular attachment within the root: the annular paradox.

Figure 43-7 The cartoon shows a section across the pulmonary root. The measurement usually taken by the echocardiographer as the annulus (red line) is at the level of the basal attachment of the leaflets. As we have shown, this is a virtual ring. The true anatomic rings in the root (blue and green lines) are rarely measured by the echocardiographer.

junction, giving an hourglass appearance that is often described as supra-valvar. In reality, the sinutubular junction is an integral part of the valvar complex. In some instances, valvar stenosis is the consequence of dysplasia of the leaflets, making them thick and mucoid. Such thickening is sufficient to produce obstruction of the valvar orifice, even should the leaflets themselves not be fused along their zones of apposition. Clinical experience indicates, however, that such thickened leaflets usually co-exist with a narrowed sinutubular junction. Most of the patients with Ullrich-Noonan's syndrome have this type of stenosis.¹¹

Although pulmonary valvar stenosis may be considered a simple lesion, it is rare for the lesion to be totally isolated. Almost always there is hypertrophy of the right ventricular wall. In the neonate with critical valvar stenosis, such hypertrophy may be severe, with accompanying fibrosis of the endocardium and thickening of the tension apparatus

of the tricuspid valve. The right ventricle then resembles the situation seen at the better end of the spectrum of pulmonary atresia with intact septum (see Chapter 30). The findings of areas of subendocardial right ventricular infarction in the absence of coronary arterial disease,¹² coupled with discovery of extensive areas of disarray in the myocardial and arterial walls in hearts from patients aged 6 days to 9 years,¹³ point to the disease being more generalised than would be expected from a simple valvar lesion producing direct haemodynamic effects. When the right ventricular wall is hypertrophied, the size of the ventricular cavity is usually relatively reduced, and this can be the consequence of overgrowth and obliteration of the apical trabecular component, again as seen in pulmonary atresia with intact septum (see Chapter 30).

An interatrial communication, be it a probe patent oval foramen or a true septal deficiency, is more frequently seen in patients with pulmonary stenosis, occurring in up to three-quarters of cases. Indeed the presence of a left-to-right shunt at atrial level may serve to accentuate the physical signs of pulmonary stenosis, which could otherwise be mild. This combination of pulmonary stenosis, atrial septal defect, and right ventricular hypertrophy was originally described by French investigators as the trilogy of Fallot,¹⁴ recalling the initial description of Fallot,¹⁵ when he identified such a combination as an alternative cause of *la maladie bleue*, and distinguished it from the tetralogy. Despite this excellent historical pedigree, there now seems little justification for retaining the notion of a trilogy.

In days gone by,¹⁶ it was also the case that cardiac cirrhosis was noted in adults dying with pulmonary stenosis, but such hepatic changes are unlikely to be encountered now. Early fibrotic changes in the livers from two children dying at the age of 6 and 7 years, nonetheless, have been reported.¹⁷

Infundibular Stenosis

Pure narrowing of the muscular subpulmonary infundibulum is rare in the setting of an intact ventricular septum, or with an apical ventricular septal defect. Of the cases seen at the Hospital for Sick Children, Toronto, over a period of almost 25 years, only 2.7% had this type of stenosis.¹⁷ It is probable that many of the cases described as having isolated infundibular stenosis have previously also had a ventricular septal defect that closed spontaneously.

Combined Valvar and Infundibular Stenosis

Hypertrophy of the subpulmonary infundibulum occurs along with hypertrophy of the rest of the right ventricle in response to valvar stenosis. This reduces the infundibular diameter, and endocardial fibroelastosis may be seen along with the hypertrophy. Fixed stenosis of the infundibulum co-existing with valvar stenosis is exceedingly rare.¹⁷ The reactive stenosis, however, is an important component to be noted when judging the results of balloon valvoplasty, since time is needed for its regression.

Other Types of Stenosis Occurring Within the Right Ventricle

These are very rare when the ventricular septum is intact, but they must be considered as possible causes of pulmonary stenosis. Hypertrophy of the body of the septomarginal trabeculation, which in its severest form produces the typical two-chambered right ventricle, is usually found with a ventricular septal defect.¹⁸ It has been described, nonetheless, with an intact septum.¹⁹ In other patients, the valve of the embryonic venous sinus can persist, and become so expanded and aneurysmal that it can pass through the tricuspid valve and obstruct the pulmonary outflow tract (see Chapter 26). This is described as the spinnaker syndrome.²⁰ A similar case has been described in which a huge aneurysm of the membranous septum produced subpulmonary stenosis.²¹ More rarely, tumours can cause subvalvar right ventricular obstruction,²² as may aneurysm of the right coronary sinus of the aorta.²³ Hypertrophic cardiomyopathy can also afflict the right ventricle, particularly in the setting of lentiginosis, although left ventricular obstruction usually dominates.

Pulmonary Arterial Stenosis

Stenoses of the pulmonary arterial tree are frequent in association with complex malformations such as tetralogy of Fallot or transposition. They can also complicate more simple lesions such as pulmonary valvar stenosis or ventricular septal defect. Stenoses in the pulmonary arteries can also occur in isolation, and in various parts of the pulmonary arterial tree. Thus, the stenosis may be localised and central, within the pulmonary trunk or its right and left branches, localised and peripheral at the sites of branching of major intrapulmonary arteries, or more extensive, then existing as a hypoplastic arterial segment commencing either at the end of the right or left pulmonary artery or a major intrapulmonary branchpoint. When found peripherally, such stenoses may be unilateral. Reported cases were well summarised by Rowe,²⁴ who suggested that an anomaly of medial elastic tissue, together with intimal proliferations, could be the cause. It is likely that the process of disease will not be limited to the pulmonary arteries, but will involve also the systemic vessels.²⁵ In this respect, it is noteworthy that the pulmonary arteries are also involved in the so-called Macaroni syndrome, a condition that primarily narrows the ascending aorta.

Pathogenesis

It is now well recognised that dome-shaped stenosis of the pulmonary valve develops as an acquired condition during intra-uterine life,²⁶ often progressing to produce pulmonary valvar atresia with an intact ventricular septum (see the extensive discussion of this topic in Chapter 30). The degree of severity seen at birth depends upon the extent of the process during gestation. Peripheral pulmonary arterial stenoses may be caused by congenital rubella,²⁷ and they are seen in recognisable syndromes of malformation such

as Alagille's syndrome²⁸ and Williams' syndrome.^{29–31} Alagille's syndrome, also known as arteriohepatic dysplasia, has been linked to several genetic malformations, such as *Jag1*^{32,33} and *NOTCH2*,³⁴ and often includes severe intrapulmonary arterial stenoses associated with other abnormalities, including problems of the liver, eyes, and spine. Indeed, the hepatic malformation may appear to be more severe than the pulmonary arterial pathology, although experience has shown that aggressive management, such as hepatic transplantation, can be complicated by the pre-existing pulmonary arterial pathology and intracardiac abnormalities.³⁵ Williams' syndrome, a deficiency of elastin with a gene located on 7q22,³⁰ is associated with peripheral pulmonary stenosis, supravalvar aortic stenosis, and descending aortic hypoplasia.^{29,36}

Pulmonary Arterial Disconnection

An important group of patients have an apparent disconnection of one pulmonary artery from the pulmonary trunk.^{37,38} The disconnected pulmonary artery may have originally been connected by the arterial duct to the aorta or the subclavian artery, and is therefore a true embryological failure, with luminal and adventitial discontinuity from the pulmonary trunk, though sometimes a vestigial duct is still demonstrable (Fig. 43-8). Alternatively, the disconnection may have been acquired as a process of coarctation, where ductal tissue has constricted the lumen of the pulmonary artery to the point of obliteration. In this case, of course, there is still adventitial continuity between the pulmonary trunk and the disconnected pulmonary artery. These considerations are important when surgical reconstruction of the connection is considered, as is the size of the disconnected pulmonary artery at the hilum. Demonstrating the size and integrity of the native vessel when no arterial or ductal connection exists can be difficult. Echocardiography, computerised tomography and magnetic resonance scanning may not be helpful. Cardiac catheterisation and wedge intubation of the pulmonary vein on the side of the disconnected artery for a careful retrograde

Figure 43-8 In this patient with disconnection of the left pulmonary artery, an injection of contrast into a vestigial ductal remnant in the left subclavian artery reveals a left pulmonary artery at the hilum.

Figure 43-9 In this patient, also with disconnection of the left pulmonary artery, a retrograde pulmonary venous wedge injection demonstrates the native left pulmonary artery.

injection of contrast, may be the only helpful investigation³⁹ (Fig. 43-9). Where no interatrial communication exists, transarterial retrograde intubation of the pulmonary vein,⁴⁰ or needle puncture of the atrial septum permitting a trans-septal approach, will be required.

CLINICAL DIAGNOSIS

Presentation

The presentation of pulmonary stenosis depends on age and severity. In the neonate, critical pulmonary stenosis presents with life-threatening cyanosis, with a right-to-left shunt at atrial level producing cyanosis. The differential diagnosis would include other forms of neonatal cyanosis, including transposition, and the various forms of pulmonary atresia. Such patients are likely to depend on their arterial duct to provide the flow of blood to the lungs. Hence, palliation in the short term, by maintaining ductal patency with intravenous infusions of prostaglandin, is

life-saving, until a more definitive diagnosis can be made and an appropriate intervention planned.

Outside of the neonatal period, mild or moderate pulmonary stenosis is not likely to cause major symptoms, unless there are associated lesions or other factors. For example, patients with the typical phenotype of Noonan's syndrome may have difficulty with feeding and gaining weight, separate in most cases to the severity of the pulmonary stenosis. Discovery of disease of mild or moderate severity is most likely when physical signs are detected during consultations for separate matters, when most commonly a cardiac murmur is heard. In patients with more severe pulmonary stenosis, the onset of symptoms can still be delayed into late childhood or early adult life. In a small proportion of patients with pulmonary stenosis, cyanosis can be present, especially on exercise. This is a late physical sign because the cyanotic shunt is at atrial level, depending firstly on an interatrial communication, and secondly on the diastolic properties of the right ventricle. With severe right ventricular hypertrophy and poor right ventricular diastolic compliance, the passage of unoxygenated blood across an interatrial communication into the left atrium is facilitated. Reported symptoms include exercise intolerance, or dyspnoea. Chest pain of an ischaemic nature, possibly due to subendocardial ischaemia of the right ventricle, syncope, and severe dyspnoea on minimal exertion, are late findings and should prompt rapid intervention.

Physical Examination

The physical examination findings are summarised in Table 43-1. There may be a thrill at the second left intercostal space, which is not felt over the carotid arteries, differentiating the cause of the thrill from aortic stenosis. Palpating for a thrill in the suprasternal notch should be avoided, since thrills here can be due to either aortic or pulmonary stenosis.

Widened splitting of the second heart sound, and an ejection systolic murmur, is maximally heard here, with radiation into the back. It is the delayed closure of the valvar leaflets that causes the widened splitting. This is not due to electrical prolongation of systole, but rather to continued flow through the pulmonary valve even after right ventricular pressures have fallen to levels that would usually have resulted in valvar closure. This is likely to be

TABLE 43-1

PHYSICAL SIGNS THAT CAN BE ELICITED IN VALVAR PULMONARY STENOSIS

Physical Sign	SEVERITY OF PULMONARY STENOSIS		
	Mild	Moderate	Severe
Cyanosis	Absent	Absent	Possible, if interatrial septal defect
Jugular venous pulse	Normal	Normal	Possibly elevated, prominent a-wave
Praecordial thrill	Absent	Probable	Pronounced
Right ventricular heave	Absent	Probable	Pronounced
Systolic ejection click	Present	Expiratory	Probably absent
Ejection systolic murmur	Mid systolic, ejection	Long ejection systolic	Long, ejection systolic, past aortic closure sound
Second heart sound	Normal	Wide, variable	Absent pulmonary closure sound

a ventriculo-arterial interaction, favoured by a normal or increased impedance of the pulmonary vascular bed. It can be termed pulmonary hangout.

In most cases of valvar pulmonary stenosis, a systolic ejection click precedes the onset of the systolic murmur. The click is usually heard loudest separate from the area of maximal intensity of the cardiac murmur, nearer the apex, or at the left lower sternal edge. The systolic ejection click originates from the rapid deceleration of the pulmonary valvar mechanism, as the fusion along their zones of apposition prevents the valvar leaflets from reaching their intended positions against the walls of the valvar sinuses. Presence of the click also depends on the timing of opening of the pulmonary valve. In mild disease, without right ventricular hypertrophy, the pulmonary valve opens in ventricular systole with the emission of an ejection click. In severe disease, with right ventricular hypertrophy and impaired diastolic compliance, the valve opens in atrial systole, without the rapid deceleration cause by ventricular systole. Thus, no click is heard. In moderate pulmonary stenosis, inspiration augments systemic venous flow, and atrial filling. The augmented atrial pressure allows atrial systole to open the pulmonary valve. Hence, the systolic ejection click is heard only in expiration. In some patients with pulmonary stenosis and tricuspid regurgitation, the right ventricular pressure is high enough to cause a pansystolic murmur at the left lower sternal edge.

The physical findings in patients with supra-valvar stenosis are similar, except for the absence of the ejection click. Stenosis further out into the pulmonary arterial tree can be heard as long systolic or continuous murmurs in the axillas, or over the lung fields at the back. Careful general phenotypic assessment may show the signs or syndromic diagnosis, such as Noonan's syndrome, Alagille's syndrome, or Williams' syndrome.

Basic Investigations

Basic investigations are directed towards assessing the effects and the severity of the pulmonary stenosis (Table 43-2).

The Electrocardiogram

Electrocardiography may be normal, or reveal the degree of right ventricular hypertrophy, or indeed right atrial enlargement, which will be seen only in the more severe cases. There are no features of the electrocardiogram that are unique to the site of pulmonary stenosis, although the severity of stenosis is reflected in the degree of right ventricular hypertrophy and strain. A full right bundle branch block pattern is rare, but an RSR pattern can be seen, and

reflects a lesser degree of right ventricular hypertrophy than the equivalent exclusive R wave complex in V_1 .^{41,42} Rudolf proposed that, in children, the voltage of a pure R-wave recorded at V_1 correlates with approximately one fifth of the right ventricular pressure.⁴³ It turns out that the QRS axis may be a more reliable indicator of right ventricular pressure.⁴⁴ Indeed the prediction of right ventricular pressure gradient is optimised by use of a number of variables in addition to the measurements of voltage on the electrocardiogram, as proposed by Ellison and colleagues,⁴⁵ as follows:

$$\Delta P = RV_1 + 1.5 \cdot (SV_6) + 15 \cdot (\text{murmur}[\text{grade } 0 - 6]) +$$

$$\text{Clinical Score} - 30$$

The clinical score included presence of cyanosis, worth + 25; the pulmonary component of the second sound, if diminished worth 15, or 25 if inaudible; a QRS axis of greater than 90 degrees, worth 10; and negative T waves in aVF and V_1 , worth 35, and with RV_1 above 10 mm worth 15.

This complex formula has been superseded by the quicker, more accurate, and more reliable use of Doppler echocardiography.

The Chest X-Ray

The investigation shows the features of right ventricular hypertrophy, and if present, post-stenotic dilation of the pulmonary trunk. Right ventricular hypertrophy is seen as an upturned cardiac apex. The dilated pulmonary trunk is seen as a prominence of the left upper heart border, inferior to the aortic knuckle (Fig. 43-10). Right atrial enlargement causes a more pronounced convexity of the right lower heart border.

Echocardiography

The gold standard investigation for the assessment of the morphology of pulmonary stenosis is cross sectional echocardiography, coupled with Doppler analysis of the flow in the right ventricular outflow tract and pulmonary arteries.

Figure 43-10 The frontal chest X-ray of mild pulmonary stenosis shows a prominent pulmonary trunk, without features of right ventricular hypertrophy.

TABLE 43-2

SEVERITY OF PULMONARY STENOSIS

	Mild	Moderate	Severe
Electrical axis	Normal	90–130 degrees	110–150 degrees
R:S ratio	Normal	Up to 4:1 in V_1	Inverted in left leads also
V_1 R amplitude	Normal	10–20 mV	>28 mV
Right atrial enlargement	Normal	Possible	Present

M-mode echocardiography no longer has a part to play in the diagnostic process, although many echocardiographers will still employ M-mode to analyse timing of pulmonary valvar motion.

Cross sectional echocardiography will define whether the obstruction is at the level of the valvar leaflets (Fig. 43-11), or is subvalvar (Fig. 43-12) or supra-valvar (Fig. 43-13). The presence and severity of restricted motion of the leaflets, and dysplasia, can readily be assessed, along with any post-stenotic dilation of the pulmonary trunk (Fig. 43-14). The diameter of the pulmonary valve, at the haemodynamic ventriculo-arterial junction, can be measured accurately (Fig. 43-15), facilitating the planning of intervention.

Distal to the valve, it is possible to identify stenosis within the proximal pulmonary arterial tree, although other forms of imaging are necessary to assess pulmonary arterial pathology distal to the bifurcation. The presence of additional abnormalities, such as atrial septal defects, can be recorded.

Previously, electrocardiography was the mainstay of non-invasive assessment of severity of pulmonary stenosis, although electrocardiographic correlates of right ventricular hypertrophy are relatively weak. Since the advent of Doppler echocardiography, assessment is greatly simplified. Colour flow shows turbulent blood originating at the

Figure 43-11 Echocardiographic assessment of pulmonary valvar stenosis.

Figure 43-12 The image shows subvalvar pulmonary stenosis.

Figure 43-13 In this image, the stenosis is at the supra-valvar level.

Figure 43-14 The echo shows post-stenotic dilation of the pulmonary trunk.

point of stenosis (Fig. 43-16). Both pulsed and continuous wave interrogations permit measurement of the maximal velocity of the flow across the stenosis (Fig. 43-17). The pressure gradient can be estimated more accurately using the modified and simplified Bernoulli equation, where the valvar pressure gradient, expressed in millimetres of mercury, or ΔP , is calculated from the maximal Doppler velocity at metres per second, or V , across the pulmonary valve:

$$\Delta P = 4 \cdot V^2$$

Similarly, the right ventricular pressure can also be estimated by the velocity of the jet of tricuspid valvar incompetence, where present, added to the estimated right atrial pressure (Fig. 43-18).

Calculations of estimated pressure gradients derived from Doppler measurements of velocity are now an automatic part of all commercially available systems for cardiac ultrasonic investigation.

Magnetic Resonance Imaging and Computerised Tomography

Cross sectional techniques, such as magnetic resonance angiography (Fig. 43-19), or computerised multi-slice spiral tomography, are considered to be less invasive than cardiac catheterisation, but advantages in small children may still be off-set by the need for general anaesthesia in order to allow

Figure 43-15 The diameter of the pulmonary valve, at the haemodynamic ventriculo-arterial junction, can be measured accurately with echocardiography, to aid planning of intervention.

compliance with respiratory manoeuvres, such as breath-holding. More recent advances in the acquisition of magnetic resonance images, using free breathing techniques, and thus obviating the need for breath-holding, may improve applicability to smaller children without anaesthesia (V. Muthurangu, personal communication, January 1, 2007). The techniques, particularly three-dimensional reconstructions (Fig. 43-20), are helpful when assessing the pulmonary trunk and its branches, particularly in relation to surrounding structures, but with present technology are less helpful for assessment of the pulmonary valve. Future technological

advances in speed of acquisition of images, electrocardiograph gating, and post-processing may bring these techniques into the forefront for investigation of pulmonary stenosis. Presently, it is likely that more information about the morphology of the pulmonary valve, and the immediate supra-valvar region, is available with echocardiography.

Cardiac Catheterisation and Angiography

Diagnostic cardiac catheterisation has become almost completely superseded by less invasive techniques, such as echocardiography, for the assessment of pulmonary valvar stenosis, and is now undertaken only to perform catheter interventions.

For assessment of more distal stenosis, such as stenoses in the right or left pulmonary arteries or intrapulmonary arterial stenosis, or when access to high quality magnetic resonance or computerised tomographic techniques is not available, cardiac catheterisation and angiography can still play a useful role. Indeed, demonstration of intrapulmonary arterial stenosis, or stenoses at multiple levels, may still best be performed by conventional pulmonary arteriography. Where either the right or left pulmonary artery is thought to be interrupted from the pulmonary trunk, intubation of a pulmonary vein on the same side, and wedge injection of contrast, may be the only way to demonstrate the presence of the proximal pulmonary artery (see Fig. 43-9).

The one advantage of cardiac catheterisation over the other imaging techniques is the accurate measurement of ventricular and pulmonary arterial pressures. Using end-hole or monorail catheters, any gradient across a stenosis can be recorded. The gradient cannot be completely compared to that estimated with echocardiography because of differences in the techniques. Doppler echocardiography estimates peak instantaneous differences in pressure by application of the Bernoulli equation to the measured maximal velocity across the stenosis (see Fig. 43-17). Gradients measure using catheters show a peak-to-peak

Figure 43-21 Peak-to-peak pullback gradient measured at cardiac catheterisation.

difference in pressure between the sites of measurement (Fig. 43-21).

Key Diagnostic Features

The key features are summarised in Box 43-1.

HAEMODYNAMICS AND PHYSIOLOGY

The consequence of obstruction at the right ventricular outflow necessitates an increase in right ventricular pressure in order to force blood through the stenosed valve. The right ventricular pressure developed is usually proportional to the degree of obstruction present. If stenosis develops early in fetal or neonatal life, right ventricular mass increases by ventricular myocytic hyperplasia, as well as hyperplasia of the supporting apparatus, such as

BOX 43-1

Key Diagnostic Features of Pulmonary Valve Stenosis

the capillaries supplying blood to the myocytes, such that the density of capillaries remains normal. In this way, in newborns or neonates, the capacity for the right ventricle to generate high pressures and tolerate moderate stenosis is high. Where pulmonary stenosis develops later in life, after the neonatal period, the capacity for hyperplasia is lost, and the increase in ventricular bulk is due to a hypertrophic response. There is a compensatory increase in capillary supply, but this does not compensate for the increase in ventricular myocardial mass, and there is a reduction in capillary density. Thus, the capacity for the ventricle to sustain high pressures, and tolerate stenosis, is less than in the newborn. In the fetus, severe forms of pulmonary stenosis may result in a circulation that resembles pulmonary atresia, and right ventricular development may be impaired, resulting in the development of a hypertrophic right ventricle with a hypoplastic cavity.

When right ventricular dilation is severe, interventricular interaction may occur, such that the left ventricle is constrained within the pericardium, impairing its ability to fill, and contributing to the compromised circulation. Central cyanosis can occur in neonates when there is a duct-dependent pulmonary circulation, or when right ventricular diastolic dysfunction allows right atrial pressure to exceed left atrial pressure, producing a cyanotic shunt across a defect in the atrial septum.

NATURAL HISTORY

Mild pulmonary valvar stenosis, with a gradient of less than 40 mm Hg, seen after the first 6 months of life is, in general, a benign condition. The severity of the disease may even improve as the child grows,⁴⁶⁻⁴⁹ certainly with a very low incidence of deterioration to the point of requiring an intervention. In children with moderate, or even severe, pulmonary stenosis, right ventricular function seems to be maintained.⁵⁰ When first seen in infancy, however, even mild pulmonary stenosis can deteriorate.⁵¹ Using Doppler echocardiography monitoring, one-quarter of infants with mild pulmonary stenosis in the neonatal period were shown to develop further significant stenosis,⁴⁷ and up to half of these patients require intervention.⁴⁶ Thus, it is important to monitor infants carefully, especially when the diagnosis is made in the neonatal period, regardless of their severity of pulmonary stenosis. The appearance of the valve, in terms of the thickness and mobility of the leaflets, is only weakly predictive of future deterioration.⁴⁷

In patients with deteriorating pulmonary stenosis and intact ventricular septum, over time, right ventricular pressure may exceed left ventricular pressure. The ventricular pressure waveform changes, from a broad based triangular shape with early peak maximal pressure (Fig. 43-22), to a tall peaked waveform with the point of maximal pressure delayed to close to the end of systole (Fig. 43-23). Compensation for fixed severe stenosis with right ventricular hypertrophy can fail as the patient grows and further demands are made on the ventricle. At this stage, the right ventricle may decompensate by dilating and the onset of heart failure occurs. Further compensatory mechanisms for low cardiac output include increased extraction of oxygen. During exercise, even this compensatory mechanism is

Figure 43-22 Normal low-pressure right ventricular waveform showing a broad-based triangular-shaped waveform with an early point of maximal pressure.

insufficient, and exercise intolerance is noted, often with the presence of peripheral cyanosis.

THERAPEUTIC OPTIONS

Historical Perspective

Though pulmonary stenosis has been recognised as a pathological entity since 1761, management of this disease has only been possible in the past 60 years or so. The first reported attempt, unsuccessful, was published in 1913.⁵² The first successful pulmonary valvotomy was performed in London, by Holmes Sellors,⁵³ in December of 1947. The patient had tetralogy of Fallot, and although the intention had been to perform a Blalock-Taussig shunt, a stenosed pulmonary valve was palpable. A trans-fundibular approach was made to incise the stenosed pulmonary valve in two directions, resulting in immediate relief of cyanosis. Perversely, this operation was reported two weeks after the report by Brock of his own three successful operations, performed later in 1948.⁵⁴ Brock continued along the theme of direct relief of pulmonary stenosis and tetralogy of Fallot, and designed a complementary series of instruments, comprising a valvulotome to cut the stenosed valve, an expanding dilator to split the valve, and an infundibular punch to resect the thickened infundibular muscle (Figs. 43-24 and 43-25). He reported

Figure 43-23 The waveform in severe pulmonary stenosis shows a taller, squarer waveform with a delayed point of maximal pressure close to the end of systole.

the successful use of these instruments in 1950,⁵⁵ and described a miraculous transformation in his subjects. The Brock procedure for tetralogy of Fallot was immediately adopted for patients with pulmonary stenosis and an intact interventricular septum. The introduction of inflow occlusion,^{56,57} inflow occlusion and hypothermia,⁵⁸ and subsequently extracorporeal circulation⁵⁹ in the mid 1950s, changed the surgical approach to a more precise operation involving splitting of the fused zones of apposition of the leaflets or valvectomy.

Interventional Catheterisation

The swing to an interventional approach to the treatment of pulmonary valvar stenosis resulted from a partnership between cardiologists and radiologists. The first reported catheter intervention for pulmonary valvar stenosis was performed in 1953.⁶⁰ A ureteric catheter modified with a wire was introduced through the pulmonary valve, the wire

being tensioned to form a bow-shaped device which was used to incise the stenosed valve.⁶⁰ Later, the same technique was used for the stenosed tricuspid valve.⁶¹ The use of a standard angiographic balloon to disrupt the pulmonary valve was described in 1979.⁶² The technique involved a rapid pullback, in septostomy fashion, of the balloon catheter from the pulmonary trunk to the right ventricular outflow tract. Meanwhile, graded dilation was being developed for atherosclerotic vessels,⁶³ including important technical developments in guide-wires and catheters.^{64,65} Further refinements allowed the techniques to be applied to smaller vessels, including the coronary arteries,^{66–69} using a double lumen balloon catheter designed to be used over a guide-wire. It is not commonly known that the first successful static balloon dilation of the pulmonary valve, as we now know the technique, was performed in an English bulldog in 1980,⁷⁰ prior to the first report of the successful procedure in 1982 in a child.⁷¹ Since it was first performed, the technique has rapidly become the treatment of choice

for pulmonary valvar stenosis. Apart from improvements in the design of balloon angioplasty catheters and guide-wires, to improve the profile and tracking ability of the products, only one other interventional technique was reported to treat pulmonary stenosis. This involved an endovascular device with an extendable double blade, designed to be extended in the pulmonary trunk, and drawn back through the pulmonary valve to disrupt the stenosed leaflets.⁷² After the first report of three children treated in Shanghai, no further report has been published in the literature.

Contemporary Approaches

Indications for intervention in children are widely discussed in the literature, with equally wide variability in the criteria for selection. The indications for catheter intervention should be similar to the indications for a surgical approach, although because of the less invasive, expensive, and time-consuming advantages of catheter intervention, this technique remains the first choice in all centres. Most groups will intervene if the echocardiographically derived peak instantaneous gradient across the pulmonary valve is in excess of 64 mm Hg, correlating to a Doppler velocity of more than 4 msec⁻¹. Some groups recommend a threshold of a peak instantaneous pressure gradient of greater than 50 mm Hg⁷³ when cardiac output is normal. In patients in acute or chronic heart failure, the capacity of the ventricle to generate higher pressures is impaired, cardiac output reduced and a lower threshold for intervention must be applied. Whilst attention has been paid to intervention in more mild cases, the evidence for progression of mild stenosis is lacking,⁴⁸ and follow-up can easily determine the cases that do progress, with the option to plan an intervention still available even up until adult life.^{74–78} In adults with moderate to severe stenosis, persistent exercise intolerance, pressure overload, and the risk of right ventricular fibrosis provide good indications for intervention,⁷³ despite the usual lack of symptoms.

Infants presenting in the neonatal period with moderate or severe stenosis, especially those presenting with a duct-dependent pulmonary circulation, should be treated urgently.^{79–82}

Technique

Full physical and echocardiographic assessment should precede any intervention. Informed consent is necessary, especially since the long-term effects of intervention are not completely known. The dimension of the ventriculo-arterial junction should carefully be assessed. If resuscitation is necessary, especially in infants who may need prostaglandin to stabilise the patent arterial duct, this should precede the intervention.

Cardiac catheterisation should be performed under general anaesthesia, or local anaesthesia with intravenous sedation. Facilities for management of the airway must be nearby if a full general anaesthetic is not employed. Preparation for the catheter must proceed in standard fashion, with attention as usual to sterility of the operative fields, the equipment trolley, and the operators. In addition, we recommend antibiotic prophylactic measures.

Access to the circulation is most commonly through a femoral venous puncture. In patients with problems of vascular access due to venous thrombosis, other techniques can be employed, including the jugular,⁸³ axillary⁸⁴ or hepatic⁸⁵ veins. A curved end-hole catheter, either a right coronary catheter or one that is Cobra shaped, or a balloon tipped angiographic catheter such as the Berman, is manipulated into the right ventricle. It is important to cross the tricuspid valve in a fashion to intubate the major aperture of the valve, rather than allowing the catheter to pass between tendinous cords, since the latter can cause avulsion of the tricuspid valve when the denatured balloon catheter is withdrawn after the dilation procedure.⁸⁶ With end-hole catheters, this can best be accomplished by catching the tip of the catheter in the hepatic vein or right atrial wall to create a curve in the tip of the catheter. The tricuspid valve can be crossed with the curved tip by rotating leftwards and anteriorly from a position in the right atrium.

Right ventricular pressure can be measured and compared to left ventricular pressure. A right ventricular angiogram can most easily be performed in the neonate by a gentle injection by hand of contrast into the ventricular outflow tract below the stenosed pulmonary valve, or in older children by using a right ventricular power injection (Fig. 43-26). Care must be taken not to infiltrate contrast into the myocardium of the right ventricular outflow tract. Such an event can be poorly tolerated. The lateral projection of the right ventricular angiogram is useful to confirm the echocardiographic measurements of the ventriculo-arterial junction, and the orientation of the domed orifice of the stenosed valve. This allows the catheter to be manipulated into the pulmonary trunk with the aid of a guide-wire, into the left or right lower pulmonary artery, or even in neonates into the descending aorta through the arterial duct.⁸⁷ The choice of guide-wire is dependent on the

Figure 43-26 Right ventricular outflow tract angiogram, demonstrating the domed and stenosed pulmonary valve, and allowing measurement of the ventriculo-arterial junction.

operator, and on the age of the patient. In older patients, if stable during the procedure, our group would use a hydrophilic wire to gain a distal position in the pulmonary artery, exchanging it for a stiff exchange wire, over which a monorail multi-track catheter can be advanced and withdrawn for an accurate measurement of pressure gradient without losing position. In newborns, or if there is instability during the procedure, measurement of the pressure gradient can be abandoned in favour of a more rapid procedure. In neonates, a coronary angioplasty wire can be passed through the valve and used to deliver the angioplasty catheter.

The choice of dimension of the balloon has been the source of much discussion. It is clear that the balloon must be oversized in relation to the dimension of the pulmonary valve, but there is evidence that sizes in excess of 120% to 125% of the pulmonary valve are no more efficacious at reducing the severity of pulmonary stenosis, yet create more problems in terms of subsequent pulmonary incompetence or other complications.^{88,89} An exception could be argued in cases where the valve is markedly dysplastic and stenosed. There is no evidence to select the length of the balloon to choose. Shorter balloons may be more difficult to stabilise centrally over the pulmonary valve. Longer balloons carry more risk of damage to the tricuspid valve,⁸⁶ atrioventricular node,⁹⁰ or distal pulmonary arteries. Simple and intuitive choices are a balloon of 20 mm for neonates and infants, one of 30 mm for children, and one of 40 mm for adolescents and adults.⁷³

In most cases, therefore, a non-compliant coaxial construction angioplasty balloon of the appropriate size is selected and tracked over the guide-wire to the pulmonary valve. If the balloon fails to track through the right ventricle, then there is a good chance that the catheter has passed behind some tension apparatus of the tricuspid valve. It is better to withdraw the catheter and guide-wire, and recross the tricuspid valve so as to obtain a better position. To force the angioplasty balloon onwards is disadvantageous, because the balloon would be drawn in a denatured form back through the tricuspid valve, with the potential for serious damage.⁸⁶ When it is difficult to cross the pulmonary valve with the chosen dimension of balloon, it is often better to exchange the balloon angioplasty catheter for a smaller one, even as small as a 3-mm coronary angioplasty balloon, in order to pre-dilate the valve before returning with the original.⁹¹

The angioplasty balloon should be de-aired carefully and connected to a syringe containing a weak solution of about 20% to 25% contrast medium in saline. The balloon is inflated by hand or with an inflation device. An inflation device is usually recommended by the manufacturers of the balloon angioplasty catheter, yet in most cases, inflation at high pressure is not necessary, and hand inflation is sufficient. Whilst watching the hourglass impression of the pulmonary valve on the balloon during inflation (Fig. 43-27), the balloon might prolapse forwards or backwards, and manipulation of the balloon and the guide-wire can be required. Our group has not found it necessary to use high-frequency ventricular pacing or intravenous adenosine, and with attention to applying or relieving tension on the guide-wire, a stable position is usually maintained during inflation. The balloon is inflated until its walls are seen on fluoroscopy to be parallel. Application of higher pressure does not serve any useful purpose beyond the

Figure 43-27 Lateral projection showing an angioplasty balloon partially inflated across the pulmonary valve, with the characteristic hourglass impression imposed on the balloon by the stenosed pulmonary valve leaflets.

point at which parallel walls of the balloon have been reached, and carries a greater risk of rupture. If there is still a residual hourglass impression on the balloon during inflation, then the ventriculo-arterial junction itself may be hypoplastic and the procedure will have limited benefit.

Following the first inflation, most operators inflate one or more times, and study the way that the balloon inflates and deflates to determine whether an hourglass impression is still caused by the pulmonary valve. After inflation and withdrawal, the pressure in the right ventricle and the gradient across the pulmonary valve can be recorded. The position of the wire can be preserved using a monorail catheter or an end-hole catheter and a TuohyBorst adaptor. Careful pullback will show whether any residual gradient is confined to the pulmonary valve, or indeed present in the subvalvar right ventricular outflow tract. If there is significant valvar gradient, the decision to reattempt dilation with a larger balloon can be made. The presence of a significant subvalvar gradient is a well-described phenomenon after dilation of the pulmonary valve, and can have serious consequences with a low cardiac output state. This is the so-called suicide right ventricle. Careful attention to anaesthesia, the preoperative state of hydration, and use of β -blockade will usually be sufficient to deal with the acute right ventricular outflow tract reactivity.⁹² Residual right ventricular subvalvar narrowing will usually settle over time.

If the procedure is successful in terms of right ventricular pressure and trans-valvar gradient, then our group will terminate the procedure without performing a follow-up right ventricular angiogram. The investigations prior to discharge are completed with echocardiography to assess the result

Figure 43-28 The double balloon technique for pulmonary balloon dilation, shown (A) in frontal projection, and (B) in lateral projection.

of balloon dilation, the degree of pulmonary incompetence, and the integrity of the tricuspid valve. Outside of the neonatal period, it is usually possible to perform these procedures as day cases.

Severe or Critical Neonatal Pulmonary Stenosis

The presentation and management of pulmonary stenosis in the neonatal period deserve special discussion. Infants may present in a critically ill state, with cyanosis as result of right-to-left shunting across the atrial septum, being dependent on patency of the arterial duct for survival. The efficacy of balloon dilation of the pulmonary valve depends not just on the result of the valvotomy, but also on the size and compliance of the right ventricle, tricuspid valve, and the ventriculo-arterial junction.⁹³ Thus the size of the structures in the right heart needs to be evaluated as part of the management. Relative hypoplasia is not a contraindication for balloon dilation of the pulmonary valve, and indeed follow-up studies have shown that the rate of growth of the right heart can exceed the rate of somatic growth after successful balloon dilation.⁹³⁻⁹⁵ Immediately following balloon dilation, despite adequate opening of the pulmonary valve, it may still be difficult to separate infants from infusions of prostaglandin. This is most likely as a result of hypertrophy and diastolic dysfunction of the right ventricle, favouring a cyanotic shunt across the atrial septum. Persistent hypoxaemia may settle over a few days as the right ventricle recovers. Should hypoxaemia persist, it may be necessary to establish an alternative source of supply of blood to the lungs, such as a systemic-to-pulmonary arterial shunt, or stenting of the arterial duct. A detailed analysis of the morphology of the right heart structures may help predict whether an alternative source of such flow is going to be required. A diameter of the tricuspid valvar orifice of greater than 11 mm, right ventricular

volumes of greater than 30 mL/m², and dimension of the pulmonary valve of greater than 7 mm, appear to stratify patients who are less likely to require an intervention to increase pulmonary flow.⁹⁶

Multiple Balloon Techniques

Using the recommended sizing of balloons of 120% to 125% of the dimension of the pulmonary valve, it is clear that large balloons will be required for adolescents and adults. Such balloons may be difficult to source, and the frequency of use might make it impracticable to keep these items in stock in the paediatric catheter laboratory. Techniques using an additional balloon angioplasty catheter through an additional venous puncture, and over an additional guide-wire, have been reported (Fig. 43-28).^{74,97-99} The effective dimension of the double balloon technique is calculated thus¹⁰⁰:

$$\text{Total Diameter (mm)} = \frac{D1 + D2 + \pi \left(\frac{D1}{2} + \frac{D2}{2} \right)}{\pi}$$

The use of the multi-track double balloon mitral commissurotomy system, using two complementary angioplasty catheters designed to track along the same guide-wire, has been reported in adults with pulmonary stenosis.¹⁰¹ Whilst this technique offers an easier approach, and one less venous puncture, than the conventional double balloon technique, again the technique only offers an advantage if a single balloon of appropriate dimension is not available. Similarly, angioplasty catheters with multiple balloons, bifoil and trefoil, mounted in parallel on one shaft, have been described,¹⁰² as well as a technique using three separate angioplasty balloons, with a complicated formula described for their overall dimensions.¹⁰³ Such

balloons, or systems, as well as the double balloon technique, are argued by their proponents to facilitate some residual antegrade flow during inflation in the right ventricular outflow tract. This seems unlikely when the correct oversized dimension is chosen. In addition, they are bulky, and have largely been superseded by more modern large single balloons with lower profiles which can be introduced through smaller sheaths.

Whilst the results all of these techniques have been highly effective, and well sustained, it has since been shown that, where a single balloon is available for the appropriate dimension, no advantage is conferred using multiple balloons.¹⁰⁴ It is important, nonetheless, that all operators have an understanding of these techniques, as well as knowledge of the equipment that is available in their own local laboratory, because the final decision may be made on supply and demand of equipment.

Complications

Acute complications of balloon dilation of the pulmonary valve are summarised in Box 43-2. Balloon dilation has proved to be very successful, and has yielded minimal immediate complications. Out of 822 procedures entered into the VACA Registry, including cases of critical pulmonary stenosis, the death rate was reported as 0.24%, and the major complication rate was only 0.35%.¹⁰⁵ In a smaller multi-centric series of 172 patients, excluding critical pulmonary stenosis, there was no mortality, with emergency surgery required in only one patient (0.58%), who suffered perforation of the right ventricular outflow tract.¹⁰⁶

During inflation of the balloon, transient bradycardia and hypotension may be observed. This effect recovers quickly after deflation of the balloon. A patent oval foramen, or an atrial septal defect, helps to preserve systemic ventricular output during occlusion of the pulmonary arteries. So as to minimise these effects, inflation of the balloon should not be maintained for more than a second or two.

With modern design of sheaths and catheters, and improved techniques, loss of blood is minimal. Manipulation

of the catheter or wire in the right heart can provoke arrhythmia, right bundle branch block, and even transient or permanent complete heart block. Other complications include stroke or seizures due to embolic complications in the context of a potential right-to-left atrial shunt.

Rupture of the balloon at high pressures of inflation, pulmonary arterial tears, perforation of the right ventricular outflow tract,¹⁰⁶ and rupture of tricuspid valvar papillary muscles have all been reported.⁸⁶ Failure of technical equipment, such as failure of the balloon to deflate, or rupture and embolisation of fragments, require an innovative use of troubleshooting techniques.^{107–109}

Late Complications

Patients after dilation of the pulmonary valve are generally well, and enjoying a good quality of life. Femoral venous occlusion related to the intervention is well described, and may be demonstrated in over one-fifth of patients requiring further venous access.¹¹⁰ Recurrence of pulmonary stenosis is reported in up to one-tenth.¹¹¹ Perhaps more topical is the early and progressive development of pulmonary incompetence in the early cohort of treated patients. The ratio of the balloon to the pulmonary valve has been discussed already, and moving away from the use of oversized balloons may reduce this trend. Indeed, late pulmonary incompetence is usually very well tolerated.¹¹² Nevertheless, consideration of replacement of the valve may be necessary when right ventricular dilation, right ventricular dysfunction, or symptoms develop late after dilation. Aside from these long-term complications, and allowing for anecdotal case reports, such as spontaneous pulmonary arterial dissection late after dilation,¹¹³ the long-term follow-up is remarkably good.

OUTCOMES OF INTERVENTION

Surgical Valvotomy

The first description of surgical valvotomy included 33 patients in whom 18 had pure pulmonary valvar stenosis. Of those 18 patients who underwent the landmark Brock procedure,⁵⁴ 7 patients died, although many of these patients were adult, and were severely ill at the time of the procedure. In addition, an effect of the era was identified, with the mortality improving for the whole series from 50% to 18% after the first 11 patients. The survivors were followed up, and the outcome in the medium term was good. The authors recommended that the technique was best applied to patients less than 10 years of age.

The Second Natural History Study¹¹⁴ identified a cohort of 592 patients with pulmonary stenosis. Of the patients who had had valvotomy, only 4% required a second operation. Patients enjoyed a quality of life similar to that of the normal population. Similar results were found in survivors followed up to 17 years after the procedure.¹¹⁵ The long-term follow-up of a group of 191 consecutive patients who underwent surgery for isolated pulmonary valve stenosis at the Mayo Clinic has been excellent. The survival curve is shown in Figure 43-29. The long-term survival of patients surviving operation before 21 years of age is similar to that of an age- and sex-matched control population.¹¹⁶ In the patients who had operations at a later age, there was some late attrition, possibly due to the sequels of long-standing right ventricular hypertrophy.

BOX 43-2

Complications of Balloon Pulmonary Dilation

ACCESS

- Haemorrhage from access points

CATHETER/WIRE MANIPULATION

- Arrhythmia and hypotension
- Atrioventricular conduction block
- Embolic complications

BALLOON INFLATION

- Pulmonary arterial tear
- Tricuspid valvar papillary muscle rupture
- Cardiac perforation and tamponade

AFTER INFLATION

- Severe reactive infundibular stenosis

LATE COMPLICATIONS

- Femoral venous stenosis or occlusion
- Recurrence of pulmonary stenosis
- Pulmonary incompetence

Figure 43-29 Post-discharge survival after surgery for pulmonary stenosis. Kaplan-Meier survival curve of the 88 patients who were discharged after surgery between 1968 and 1980. (Reproduced with permission from Roos-Hesselink JW, Meijboom FJ, Spitaels SEC, et al: Long-term outcome after surgery for pulmonary stenosis [a longitudinal study of 22–33 years]. *Eur Heart J* 2006;27:482–488.)

The longest study reported describes up to 33 years follow up after surgical valvotomy.¹¹⁷ Survival at 25 years was 93%. Quality of life was good with 67% of patients falling into the first class of the categorisation of the New York Heart Association, and a measured exercise capacity of 90% predicted. One-sixth required surgical reintervention, but this particular cohort reflects the developing understanding of the effects of pulmonary incompetence and the need for intervention, a point that had not been appreciated in previous reports. A risk factor for reintervention included the use of a transvalvar patch.

Balloon Dilation

Long-term results of balloon dilation during childhood are excellent.¹¹² Figure 43-30 shows the freedom from re-intervention in a large series of patients who were discharged after surgery for pulmonary stenosis between 1968 and 1980. Although late pulmonary incompetence commonly occurs, it appears well tolerated in the first decade after intervention. For those children with severe pulmonary incompetence, longer follow-up is necessary to determine if they develop or can be predicted to develop right

Figure 43-30 Freedom from reintervention after balloon dilation of the stenosed pulmonary valve. Ninety-five percent confidence intervals are indicated by the dotted lines. Numbers above the x-axis indicate children at risk. (Reproduced with permission from Garty Y, Veldtman G, Lee K, Benson L: Late outcomes after pulmonary valve balloon dilatation in neonates, infants and children. *J Invasive Cardiol* 2005;17:318–322.)

Figure 43-31 Pulmonary valvar gradients before, immediately after, and late after balloon pulmonary valvuloplasty. (Reproduced with permission from Sadr-Ameli MA, Sheikholeslami F, Firoozi I, Azarnik H: Late results of balloon pulmonary valvuloplasty in adults. *Am J Cardiol* 1998;82:398–400.)

ventricular decompensation and require replacement of the valve. Life-long follow-up is essential in children who have balloon dilation where pulmonary incompetence is present.

In adults, balloon dilation is similarly feasible.^{75,97,118} Long-term follow up has again been excellent, with minimal recurrence of pulmonary stenosis.^{77,119} Observed infundibular hypertrophy and tricuspid incompetence resolves over time.^{76,120} In a large study of 127 adults who underwent balloon dilation, immediate relief of pulmonary stenosis was achieved, with further reduction in the measured gradient from 6 to 8 years later (Fig. 43-31).⁷⁷

Surgery as Opposed to Balloon Dilation

In a large series of 170 patients in a single Dutch centre, direct comparison between surgical valvotomy and balloon dilation was possible.¹²¹ Surgical relief of pulmonary stenosis yielded lower long-term gradients and a longer freedom from reintervention (Fig. 43-32). Nevertheless, in

Figure 43-32 Kaplan-Meier curves illustrating freedom from reintervention in isolated pulmonary valve stenosis managed by surgery in 54 patients or balloon dilation in 92 patients. (Reproduced with permission from Peterson C, Schilthuis JJ, Dodge-Khatami A, et al: Comparative long-term results of surgery versus balloon valvuloplasty for pulmonary valve stenosis in infants and children. *Ann Thorac Surg* 2003;76:1078–1082.)

most centres, the less invasive, less expensive, and shorter hospital stay, would favour the routine use of balloon dilation over surgery for pulmonary stenosis.

RECOMMENDATIONS FOR LONG-TERM FOLLOW-UP

Once pulmonary stenosis has been treated, usually by balloon dilation, follow-up is mandatory. Many units will have their own protocols for follow up, laid down by senior members of the department. Without guidelines for follow-up however, it is likely that patients will be seen too often, and an unnecessary burden made on bookings. Algorithms for follow-up of many congenital cardiac malformations have been published,¹²² and are still relevant to current practice, subject to the up-to-date knowledge of the conditions described. In the case of pulmonary stenosis, the natural and unnatural history has been analysed in detail, and stratification of pathways for follow-up can be made based on physiological and anatomical considerations. For instance, Figure 43-33 presents an algorithm for follow-up of patients after treatment of pulmonary stenosis. This particular algorithm must be considered also with the emerging understanding that reintervention is prompted by the effects of pulmonary incompetence, and investigations to assess this must also be performed. In our own unit we would perform serial interval cardiac magnetic resonance imaging and cardiopulmonary exercise testing, to assess the effects of pulmonary incompetence on the anatomy, physiology and

functional state of the patient, and help to determine whether further interventions will be necessary.

Prophylaxis Against Endocarditis

Recent changes in the guidelines for the use of antibiotics to prevent infective endocarditis have been published.¹²³ Pulmonary stenosis is no longer considered to be a condition at high risk for endocarditis, either before or after balloon dilation. The current guidelines published by the American Heart Association recommend that repaired malformations with residual defects at the site of a prosthetic patch or prosthetic device, which may inhibit endothelialisation, be considered an indication for prophylaxis. The National Institute for Health and Clinical Excellence (NICE) of the United Kingdom has concluded that bacterial endocarditis prophylaxis is no longer indicated at all, unless there is existing infection at the operation site.

Recommendations for Exercise

Prior to Intervention

The recommendations for participation in exercise by patients with pulmonary stenosis is based on analysis of the known features of this disease by a taskforce of experts.¹²⁴ For these recommendations, the classification of exercise intensity is also important (Fig. 43-34).¹²⁵

Asymptomatic patients with untreated pulmonary stenosis with peak Doppler systolic gradients of less than

40 mm Hg are encouraged to live a normal life, including any competitive sports. Patients with gradients greater than 40 mm Hg can participate in low-intensity competition, but would usually be considered for intervention.

After Intervention for Pulmonary Stenosis

Following balloon dilation, the return to all competitive sports can be counselled in patients with no or mild residual stenosis, 2 to 4 weeks after the procedure. A longer interval of about 3 months is recommended after surgical relief. Those with residual moderate pulmonary stenosis, with a gradient of greater than 40 mm Hg, should follow the same recommendations as patients before interventions. Patients with severe pulmonary incompetence and right ventricular enlargement are recommended only to participate in exercise intensities to the first classes. Care to avoid blows to the chest would be prudent.¹²⁴

IMPLICATIONS IN ADULT LIFE

In previous years, and indeed in the present in countries with a less well developed system for healthcare, patients with pulmonary stenosis could survive without intervention into adult life. In a retrospective study of 20 years in a developing country, pulmonary stenosis accounted for 6% of unoperated adults presenting with congenitally malformed hearts.¹²⁶ Whilst there is little data in the literature, persistent and slowly progressive obstruction of the right ventricular outflow tract has led to anecdotal reports of severely debilitated patients with low cardiac output and right heart failure, particularly in developing countries. The same anecdotal reports show that, despite catastrophic existing morbidity, a successful intervention to relieve pulmonary stenosis can yield rapid and impressive improvements in clinical state.

Contraception

All advice concerning family planning and genetic counselling should be offered to patients on an individual

basis, based on their primary diagnosis, interventions and sequels.^{127–129} The patient will normally choose her own method of contraceptive, but the cardiologist may need to provide informed advice. In pulmonary stenosis, before or after intervention, the combined oral contraceptive pill is effective and well tolerated, for family planning and also for management of menstrual disorders. The risk of thromboembolism is low, but where a potential for right-to-left shunting exists at atrial level, the combined contraceptive pill is contra-indicated unless supplanted by anticoagulation. Progesterone-only pills, depot injections and implants are recommended where the combined oral contraceptive pill is contra-indicated. Preparations of progesterone alone are less effective, less convenient because they must be taken during a short daily time window, and may provoke depression, retention of fluid, or menstrual irregularities.

Intra-uterine devices have historically been associated with pelvic inflammatory disease, and have therefore generally been contra-indicated, especially in treated patients who need to observe precautions against endocarditis. The risk of endocarditis in patients with intra-uterine devices, nonetheless, is extremely low, and indeed an intra-uterine device releasing levonorgestrel has been approved for patients who have experienced pregnancy and remain at risk of endocarditis.¹³⁰ This device has similar efficacy to the oral combined contraceptive pill. Its local release of progesterone reduces the bleeding that is associated with other devices, albeit that more frequent replacement is necessary. The use of barrier methods remains extremely effective, especially in couples over 35 years old.

Pregnancy

Women with isolated pulmonary stenosis have been shown to tolerate pregnancy well, despite the gestational volume load as an additive effect to a potentially

hypertensive right ventricle.^{131–135} Vaginal delivery is tolerated well.¹³³ No deaths attributable to pulmonary stenosis have been reported. A meta-analysis of 2491 pregnancies over a 20-year period from 1985 in patients with congenital heart disease identified up to 127 women with pulmonary stenosis.¹³⁶ The rate of miscarriage was equivalent to that of the normal population. There were no reported cases of arrhythmia, heart failure, or endocarditis. The rates of premature delivery and stillbirth were comparable to the expected, and the babies were not growth retarded. Interestingly, there is an increased risk of non-cardiac maternal complications, such as hypertension, suffered by pregnant women with pulmonary stenosis.¹³²

Whilst pregnancy is usually well tolerated in women with pulmonary stenosis, symptomatic pulmonary valvar stenosis has been reported in pregnancy.^{135,137,138} Interventions during pregnancy, either surgical or by catheter intervention, were reported from as early as 1955.^{137,138}

Life Insurance, Mortgage Application and Employment

Pulmonary stenosis is a survivable lesion, and children with pulmonary stenosis are destined to reach adult life. The results of the second natural history study¹¹⁴ showed that 95.7% of the original cohort of 592 patients with pulmonary stenosis survived to 25 years. Almost none of the patients with mild pulmonary stenosis, that is a peak systolic gradient less than 25 mm Hg, required an operation at an older age, and the results of surgery for 283 patients with more severe disease were excellent. The employment record of these young adults was similar to that of the general population, with approximately 93% practising a profession, holding a job, or engaged in full-time education. It appears from these data that children with pulmonary stenosis develop into productive adults leading a high quality of life, becoming well educated and achieving employment. It is difficult to see how these patients can be classed as a burden to the health care or welfare systems.

Despite this, the impact of a congenitally malformed heart on an adult looking for life or health insurance has been the subject of a number of papers.^{139–144} Adult patients with pulmonary stenosis are represented in this group, although the total numbers are small. In general, for patients with congenitally malformed hearts, barriers are frequently encountered, mostly based on the diagnostic code of the patient from the point of view of the insurance company, rather than on a careful functional assessment and risk stratification by the cardiologist.¹⁴⁰ Indeed, a simple functional classification of the severity of disease into grades of mild, significant, or complex appears to have no effect on the success of life insurance or mortgage application outcomes.

A questionnaire-based study¹³⁹ addressed to providers of mortgages and insurance showed that normal premiums applied to patients with mitral prolapse without regurgitation, postoperative patients with a closed but previously patent arterial duct, and perhaps

surprisingly, subsequent to repair of coarctation. Other lesions, repaired or otherwise, including pulmonary stenosis, attracted a larger premium, or else were refused.¹³⁹ Some insurance companies allowed for cover to be arranged with exclusion of benefit for disorders relating to the congenital cardiac disease. Just over two-fifths of patients with congenitally malformed hearts who were initially refused an application for life insurance were successful in subsequent applications.¹⁴⁰ This may be explained by the applicants learning to place a different emphasis on their medical history, and submitting their applications to a different company. It is known that there are inconsistencies between companies offering insurance, which could be of benefit to adults with congenitally malformed hearts who are shopping around. There are no data published, however, on the rate of successful insurance claims, and whether such claims can be jeopardised when the medical history is de-emphasised in the application process.

Whilst the evidence suggests that pulmonary stenosis should be considered to be a mild, or certainly an easily treatable, disease, in practice these patients can be denied insurance, the facility to arrange a mortgage, or may only be accepted for insurance at an inflated rate. Inconsistencies found in insurance and job policies may be due to lack of knowledge or appropriate guidelines for the outcome of young adults with corrected and uncorrected congenital cardiac disease. A more evidence-based approach is emerging from insurance and mortgaging companies as long-term follow-up data becomes available, and a recent publication described three modern insurance companies which identified the risk for mortality in adults with pulmonary stenosis to be approximately equal to that of the general population.¹⁴⁴

Practical strategies may be of help to patients seeking insurance, or applying for mortgages or employment. Declined patients, or patients offered high premium rate insurance can approach different companies. The local Adult Congenital Heart Disease Patients Association may have information about insurers who have a track record of covering patients with congenitally malformed hearts. Group insurance policies available through employers or professional associations often do not require individual evaluation, and even adult patients with complex congenital heart disease may therefore obtain insurance benefits by this route. The avoidance of smoking, and the adoption of good health practices, will lower overall risk and further increase the chances of insurability. Patients who are followed up in a specialist adult congenital clinic, where management of congenital heart disease and its late complications are routinely practised, may receive a more favourable response from provider companies. Cardiologists in the field of adult congenital heart disease are in a position to make recommendations for individual patients with pulmonary stenosis, by presenting the history, supporting investigations, and furnishing insurers with up-to-date information on long-term follow-up where necessary.

Severe forms of pulmonary stenosis, or pulmonary atresia, are associated with a hypoplastic right ventricle. Yet there is evidence that the structures will grow if obstruction is relieved. The above article investigates the predictors of successful outcome to biventricular repair in patients with borderline right ventricles.
- Roos-Hesselink JW, Meijboom FJ, Spitaels SEC, et al: Long-term outcome after surgery for pulmonary stenosis (a longitudinal study of 22–33 years). *Eur Heart J* 2006;27:482–488.
- Peterson C, Schilthuis JJ, Dodge-Khatami A, et al: Comparative long-term results of surgery versus balloon valvuloplasty for pulmonary valve stenosis in infants and children. *Ann Thorac Surg* 2003;76:1078–1082.
These articles summarise the emerging long-term results of surgical and interventional treatments for pulmonary stenosis. At present, the freedom from intervention and maintenance of the relief of obstruction appears to be slightly better with surgical techniques. Balloon dilation of the pulmonary valve, however, is quicker, less invasive, and cheaper, and requires a shorter hospital stay. For this reason, balloon dilation remains the treatment of choice where the facility is available.

Congenital Anomalies of the Aortic Valve and Left Ventricular Outflow Tract

JEFFREY F. SMALLHORN, ANDREW N. REDINGTON, and ROBERT H. ANDERSON

Abnormalities of the left ventricular outflow tract may occur at the subvalvar level, valvar, supra-ventricular, or a combination thereof. These abnormalities commonly co-exist with other left-sided lesions, such as aortic coarctation or anomalies of the mitral valve, as well as forming an important component of the pathophysiology of more complex lesions, such as atrioventricular septal defect with common atrioventricular junction, or discordant ventriculo-arterial connections. The latter lesions will be discussed in detail in the relevant chapters, while in this chapter we will deal predominantly with anomalies of the left ventricular outflow tract as seen in the setting of concordant connections.

Within the whole overall group, three-quarters of patients have valvar stenosis, just under one-quarter have discrete subaortic stenosis, and the remaining small proportion have isolated supra-ventricular obstruction. Congenital aortic valvar stenosis itself accounts for 5% of all cardiac abnormalities.¹ If all those with bifoliate aortic valves are included, then this may be the commonest of all congenital abnormalities.^{2,3} It is difficult to know the true incidence, however, as congenitally abnormal aortic valves may not be recognised in childhood. Isolated stenosis as a presenting feature is more common than regurgitation, albeit that mixed lesions tend to occur over time, providing a challenge in management for the cardiologist.

MORPHOLOGY

The Normal Aortic Root

To understand the mechanisms of obstruction at any level within the left ventricular outflow tract, it is necessary first to understand the normal arrangement. Most accounts remain based on the concept of an aortic annulus, albeit this enigmatic feature is rarely described in consistent and satisfactory fashion.⁴ An annulus, if defined literally, is no more than a little ring. There are several rings within the normal aortic root, but none of them support the leaflets of the aortic valve. The essence of normality is that the leaflets are hinged within the arterial root in semilunar fashion (Fig. 44-1). The root itself is formed by interlocking of the aortic valvar sinuses and the supporting ventricular structures. Because of the interlocking, there is a marked discrepancy between the locus of the haemodynamic as opposed to the anatomic ventriculo-arterial junctions.⁵ The anatomical ventriculo-arterial junction is the line over which the fibroelastic walls of the aortic sinuses are

supported by the base of the left ventricle. This line does form a ring, with parts supported by the musculature of the ventricular septum and the parietal left ventricular wall and the remainder integrated within the fibrous curtain formed by the continuity between the leaflets of the aortic valve and the aortic, or anterior, leaflet of the mitral valve. The rightward extent of this area of fibrous continuity also incorporates the membranous part of the ventricular septum (see Fig. 44-1). The haemodynamic junction is marked by the semilunar lines of attachment of the aortic valvar leaflets (see Fig. 44-1). These semilunar hinges cross the ring at six points. As a result, three crescents of ventricular tissue, two muscular and one fibrous, are incorporated into the bases of the three aortic sinuses of Valsalva, while three fibrous triangles are incorporated at the distal extent of the ventricular outflow tract (Fig. 44-2).

The triangles extend distally to the level of the most distal attachment of the leaflets at the sinutubular junction. This structure is also an obvious ring, marking the line over which the expanded aortic sinuses become continuous

Figure 44-1 The normal aortic root has been opened through an incision in the aortic leaflet of the mitral valve (*stars*), and the leaflets of the aortic valve have been removed, showing the semilunar attachments of the three leaflets. The arrangement is such to incorporate crescents of ventricular myocardium at the base of the two leaflets attached within the coronary arterial sinuses (*arrows*). Triangles of fibrous tissue are incorporated into the outflow tract beneath the zones of apposition of the leaflets, with the membranous septum continuous with the triangle found beneath the zone of apposition between the right coronary and non-coronary leaflets of the valve.

Figure 44-2 The cartoon shows an idealised view of the bisected aortic root. Note how the semilunar attachments of the valvar leaflets, marking the haemodynamic ventriculo-arterial (VA) junction, cross the anatomic junction. See text for discussion.

with the tubular aorta. It marks the distal extent of the aortic root. Since it is unequivocally part of the root, and valvar competence depends on its integrity, it is somewhat illogical to describe stenosis at this level as being supra-valvar. It is also illogical to consider only the peripheral attachment of the valvar leaflets to the sinutubular junction as the commissures, as is currently the usual practise. Defined literally, a commissure is a zone of apposition. The zones of apposition between the normal valvar leaflets extend from the centre to the periphery of the valve (Fig. 44-3). All parts of these zones need to open without hindrance if the valve is to function properly. There is then one further ring within the outflow tract. This ring is constructed by joining together

Figure 44-3 The closed normal aortic valve has been photographed from its arterial aspect. Note that the zones of apposition (arrows) between the three leaflets, numbered 1 to 3, extend from their attachments at the sinutubular junction (stars) to the centre of the valvar orifice (circle). It is the entirety of these zones which represents the commissures although traditionally it is only the peripheral attachments that are credited with this title.

Figure 44-4 The cartoon shows the crown-like arrangement of the semilunar attachments of the leaflets of the aortic valve (red line), and how these extend from the sinutubular junction (blue ring) to the virtual basal ring (green ring) constructed by joining together the most proximal attachments of the leaflets within the left ventricle. Note that the semilunar attachments cross the anatomic ventriculo-arterial junction (yellow ring) six times.

the most proximal attachments of the three valvar leaflets within the left ventricle. This third ring, therefore, is a virtual structure (see Fig. 44-2), whereas the sinutubular junction and the anatomic ventriculo-arterial junctions are true anatomic entities. The entirety of the root, considered in three dimensions, takes the form of a crown (Fig. 44-4).

Annulus, therefore, does not seem the most obvious word the arrangement of the valvar leaflets within the root. The overall anatomic arrangement should also be taken into account when measurements are made of the outflow tract. When diagrams are made to illustrate the concept of measurement of the annulus, they often show a line drawn between proximal points of attachment of the leaflets (Fig. 44-5). Such diagrams must involve a degree of poetic licence on behalf of the observer, since the section illustrated can never cut the full diameter of the arterial root (Fig. 44-6).

All of this normal anatomy is of relevance when considering the structure of stenotic lesions within the outflow tract, particularly the fact that so-called supra-valvar stenosis involves tethering of the valvar leaflets at the level of the sinutubular junction.

Valvar Stenosis

The stenotic aortic valve is traditionally considered as showing unicuspid, bicuspid, or tricuspid patterns. Strictly speaking, a cusp is a point or elevation. Despite its popularity, it is not the ideal adjective to use when accounting for lesions of the abnormal valve. Our preference is to describe unifoliate, bifoliate, or trifoliate valves, according to the number of leaflets present. When making such descriptions, note should also be taken of the number of sinuses present, since almost always, even when the curtain of leaflet tissue is compartmented to produce less than three obvious sinuses, the curtain is still suspended within three obvious sinuses. In the presence, for example, of the so-called unifoliate and unicommisural valve (Fig. 44-7), with examination from the arterial aspect showing a solitary slit-like opening within the valvar curtain, examination from the ventricular side typically reveals three interleaflet triangles, albeit with two of them being vestigial.⁶

Figure 44-5 The cartoon shows an idealised arrangement of the aortic root, as frequently illustrated when demonstrating measurements for the aortic annulus. The dimension usually taken is the basal one, between the attachments of opposing leaflets (*blue double-headed arrow*). As shown in Figure 44-6, this dimension does not represent the widest diameter of the root. It is also important to take note of the dimensions at mid-sinusal level (*green double-headed arrow*), and at the sinutubular junction (*red double-headed arrow*).

Similarly, examination of the majority of the valves showing a bifoliate pattern of the leaflets (Fig. 44-8) reveals that they are formed within a trisinate prototype.^{7,8} In

Figure 44-6 The aortic valve shown in Figure 44-3 has been relabelled to show how measurements from the basal attachment of one leaflet to the most basal attachment of an adjacent leaflet can never cut the widest diameter of the valvar orifice (*red arrow*). The widest diameter would be represented by a measurement from the basal attachment of one leaflet to the opposite interleaflet triangle (*blue arrow*).

Figure 44-7 This photograph shows a unifoliate and unicommissural aortic valve. If examined from the ventricular aspect, vestigial interleaflet triangles would be found beneath the raphes in the apparently unifoliate valvar curtain. Note the tethering of the solitary zone of apposition at the sinutubular junction (*star*). (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

the unifoliate, or unicommissural, valve, typically seen in infants with so-called critical stenosis, the keyhole opening within the valvar curtain represents the only properly developed zone of apposition (see Fig. 44-7). This is usually formed between the left and non-coronary aortic leaflets, and points towards the mitral valve. The other leaflets are abnormally attached in annular fashion to the ventricular wall because of the vestigial nature of the putative zones of apposition between the other leaflets (Fig. 44-9). It is paradoxical, therefore, that valvar leaflets attached more closely in annular fashion are likely to be stenotic or regurgitant.

Figure 44-8 This picture shows a typical bifoliate aortic valve, with a raphe between the conjoined leaflet guarding the two aortic sinuses. Note the failure of formation of the interleaflet triangle beneath the raphe.

Figure 44-9 The cartoon shows the mechanism of formation of bifoliate or unifoliate aortic valves. There is failure of formation of the zone of apposition between the normal three leaflets of the valve, with failure of formation of the interleaflet triangles. In the bifoliate valve, it is one such zone of apposition that fails to form, but there is failure of formation of two zones when the valve is unifoliate and unicommissural.

Balloon dilation of such valves can do little more than open further the solitary zone of apposition, which is often tethered to the sinutubular junction (see Fig. 44-7). To produce a functioning trifoliate arrangement, it is necessary to create new triangles at the sites of the vestigial zones of apposition, with appropriate extension of the rudimentary and malformed leaflets. When seen in pathological archives, such valves are usually housed in small fibroelastic left ventricles, the heart itself often fulfilling many of the anatomic criteria for inclusion within the hypoplastic left heart syndrome (see Chapter 29).

The bifoliate aortic valve is also often described in association with critical aortic stenosis, albeit again formed on a trisinate prototype,⁸ but is also found in asymptomatic individuals. The leaflets themselves guard markedly dissimilar parts of the valvar orifice, with the larger leaflet formed by fusion of two putative leaflets, typically with a raphe showing the line of non-separation between them (see Fig. 44-8). The conjoint leaflet usually represents either fusion of the two coronary leaflets, or fusion of the right and non-coronary leaflets.⁷ Truly bisinuate and bifoliate valves do exist, but are rare, as are trisinate but bifoliate valves without evidence of a raphe between the presumed conjoint leaflets. Stenosis, when it occurs, is the result of fusion of the ends of the zone of apposition between the two leaflets. Bifoliate valves can also produce problems when they become incompetent due to prolapse, or if they provide a nidus for endocarditis. This is more likely to occur in adult life,⁹ and is rarely seen in childhood.

Stenosis producing problems in childhood can also be seen in the setting of a trifoliate valve, but more usually such valves are the seat of senile aortic calcification.¹⁰ When seen in childhood, the trifoliate valve, with dysplastic leaf-

lets, is encountered most frequently in infants. A stenotic trifoliate valve is rare in older children and adolescents unless they have undergone previous surgery.

Calcification of the aortic valve can develop from the third decade in all patients with mildly stenotic or bifoliate valves. It may start as early as the second decade, particularly if the valves are dysplastic and myxomatous. Most patients, however, present in later life with severe calcific aortic stenosis in what was initially no more than a mildly stenosed valve, or a valve with leaflets initially of markedly dissimilar size.¹⁰ The changes are more common in males than females. Patients with familial hypocholesterolaemia, progeria, and rickets develop calcification earlier, even if the aortic valve is only mildly abnormal. Patients with bifoliate valves producing minimal stenosis usually do not develop calcific stenosis until the sixth or seventh decade, but presence of moderate or severe stenosis in childhood can lead to quite heavy calcification in the third and fourth decades.

Subvalvar Stenosis

A variety of lesions can obstruct the subaortic outflow tract, with or without a co-existing ventricular septal defect. When there is an interventricular communication, then postero-caudal deviation of the muscular outlet septum is usually the most important lesion.¹¹ We discuss this lesion in the chapters devoted to ventricular septal defect and interruption of the aortic arch. Obstruction can also be produced by hypertrophy of the ventricular septum, as seen in hypertrophic cardiomyopathy (see Chapter 54), by anomalous tissue tags derived from the membranous septum or the leaflets of the atrioventricular valves, or by anomalous attachment of the tension apparatus of the left atrioventricular valve (Fig. 44-10). The last two lesions are also more likely to be found when there is a ventricular septal defect, or in the setting of common atrioventricular junction and deficient atrioventricular septation.

Figure 44-10 The cartoon shows the lesion producing obstruction of the morphologically left ventricular outflow tract. They produce aortic obstruction when the ventriculo-arterial connections are concordant, but subpulmonary obstruction in the setting of discordant ventriculo-arterial connections.

Figure 44-11 The aortic outflow tract has been opened to reveal a fibrous subaortic diaphragm. Note that the shelf-like lesion is also attached the aortic leaflet of the mitral valve (arrow). The aortic valve in this instance is normal.

When the ventricular septum is intact, the most significant lesion is the subvalvar fibrous ridge, or diaphragm (Fig. 44-11). This lesion has been described in many ways. Although often termed membranous, almost always the lesion is a firm fibrous shelf that encircles the outflow tract, often extending to be attached also to the aortic valvar leaflets. The septal component of the obstructive lesion overlies the left bundle branch as it crosses the ventricular septum. A discrete plane of cleavage almost always exists between the shelf and the musculature. Because of this, it can readily be stripped away by surgery (Fig. 44-12). Since the lesion is acquired, there is always the likelihood of recurrence. The position can vary with regard to its proximity to the valvar leaflets. If extensive, it can produce so-called tunnel

Figure 44-12 This fibrous diaphragm has been stripped away from the subaortic area by blunt dissection in a patient with discrete subaortic stenosis. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

stenosis. In florid cases, there is a marked abnormality in the alignment between the plane of the aortic root and the ventricular septum. This has been promoted as a potential cause of the malformation.¹¹

Supravalvar Aortic Stenosis

Supravalvar stenosis accounts for only 1% to 2% of cases of aortic stenosis seen in childhood. The condition may be familial, or may be associated with disorders of calcium metabolism, the so-called Williams syndrome.¹² The original description included failure to thrive, gastrointestinal upset, and mental retardation.¹³ The stenosis typically lies above the aortic sinuses and the coronary orifices, but incorporates the sinutubular junction (Fig. 44-13). The aortic sinuses themselves are enlarged and bulge laterally, while the aortic leaflets are often slightly thickened, and are disproportionately long in relation to the portion of sinutubular junction to which they are related. The coronary arteries, which take origin below the obstruction, are typically dilated, thick walled and ectatic. The possibility of orificial stenosis must be considered in these patients, nonetheless, as hoods, entrapment by leaflet tissue, and slit-like orifices may all lead to myocardial ischaemia. The nature of the narrowing is variable.¹⁴ The most common form is the hourglass variety with dilation of the distal aorta (see Fig. 44-13). There are also diffuse or tubular varieties, and, very rarely, a diaphragmatic or localised form. Irrespective of the type, the ascending aorta is usually grossly abnormal, with a thickened wall and disorganisation of the media. The narrowing and scarring are not exclusive to the aorta, and may be found in the iliac arteries, and in the abdominal and renal vessels.

Figure 44-13 The illustration shows the typical hourglass variant of so-called supravalvar aortic stenosis. As can be seen, the stenosis is at the level of the sinutubular junction (double-headed arrow), and involves the peripheral attachments of the zones of apposition between the valvar leaflets. Note the disproportionate length of the free edge of the leaflets relative to their supporting sinuses.

Figure 44-14 This specimen demonstrates an aorto–left ventricular tunnel. Note that the right coronary leaflet is suspended across the tunnel, and is also dysplastic.

Stenosis of the origin of the carotid and subclavian arteries, and less frequently the renal and mesenteric arteries, occurs in up to half the patients. The pulmonary circulation is also affected. In one-fifth of patients, there are multiple pulmonary arterial stenoses. These are mostly peripheral, being seen where the major vessels enter the lung. Consequently, supraaortic stenosis in most, but not all, patients is part of a more widespread abnormality of the cardiovascular system involving the major conducting arteries. Histological findings away from the site of the obstruction in the aorta show irregular thickening and branching of medial elastic fibres. This appearance has been dubbed a mosaic pattern,⁹ or higgledy-piggledy arteriopathy.¹⁵

Aortic Regurgitation

The stenotic aortic valve can also be regurgitant if the lesions producing stenosis also prevent the valvar leaflets coapting snugly during ventricular diastole. Isolated aortic regurgitation is much rarer than stenosis. If seen as an isolated finding in the neonatal period, then reflux through an aorto–left ventricular tunnel should be excluded. In this entity, one of the valvar leaflets is suspended across the ventriculo-arterial junction, so that blood is able to flow around the part that should be attached within the aortic root (Fig. 44-14). Regurgitation can also be produced by abnormalities of the leaflets, such as perforations produced by infectious endocarditis, or iatrogenic damage subsequent to balloon dilation. Dilation of the sinutubular junction will also prevent the valvar leaflets coapting, but this is an acquired rather than a congenital malformation (Fig. 44-15).

VALVAR AORTIC STENOSIS

Genetics

A bicuspid or bifoliate aortic valve occurs with a frequency of 1% to 2%, with a ratio of two males to each female. Familial clustering is recognised, as well as a common association with other left-sided obstructive lesions, such as aortic coarctation. Studies assessing first-degree relatives

Figure 44-15 In this heart, there has been acquired dilation of the sinutubular junction. This makes it impossible for the valvar leaflets to coapt during ventricular diastole, and results in gross aortic regurgitation.

by echocardiography have demonstrated an incidence of associated bicuspid or bifoliate aortic valve from 4.7% to 24%, with a higher incidence of other left-sided lesions in these families.^{15–19}

Critical Stenosis in the Neonate and Young Infant

Aortic stenosis is an important cause of heart failure in the neonate and young infant. It is being identified more frequently in the prenatal period and indeed, intervention has now been attempted in a group of fetuses with the lesion, with varying degrees of success.^{20,21} The main issue at this stage, as well as for those presenting in the newborn period, relates to the adequacy of the left ventricle to support the systemic circulation. Although many attempts have been made to address this problem, it still remains controversial as to when a left ventricle is too small, such that a biventricular repair is abandoned in favor of the Norwood protocol or cardiac transplantation.^{22,23} The problem is magnified by the fact that many patients have associated endocardial fibro-elastosis, mitral valvar abnormalities, or coarctation of the aorta in addition to the stenosis of the aortic valve. Hypoplasia of the aortic root and ascending aorta may also be seen, usually in those patients having borderline left ventricles. The pathogenesis is still poorly understood, but it most likely involves a primary left-sided insult, with secondary failure of growth of the left ventricle. This theory is supported by observation that left ventricular growth is seen following relief of the obstruction, even in those with borderline left ventricular volume at the time of first presentation.²¹ What is also clear is that the associated left-sided lesions have an ongoing impact on morbidity, even in those patients undergoing adequate relief of the obstruction.²¹

Pathophysiology in the Newborn Period

Why do neonates and young infants with critical aortic valve stenosis present in heart failure? In those patients with a left ventricle having borderline volume, there is associated right ventricular hypertension in addition to left ventricular

failure. The right ventricular dilation associated with the pulmonary hypertension has a further negative effect on left ventricular output, due to interactions between the ventricles. The ventricular septum bows into the left ventricle, further reducing its volume, and compounding the underlying problem. Tricuspid valvar regurgitation, if present, may also result in further dilation of the right ventricle. In other cases, where the left ventricular volume is adequate, failure is most likely due to a sudden increase in left ventricular afterload after birth as a result of reduced mass necessary to normalise mural myocardial stress.

Clinical Presentation and Physical Findings in the Neonate and Young Infant

The newborn or young infant presents in one of three ways. The first is with a picture similar to other forms of left-sided obstructive disease, such as aortic coarctation, interruption of the aortic arch, or hypoplastic left heart syndrome. These patients usually have a left ventricle with borderline volume, and become profoundly unwell subsequent to closure of the arterial duct. Clinically, they are in cardiac failure, or else present with cardiovascular collapse once they become acidotic. These neonates and young infants are tachypnoeic, tachycardic, and often cyanosed, due to the combination of pulmonary venous congestion and right-to-left shunting across the duct. Of note, the shunting through the oval foramen is from left to right. The physical examination reveals hepatomegaly, right ventricular enlargement, diffusely weak pulses, and frequently no murmur to suggest aortic valvar stenosis. An ejection click is uncommon. If they have right ventricular hypertension and failure, they may have a systolic murmur of tricuspid valvar regurgitation with an associated gallop. The second heart sound is invariably single. The patients are differentiated from those with aortic coarctation or interruption in that all the pulses are weak, as opposed to the right brachial and temporal pulses being palpable when the obstruction is within the aortic arch. The neonates with problems at valvar level are best described as having critical stenosis, since they are dependent on the patency of the arterial duct to sustain systemic cardiac output.

The second mode of presentation is seen in neonates or young infants with left-sided cardiac failure, but in the absence of acidosis, in other words, without ductal dependency. In this setting, the patients are tachypnoeic, have pulses that are usually low volume, and exhibit significantly less hepatomegaly. Auscultatory findings may reveal an ejection click heard along the lower left sternal border and at the apex, with a systolic ejection murmur that is heard in the same area, with radiation towards the upper right clavicular region. An associated systolic thrill is uncommon, as is the clinical detection of associated aortic regurgitation. While these patients usually have severe valvar stenosis, they are differentiated from those with the critical form by their lack of ductal dependency, and are often somewhat older at presentation. Consequently, as we will discuss, their outcomes tend to be better.

In the third situation, some patients are referred as neonates, or during the early period of infancy, for the evaluation of a systolic murmur. These patients do not have severe stenosis. They are more likely to have an ejection

click, with an associated systolic murmur, but no signs of congestive cardiac failure. Of note, the pulses are usually of normal volume.

Investigations in the Newborn and Young Infant

The Electrocardiogram

The tracings at this age may look very similar to those seen in aortic coarctation or interruption, or hypoplastic left heart syndrome. There is right ventricular dominance, with upright T waves in lead V1, and a paucity of left-sided forces. Of note, there may also be diffuse changes in the S-T/T waves related to diffuse subendocardial ischaemia. In other cases with a larger left ventricle there is still right ventricular dominance, but with better left-sided forces. In those without pulmonary hypertension, there is evidence of left ventricular hypertrophy with associated strain.

Chest Radiograph

This may demonstrate cardiomegaly, with evidence of right ventricular enlargement and associated pulmonary oedema.

Echocardiography

The echocardiographer is presented with a challenge, particularly in those cases where the left ventricle is relatively hypoplastic (Fig. 44-16). There is usually right ventricular dilation due to the associated pulmonary hypertension, as well as associated left ventricular dysfunction. The left atrium is dilated, and there is usually left-to-right shunting at high velocity across the oval foramen. Of note, this mean gradient can be used to obtain an indirect assessment of left atrial pressure, by adding the estimated mean right atrial pressure. Usually, if the inferior caval vein is non-pulsatile, then the mean right atrial pressure is greater than 10 mm Hg. An estimated systolic right ventricular pressure can be obtained from associated tricuspid valvar regurgitation, and the mean pulmonary arterial pressure via the arterial

Figure 44-16 This patient has critical aortic stenosis, produced by the so-called unicommissural valve. There is borderline left ventricular volume. LA, left atrium; LV, left ventricle; RV, right ventricle.

duct. There is usually some degree of hypoplasia of the left ventricle and aortic root. Although it is possible to measure the left ventricular volume by using the calculations in the biplane Simpson approach, this is probably an underestimation of the true volume, since the left ventricle has an abnormal shape due to the associated septal shift in cases with systemic right ventricular pressures. With newer three-dimensional echocardiographic techniques, or with magnetic resonance imaging, this limitation should be overcome. In some patients, nonetheless, the true left ventricular volume remains unknown until the stenosis is relieved.

The aortic valve is more likely to be unifoliate and unicommissural in those presenting with critical aortic valve stenosis (see Fig. 44-16). In some cases, the valve appears to be so dysplastic that the precise nature of the morphology of the leaflets is difficult to determine.

Associated supravalvar and subvalvar stenosis is uncommon, albeit that endocardial fibroelastosis, and pathology involving the mitral valve, are common associations. When the endocardial fibroelastosis is extensive, this is seen as a bright layer covering the entire endocardium. When it is more patchy, it may be difficult to detect by echocardiography, which is not a good method for assessing the character of the insonated tissues. Assessing the severity of any associated mitral valvar pathology may also be difficult upon presentation due to poor left ventricular function, which in itself results in immobility of the leaflets (Fig. 44-17). Similarly, Doppler echocardiography is of limited value in determining the severity of the stenosis in the presence of a dilated ventricle with poor function. Despite this, if there is turbulence across the valve, then it most likely represents stenosis, rather than a dilated cardiomyopathy with an associated abnormality of the aortic valve, or more

commonly aortic coarctation associated with a bifoliate aortic valve. Problems are created in the patients with moderate aortic valvar stenosis, coarctation of the aorta, and poor left ventricular function. In this setting, it usual first to deal with the coarctation, followed by reassessment of the aortic valve.

Magnetic Resonance Imaging

More recently this technique has been employed by some to gain a more reliable assessment of left ventricular volume, though whether such measurements are accurate remains unclear.

Management of Critical Aortic Valvar Stenosis

In this current era, management starts in the prenatal period. There has been an interest in intervening prenatally in the fetus with aortic valvar stenosis, in an attempt to promote left ventricular growth. Although first described more than 10 years ago, more recently this approach has been extensively examined by the group working at Boston Children's Hospital, who now have significant experience with this technique.^{20,21} The procedure involves paralyzing the fetus, and then either directly via the maternal abdomen, or through the exposed uterus, an attempt is made percutaneously to dilate the aortic valve with a balloon. The results have been variable, but biventricular repair has been achieved in some who previously would have been destined to undergo functionally univentricular palliation. There is, however, mortality and morbidity associated with the procedure. It remains a matter of debate as to whether the long-term outcome of the borderline biventricular repair is better than the alternative palliation culminating in conversion to the Fontan circulation.

For the neonate or young infant where the left ventricle is deemed adequate to support the systemic circulation, balloon dilation of the left ventricular outflow tract has become the mainstay of initial therapy. With follow-up it is clear that the early results are comparable to earlier surgical outcomes, though there appears to be a higher incidence of aortic regurgitation when the valve is dilated with a balloon.²⁴⁻²⁸ In the majority of patients, such regurgitation is well tolerated, at least for the first few years of life. Interventional cardiologists are very cautious not to oversize the balloon, since this introduces a greater chance of producing substantial regurgitation, which itself then requires further intervention. Should regurgitation ensue, then a neonatal Ross procedure is the treatment of choice.²⁹⁻³¹ In general, this approach has a high rate of success, with the results in the early and medium terms being encouraging.

Those patients who present during the neonatal period or early infancy without cardiac failure present another challenge. In comparison to their older counterparts, the modest gradient seen across the valve in the early phase may progress fairly rapidly during the first one to two years of life, necessitating closer follow-up in this population.³²⁻³⁵ If faced with this dilemma, it is advisable to repeat the echocardiogram every 2 to 3 months, until reassured that the rise in gradient is not rapidly progressive. A similar issue arises in those cases with combined aortic valvar stenosis and coarctation of the aorta. In this setting, the downstream obstruction results in an underestimation of the severity of the valvar stenosis, even in the presence of reasonable left ventricular function.

Figure 44-17 In this patient with critical aortic stenosis, there is also significant mitral valvar regurgitation. Note the adequate size of the left ventricle. Doppler interrogation of the pulmonary valvar regurgitation demonstrates high pulmonary arterial pressure. In addition, the Doppler trace of the pulmonary venous flow shows a reduced S wave (arrow), indicating a high left atrial pressure. LA, left atrium; LV, left ventricle.

Again, close follow-up is warranted once the coarctation has been addressed.

Outlook in the Longer Term

Presentation during the neonatal period represents the severe end of the spectrum of this disease, with those presenting earliest usually having the most severe lesions. When the predominant lesion is stenosis, these children are likely to require further intervention in the future, in the form of further balloon dilation, while those with significant regurgitation will likely require replacement of the valve. Associated lesions such as endocardial fibroelastosis and mitral valvar disease, add to the morbidity in this group. The presence of significant endocardial fibroelastosis results in diastolic dysfunction and left atrial hypertension. To address this, some groups have attempted surgically to remove the thick peel of endocardial fibroelastosis, attempting to improve both left ventricular growth and diastolic function. The results of this strategy over the long term remain to be seen, and it has not yet been widely adopted.

AORTIC VALVAR DISEASE IN THE OLDER CHILD

Isolated Bifoliate, or Bicuspid, Aortic Valve

These children are asymptomatic. They typically present when the lesion is detected during routine evaluation, or after an episode of bacterial endocarditis. The findings at clinical examination consist of a high pitched ejection click that is heard at the lower left sternal border and at the apex, with some increase in intensity during expiration. The second heart sound is usually normal. An evaluation of the femoral pulses is essential to exclude associated aortic coarctation. Investigations reveal a normal electrocardiogram, chest radiograph, with the diagnosis being confirmed

Figure 44-18 This image shows a bifoliate, or bicuspid, aortic valve with no associated aortic regurgitation. Note the thin leaflets and the horizontal line of closure. AO, aorta; LV, left ventricle.

Figure 44-19 This bifoliate aortic valve is mildly regurgitant. Note the vestigial interleaflet triangle. AO, aorta; LA, left atrium; LV, left ventricle.

on echocardiography. Even though echocardiography is unnecessary to make the diagnosis, it is an essential part of the management in those cases with an asymptomatic and isolated bifoliate aortic valve (Figs. 44-18 and 44-19).

This relates to the fact that dilation of the aortic root can be seen in patients who do not develop stenosis or regurgitation early on in life. It is now recognised that these individuals have structural abnormalities of their aortic wall, which places them at higher risk for ongoing dilation of the aortic root, and eventual dissection.^{36,37} Whether this can be prevented or delayed by β -blockade is still unclear. Because of this, these individuals should have an echocardiogram every couple of years to track the dimensions of their aortic roots, comparing the results to age-matched controls. This follow-up should continue into adult life.

Cases with Clinical Evidence of Aortic Valvar Stenosis

In this setting, the patient is usually referred for the evaluation of a heart murmur. It is important to distinguish murmurs emanating from the aortic valve from those produced by pulmonary valvar stenosis, which may be confusing to the untrained ear. The patients with aortic lesions are usually asymptomatic, as they have preserved left ventricular systolic function, the diastolic abnormalities not being of sufficient severity to cause symptoms. Congestive cardiac failure is rare, as with time the patients are able to stabilise their left ventricular mural stress by increasing mass. The physical examination depends on the severity of the stenosis. The peripheral pulses are usually normal in those patients with mild, and even moderate, stenosis. Those with significant stenosis have low volume, or plateau pulses. In some patients, the right carotid and brachial pulses have a rapid upstroke when compared to the left-sided pulses. This is due to transmission of the impulse towards the brachiocephalic artery. A systolic thrill may be felt in the right infraclavicular region, along the left sternal border in some, as well as over the carotid artery or suprasternal notch. The first heart sound is normal, and is frequently followed by a high pitched ejection click, which is best heard at the lower left sternal border, and may be maximal at the apex. This latter finding differentiates it from a click produced by the pulmonary valve, which is often lower pitched, and heard along the upper left sternal border. The second heart sound is usually normal, and the narrowly split, single or reversed splitting that may be identified in adults is uncommon in children. The reversed splitting occurs due to the significant inspiratory delay in

the opening of the aortic valve in those with reduced left ventricular function. Clinical cardiomegaly is uncommon in the absence of associated aortic regurgitation, as the left ventricular internal dimension is not increased.

Although sudden death is more common in aortic stenosis than in other forms of congenital cardiac disease, the risk is small.³⁸ The danger of sudden death is confined to those with severe stenosis. The exact cause of the sudden death is uncertain, but ventricular arrhythmias following myocardial ischaemia may be the underlying problem.

Although syncope may occur after extreme effort with mild or moderate obstruction, it is usually found only in those with severe stenosis. It results from the inability of the left ventricle to increase its output appropriately with exercise. Auscultation reveals the click, and a long ejection systolic murmur with maximum intensity late in systole. Diastolic murmurs are heard if there is associated aortic regurgitation.

Investigations

Electrocardiogram

This shows a variable degree of left ventricular hypertrophy depending on the degree of severity.³⁹ Left ventricular voltages increase, with upright T waves which, with increased severity, many invert with associated depression of the ST segment in the infero-lateral leads. The presence of Q waves in the left ventricular leads is uncommon, and may suggest associated lesions. The electrical axis is usually normal.

Chest Radiograph

In the current era, it is probably unnecessary to request this investigation in a newly diagnosed case of aortic valvar stenosis. Dilations of the aortic root, and calcification in later years, however, are the features that might be identified if the procedure is performed.

Exercise Testing

The role and advisability of exercise testing remain a subject of debate. In those with mild and moderate stenosis, it is safe, but the interpretation of abnormalities is difficult, and they rarely guide treatment. The role of new depression of the ST segments on exercise is also uncertain.⁴⁰ While usually associated with higher resting gradients, and presumably reflecting a degree of exercise-induced subendocardial ischaemia, its relevance to decision-making remains poorly defined.

Echocardiography

This is currently the mainstay for the process of decision-making in children. The valvar morphology is best seen from the parasternal short-axis view (see Fig. 44-18), where the number of leaflets and their zones of apposition can be seen.⁴¹ The parasternal long-axis view is currently favoured for measurement of the aortic root, from its left ventricular origin to the sinutubular junction (see Fig. 44-19). From a slightly more rightward location, the more distal ascending aorta can be imaged and measured. Unlike our adult counterparts, assessment of the absolute gradient is used as the basis for the timing of intervention, rather than the area of the orifice of the stenotic valve. This is for two reasons. First, outside the neonatal period and early infancy, the majority of children and adolescents have preserved, and even supernormal, left ventricular systolic function. This differs from adults, who may have mixed aortic valvar

disease, with associated left ventricular dysfunction which invalidates the assessment of the pure gradient. In this setting, calculation of the area of the aortic valvar orifice is more reliable, using a modified Gorlin formula. Direct measurement of the area of the stenotic orifice by planimetry from the cross sectional echocardiogram is difficult because of its eccentric nature and the thickening of the leaflets. The continuity equation offers a theoretically satisfying method for measuring valvar area using echocardiography and Doppler.⁴² Stroke volume in the left ventricular outflow tract is the same as that across the aortic valvar orifice. Consequently, the area of the valvar orifice can be calculated from:

$$A_2 = \frac{A_1 V_1}{V_2}$$

where A₂ is the area of the aortic valve, A₁ is the subaortic area, V₂ is the aortic valvar velocity time integral, and V₁ is the subaortic velocity time integral. Although its protagonists stress the usefulness of this method, it has inherent practical problems, and is not of proven clinical value in children.

The major source of error in using the continuity theorem lies in the difficulty in measuring accurately the left ventricular outflow tract. Doppler ultrasound seems to provide a workable method for assessing severity of stenosis. This is of particular importance in children, where the left ventricular outflow tract is smaller than in the adult, thus increasing the error, as the measurement has to be squared in the calculation. The other more practical issue is that, in the previous studies of natural history, calculations were based on peak-to-peak gradients derived at catheterisation, and not on valvar area. In general, for fully grown adolescents and adults, an area of the stenotic orifice of less than 1 cm² indicates significant stenosis, whereas for children this would vary considerably, due to the different ages and body surface area.

Measurement of the gradient across the aortic valve using continuous wave Doppler, therefore, is the current mainstay of timing for intervention, in conjunction with the presence of left ventricular hypertrophy. The peak instantaneous gradient across the left ventricular outflow tract, obtained from a combination of apical, suprasternal, and right parasternal locations, is also frequently used. The problem with this approach is that there is a poor correlation between the maximal instantaneous gradient and the peak-to-peak gradient as derived from catheterisation at lower gradients. This relates to the time difference between these events, with the peak-to-peak gradient occurring later than the maximal peak instantaneous gradient (Fig. 44-20).

Of note, the peak-to-peak gradient as assessed by haemodynamics is a non-physiological event, whereas the peak instantaneous gradient is physiological (Fig. 44-21). The other issue that compounds the problem is the concept of recovery of pressure. When stenosis is discrete, a jet rapidly loses its momentum, just distal to the obstruction, with some recovery of pressure downstream.⁴³ Doppler techniques measure the instantaneous drop in pressure across the valve, while at catheterisation the end of the catheter is invariably more distal to the obstruction. At that more distal location, there has already been some recovery of pressure, thus reducing the calculated gradient in pressure

Figure 44-20 The tracing shows a gradient across the outflow tract demonstrated by continuous wave Doppler interrogation. This provides a combination of peak instantaneous and mean Doppler gradients.

Figure 44-21 This pressure trace shows the difference between peak-to-peak and peak instantaneous measurements of pressure by catheterisation. Note that the peak-to-peak gradient is lower.

from immediately beyond the valve to the more distal site. As the stenosis becomes more severe, the aortic pressure trace shows a greater plateau, which results in an improved correlation between peak-to-peak and peak instantaneous gradients. To help overcome some of these limitations, it is possible to determine the mean aortic valvar gradient by planimetry of the Doppler spectral trace, with excellent correlation with results derived at catheterisation.

Other authors have provided regression equations that calculate a peak-to-peak gradient from the mean Doppler gradient in conjunction with the pulse pressure.⁴⁴ This is attractive, since it helps to accommodate those patients with mixed stenosis and regurgitation. A wide pulse pressure

from aortic regurgitation, for example, reduces the calculated peak-to-peak gradients.

How does the clinician decide on the timing for intervention? In this current era, intervention for isolated aortic stenosis in children is invariably by balloon dilation. The timing varies from centre to centre, depending on the criteria used. It would be fair to state that intervention now takes place much earlier than was the case when cardiac catheterisation alone was used to establish the severity of the stenosis. In general, if there is a peak instantaneous gradient of more than 60 to 70 mm Hg, in the presence of left ventricular hypertrophy, then intervention is justified.

Cardiac Catheterisation

This is usually no longer performed to make the diagnosis, or to guide decision-making, but rather as an intervention when the decision has been made to treat.^{45,46} The procedure may be performed antegradely in some infants, but more usually retrogradely. In older children, stripping of the balloon back and forth across the valve in diastole and systole is thought to contribute to valvar damage, and can be avoided by rapid ventricular pacing via a temporary wire placed in the right ventricle, thus lowering cardiac output and stroke volume. Oversizing of the balloon is avoided, as this results in a higher incidence of post-procedural valvar regurgitation. With current catheters having low profiles, the incidence of femoral arterial trauma is less common, though is still an ongoing morbidity, particularly in smaller children. In general, the decision to dilate the valve is made prior to commencing the catheterisation, as the estimated peak-to-peak gradient is always lower under general anaesthesia.

Surgical Intervention

In the more recent era, surgical aortic valvotomy is rarely used as the primary mode of treatment in children and young adolescents with aortic valvar stenosis. Although the results of surgical intervention are comparable to those achieved by balloon dilation, the latter technique can be performed as an outpatient with a relatively low morbidity, even in the neonatal period.²⁴⁻²⁹

AORTIC REGURGITATION

Pathophysiology

There is an increase in both preload and afterload when the aortic valve is regurgitant. While the cause of the increased preload is obvious, the change in afterload is related to the law of Laplace, which states that mural tension is related to the product of pressure and dimension divided by mural thickness. This is the basis of the equation that is used to calculate mural stress or afterload. As the left ventricular dimension increases with aortic regurgitation, so does the mural thickness in an attempt to normalise mural stress or afterload. With increasing severity of aortic regurgitation, the left ventricular hypertrophy cannot keep up with the dilation, resulting in an increase in left ventricular afterload. In general the left ventricular filling pressures are usually normal, as the left ventricle acts as a very compliant pump. The degree of regurgitation decreases with exercise as the heart rate increases and the peripheral resistance falls. As a result, there is an increase in cardiac output without a significant increase in end-diastolic pressure or volume.

Clinical Features

Symptomatic aortic regurgitation is very uncommon during infancy and childhood. Despite this, asymptomatic aortic regurgitation is encountered in those with a congenitally abnormal aortic valve, or as an acquired lesion in patients with associated subaortic stenosis, ventricular septal defect and aortic valvar prolapse, or as a result of infective endocarditis. Symptoms from chronic regurgitation result from left ventricular dysfunction, with exertional dyspnoea, pulmonary oedema, and occasionally heart failure. Angina is uncommon unless there is an abnormality of the coronary arterial orifices.

Physical Examination

Except in the presence of cardiac failure, the pulse pressure reflects the degree of aortic regurgitation. The carotid arterial pulsations are usually easily visible in those with severe regurgitation. The head of the patient may nod in time with systole, a feature called the sign of de Musset, who in this instance was the patient. The pulses have an abrupt upstroke with rapid collapse, the water hammer pulse of Watson, or Corrigan's pulse. The praecordial examination is normal in mild regurgitation, albeit that as the severity increases, and the left ventricle dilates, there is evidence of a hyperdynamic and laterally displaced apical impulse. In cases with a dilated aortic root, a diastolic thrill may be present, while those with significant regurgitation may have a systolic thrill due to the increased stroke volume.

Auscultation reveals an early diastolic murmur, which is heard along the upper left sternal border, being accentuated when the patient is sitting up. As well, interventions that increase the systolic pressure, such as squatting, also accentuate the murmur of aortic insufficiency. A systolic ejection murmur can also be heard, and is related to the increased stroke volume across the left ventricular outflow tract. A mid-diastolic murmur at the apex, the Austin–Flint murmur, may be heard. It is related to the narrowing of the mitral orifice due to a sudden rise in the left ventricular end-diastolic pressure. In cases with left ventricular dysfunction, it may also be possible to hear a third sound.

Investigations

Electrocardiogram

The electrocardiographic changes depend on severity and duration of regurgitation. Voltages in the left ventricular leads increase, with deep S waves in leads V1, and R waves in leads I, AVL, V5 and V6. The T waves usually remain tall and upright until left ventricular dysfunction has occurred, when depression and inversion of the ST segment is present. Unless there is disease of the aortic root involving the coronary arterial orifices, Q waves due to dilation of the cavity precede the tall R waves in the left ventricular leads. Once regurgitation is severe and long established, so-called P mitrale is sometimes seen on the electrocardiogram.

The Chest Radiograph

The chest radiograph shows cardiomegaly, with left atrial dilation and prominence of the ascending aorta and aortic knuckle. The mildest lesions are associated with a normal chest radiograph.

Figure 44-22 The parasternal long-axis view demonstrates thickened leaflets of the regurgitant aortic valve. The arrow points to the site for measurement of the ratio of width of the jet to the aorta. AO, aorta; LA, left atrium; LV, left ventricle.

Echocardiography

This technique is used to detect the presence and severity of aortic regurgitation, in conjunction with an evaluation of left ventricular function. The morphology of the aortic valve can be assessed in the praecordial short-axis view, as well as the relationship of the leaflets to the coronary arterial orifices. The presence of associated left-sided pathology can be determined, as well as an associated ventricular septal defect when this is the mechanism for regurgitation.

The severity of the aortic regurgitation is best assessed by Doppler echocardiography. Colour flow Doppler is useful for providing a semiquantitative measurement of degree, as the size of the jet (Fig. 44-22) just distal to the leaflets has a reasonable correlation with regurgitant volume.^{47,48} Other measurements to be made are the pressure half-time of aortic regurgitation, and the degree of reversal of diastolic flow in the descending aorta at the level of the diaphragm. The shorter the pressure half-time, the more significant is the regurgitation. The problem in children is that any measurement of time is related to the heart rate, which limits its usefulness. As well, if there is associated aortic regurgitation and left ventricular diastolic dysfunction, the pressure half-time may be short due to the raised end-diastolic pressure. Reversal of aortic holodiastolic flow at the level of the diaphragm is consistent with significant regurgitation, but cannot be used in isolation to assess severity (Fig. 44-23). Quantitative methods to assess true regurgitant volume, or the effective area of the regurgitant orifice, can be used in adolescents,⁴⁷ but in small children the standard error is probably too great for this technique to be of practical value.

An assessment of left ventricular size and function is best achieved through the use of M-mode and cross sectional echocardiography. M-mode echocardiography is very good for assessing end-diastolic and end-systolic dimensions, but not for ejection fraction. Fractional shortening, along with Vcf and Vcfc, can be used to follow left ventricular function, as they are not so dependent on shape. For an accurate calculation of ejection fraction, either the biplane Simpson's rule, or three-dimensional echocardiographic assessment of left ventricular function, can be used. These methods allow for the changes in shape that occur with left ventricular dilation.

Magnetic Resonance Imaging

Although this technique is used less frequently in the evaluation of aortic regurgitation, it provides quantitative measurement of the regurgitant fraction that is comparable to echocardiographic data.⁴⁹ As well, this technique would be advantageous in those individuals with a poor ultrasound window.

Figure 44-23 This group of images is from a patient with combined valvar and subvalvar stenosis (arrow) and associated significant aortic regurgitation. Note the holodiastolic reversal of flow in the abdominal aorta, shown in lower right image, and the short pressure half time seen in the upper right panel. The lower left panel shows the anatomy of the regurgitant jet, revealing the PISA, the vena contracta, and the proximal and distal jets. LA, left atrium; LV, left ventricle.

Cardiac Catheterisation

Cardiac catheterisation and angiocardiology play a very small role in the evaluation of the patient with aortic regurgitation, particularly as associated coronary arterial disease is exceedingly rare in this population. Angiographic grading of regurgitation is subjective at best, and left ventricular function is better evaluated by either echocardiography or magnetic resonance imaging.

Timing of Intervention

This is a difficult enough problem in adults, so it presents even more of a challenge in the younger population. In adults, if there is evidence of left ventricular dysfunction with an ejection fraction of less than 55%, then replacement of the valve is indicated.⁵⁰⁻⁵² The problem is more challenging in patients with preserved left ventricular ejection fraction. Part of the problem is that left ventricular ejection fraction is significantly dependent on afterload, being somewhat less influenced by preload. As a result, exercise assessment of left ventricular function, as well as tests that take end-systolic stress into consideration, has been proposed. When using resting measurements, a left ventricular internal dimension in systole equal to or greater than 55 mm, or 25 mm/m² has been proposed to identify those patients who have improved survival after valvar replacement. At present, comparable data is not available for children. Consequently, many rely on the presence of symptoms, or the development of signs of uncompensated left ventricular dilation, such as a rising end-systolic volume index or worsening ejection fraction, as indications for intervention in children and adolescents.

Medical Treatment

Although afterload reduction has been disappointing in patients with mitral valvar regurgitation, there have been some encouraging results in patients with aortic valvar regurgitation. The theory behind this has been to reduce left ventricular volume, regurgitant volume and afterload, in an attempt to preserve left ventricular function and reduce left ventricular mass. Despite these encouraging results, some recent data has disputed this approach, failing to demonstrate any benefit in the long term with regards to delaying time to surgical intervention.⁵³

Surgical Intervention

Once the decision has been made to treat a patient with aortic regurgitation, the decision must be made as to whether to replace the valve with a mechanical prosthesis, or to proceed to the Ross procedure. The former approach is challenging in young patients, due to problems with mismatch between the aortic root and the available prostheses, so the Ross procedure has been favoured in this population.^{30,31} This latter approach also has the added advantage of not requiring anticoagulation, which is a significant issue in the active child and adolescent. The recent results of the Ross procedure are encouraging even for the smallest patient, albeit that follow-up in the medium term has identified the problem of progressive aortic root dilation and regurgitation, particularly in those having bifoliate aortic valves.^{54,55} Although repair using pericardial extension of the leaflets has been used, the results are still somewhat disappointing.^{56,57} The exception to this has been in stenotic valves that have been torn following balloon dilation, where the results of subsequent surgical repair are encouraging.⁵⁸

AORTIC-LEFT VENTRICULAR TUNNEL

Although described as a tunnel, implying that it has length and two openings, this lesion is more correctly described as a defect. The defect is produced by unhinging of the leaflet guarding the right coronary aortic sinus (see Fig. 44-14), and is usually separate from the right coronary arterial orifice,⁵⁹ although the artery can take origin from the aortic end of the defect. Free reflux occurs from the aorta to the left ventricle, producing aneurysmal dilation of the right aortic sinus, dilation of the left ventricle, and widening of the ascending aorta. In time, the whole aortic root becomes dilated, with secondary valvar regurgitation. The lesion may be associated with aortic valvar stenosis, or abnormalities of the origins of the coronary arteries. It should be considered as a differential diagnosis in any child who presents with severe aortic regurgitation in infancy or in the newborn period. The tunnel can produce cardiac failure in the infant, but more often the patient presents with well-compensated and impressive aortic regurgitation and dilation, with hypertrophy of the left ventricle. The physical signs suggest severe aortic regurgitation, with loud aortic valvar closure and a systolic thrill at the left and right sternal edges, but the murmur tends to be continuous. The dilated ascending aorta may be palpable on the right side of the chest. On the chest radiograph, the dilated right aortic sinus may protrude on to the left heart border, and the aorta is enlarged. Diagnosis can be made by cross sectional

Figure 44-24 These echocardiographic images show an aortic-left ventricular tunnel. Note the aortic regurgitation arising above the valvar leaflets. AO, aorta; LV, left ventricle; T, tunnel.

echocardiography, and in the majority of cases angiocardiology is unnecessary. In the older child, it is easy to confuse the abnormality with rupture of the sinus of Valsalva (Fig. 44-24). Surgical repair is carried out as soon as the diagnosis is made in the hope of preventing valvar regurgitation. Usually, however, the regurgitation persists despite closure, and replacement of the aortic valve may be necessary.

SUPRAVALVAR AORTIC STENOSIS

Patients with isolated supravalar stenosis rarely present in the neonatal period. More usually, infants and children present in a similar way to those with valvar stenosis, and indeed some degree of supravalar stenosis may be present in those with predominantly valvar stenosis. Particularly when associated with familial forms, or overt Williams syndrome, supravalar stenosis may be rapidly progressive, and careful follow-up is required in all such patients. The physical signs are also similar to those encountered with valvar stenosis as described above, with the exception that an ejection click is rarely heard on auscultation. In those with Williams syndrome, there will be the typical facial appearance, but careful examination of the entire vascular system should be performed to exclude significant stenosis of the thoracic or abdominal aorta or their branches. Careful evaluation of blood pressures in the limbs, and auscultation of the abdomen, is an essential part of the clinical examination.

Investigations

Electrocardiogram

This will show left ventricular hypertrophy with or without strain. As mentioned earlier, stenosis of the coronary arterial orifices is not uncommon, and repolarisation

Figure 44-25 This panel demonstrates supravalar aortic stenosis, in association with hypoplasia of the ascending aorta. Note the colour Doppler turbulence starts in the supravalar region. AO, aorta; LA, left atrium; LV, left ventricle.

abnormalities, such as inversion of the T waves or changes in the ST segments out of proportion to the degree of stenosis, should raise the suspicion of impaired coronary arterial perfusion.

Chest Radiograph

This is rarely diagnostic. Unlike valvar stenosis, however, the ascending aorta is never dilated.

Echocardiography

This is the diagnostic test of choice, but the sonographer must be alert to the possibility, otherwise a spurious diagnosis of valvar stenosis is easily made. The aortic valvar leaflets are usually thin and mobile, but are tethered at the sinutubular junction, exaggerating the usual difference in calibre between the sinuses and the diameter of the junction itself. Consequently, Doppler studies will demonstrate accelerated flow and turbulence beginning at this level (Fig. 44-25). Because the diameter of the ascending aorta is often also small, there is a tendency for spectral Doppler to overestimate the gradient measured invasively, and decision-making on the basis of Doppler-derived gradients is difficult. As mentioned above, no examination is complete without detailed assessment of the anatomy of the coronary arterial orifices and flow, as well as examination of all the branches of the aortic arch and abdominal vessels, the latter usually requiring specialist abdominal ultrasonic studies.

Treatment

There is no role for transcatheter intervention in the treatment of the supravalar stenosis itself, although treatment of thoracic and abdominal aortic stenosis and stenosis of the branches may be amenable to balloon dilation and stenting. Thus, surgical repair is the mainstay of treatment, and usually involves insertion of a patch or patches across the sinutubular junction, with variable extension into the ascending aorta and aortic arch. The results are good, and reoperation is rare.

SUBVALVAR AORTIC STENOSIS

As described in our section devoted to morphology, a variety of lesions can obstruct the subaortic outflow tract, with or without a co-existing ventricular septal defect. When there is an interventricular communication, then postero-cephalad deviation of the muscular outlet septum is usually the most important lesion. This is considered in Chapter 28. Obstruction can also be

Figure 44-26 The image shows fibromuscular subaortic stenosis (arrows). Note the distance of the fibromuscular ridge from the leaflets of the valve. There is extension of the shelf onto the aortic leaflet of the mitral leaflet. The colour Doppler trace shows that the turbulence start at the level of the subaortic obstruction. AO, aorta; LA, left atrium; LV, left ventricle.

produced by hypertrophy of the ventricular septum, as seen in hypertrophic cardiomyopathy (see Chapter 54), by anomalous tissue tags derived from the membranous septum or the leaflets of the atrioventricular valves, or by anomalous attachment of the tension apparatus of the left atrioventricular valve (see Fig. 44-10). The last two are more likely to be found when there is also a ventricular septal defect, or in the setting of common atrioventricular junction and deficient atrioventricular septation.

When the ventricular septum is intact, the most significant lesion is the so-called subvalvar ridge (Fig. 44-26). This lesion has been described in many ways, and has been the subject of multiple investigations. Although often termed membranous, almost always the lesion is a firm fibrous and muscular shelf that encircles the outflow tract in diaphragmatic fashion (see Figs. 44-11 and 44-26). The ridge often extends to be attached to the aortic valvar leaflets themselves, and overlies the left bundle branch as it crosses the ventricular septum. The position of the shelf can vary with regard to its proximity to the valvar leaflets. If extensive, it can produce so-called tunnel stenosis. In florid cases, there is a marked abnormality in the alignment between the plane of the aortic root and the ventricular septum. This has been promoted as a potential cause of the malformation, although whether this is cause or effect is far from clear. Nonetheless, subaortic ridges are not congenital in that the vast majority are acquired after birth, albeit sometimes in the setting of other congenital cardiac defects.

Clinical Features

Symptoms are uncommon with this subvalvar stenosis, even when the narrowing is severe. Occasionally, however, syncope and presyncope may occur. If undiagnosed and presenting in middle life, congestive cardiac failure, dyspnoea and syncope have been described.

The physical signs are similar to aortic valvar stenosis with a carotid thrill, a displaced and forceful left ventricular apical impulse, and an aortic ejection systolic murmur maximal in the aortic area and down the left sternal edge, conducted to the carotid arteries. As with supra-aortic stenosis, an ejection click will not be heard, and further clinical differentiation may be possible by finding the murmur to be maximal at the lower left sternal edge. There may be

Figure 44-27 This transoesophageal echocardiogram is from a patient with subaortic stenosis produced by accessory leaflet tissue derived from the mitral valve (arrow). AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

an early diastolic murmur if complicated by significant aortic regurgitation.

Investigations

Electrocardiogram

This will show varying degrees of left ventricular hypertrophy, normally without a Q wave. Interestingly, upright T waves are preserved even with quite severe obstruction, and other abnormalities of repolarisation are rare.

Chest Radiograph

This is often normal, although enlargement of left ventricle and left atrium may be present.

Echocardiography

Cross sectional examination in the parasternal long axis shows the characteristic ridge in the outflow tract (see Fig. 44-26). The full extent of the ridge may be difficult to assess from this approach. In older children and adults, transoesophageal interrogation demonstrates this lesion more fully (Fig. 44-27), and is probably a better way to identify associated lesions of the mitral and aortic valves. Increasingly, three-dimensional echocardiography is being used to demonstrate the nature of the lesion. In those with good transthoracic windows (Fig. 44-28), Doppler ultrasound is used to assess the extent of aortic regurgitation and the degree of obstruction within the left ventricular outflow tract. As in those with aortic valvar stenosis, peak velocities in the ascending aorta are the most reliable indicators of severity, although significant aortic regurgitation and obstruction over long segments may invalidate the Bernoulli equation, as already described for supra-aortic lesions.

Assessment and Treatment

Because of the progressive nature of the disorder, and the frequent development of a regurgitant aortic valve, surgery is usually advised at gradients lower than those used to determine intervention for valvar stenosis. Indeed, the presence of more than mild regurgitation is often used as justification, irrespective of gradient. In the absence of significant regurgitation, a mean gradient of 30 mm Hg is a reasonable cut-off, particularly if a documented evolution is available. There was a trend towards surgery with much lower gradients, in the hope that this would avoid regurgitation, and perhaps obviate the need for reoperation. This did not, however, prove to be the case.⁶⁰

Figure 44-28 The three-dimensional echocardiogram shows fibromuscular subaortic stenosis (arrow), as seen from below the left ventricular outflow tract. Note that in comparison to the cross sectional counterpart, shown in Figure 44-26, the three-dimensional reconstruction reveals the full extent of the obstruction. LV, left ventricle; MV, mitral valve; RV, right ventricle.

Recurrence of the fixed obstruction may be a problem in as many as one-third of patients, but more recent reports, usually describing more extensive associated septal myectomy, suggest this risk is closer to 5% to 10%. Those with a tunnel obstruction are at particular risk, and ultimately many will require enlargement of the aortic root using the Konno procedure, with or without replacement of the valve.

CHAPTER 45

Congenital Anomalies of the Coronary Arteries

ALAN H. FRIEDMAN and NORMAN H. SILVERMAN

In this chapter, we will address the various congenital coronary arterial anomalies that may be found in the otherwise structurally normal heart. The coronary arterial circulations found specifically with major cardiac structural anomalies will be discussed in the respective chapters elsewhere in this textbook. Similarly, those abnormalities of the coronary arteries that are acquired or associated with diseases will be discussed separately in their respective chapters.

INCIDENCE AND PREVALENCE

Anomalies of the coronary arteries are rare, occurring in 0.3% to 1.3% of one autopsy series.¹ The prevalence, however, is extremely difficult to estimate, as this depends upon accurate recognition and specific identification. This task is complicated by the occurrence of coronary arterial anomalies that, in many individuals, do not lead to symptoms, morbidity, or mortality. In fact, precise diagnosis may escape notice both during life and postmortem.

MORPHOLOGY

The normal coronary arterial anatomy was well described by James² (Fig. 45-1). Two arterial orifices are placed, usually relatively centrally, in the right and left sinuses of Valsalva. The right coronary artery arises from the right sinus of Valsalva. Having entered the atrioventricular groove, it sends an infundibular branch anteriorly, and then courses backward and inferiorly, terminating in the majority of hearts in the inferior interventricular groove. In approximately 50% of people, there is a separate origin of the infundibular branch.³ The main stem of the left coronary artery arises from the left sinus of Valsalva, emerging perpendicularly for a few millimetres. It then bifurcates into anterior interventricular and circumflex branches. The former courses in the anterior interventricular groove toward the cardiac apex, while the latter courses around the left atrioventricular groove and, in one-tenth of individuals, gives rise to the inferior interventricular artery, often then continuing to supply the diaphragmatic surface of the right ventricle. In 1% of people, there are separate origins of the circumflex and anterior interventricular arteries from the left sinus.³

When both right and circumflex coronary arteries supply a branch to the inferior interventricular groove, the system is said to be balanced. More usually, in 90% of individuals, it is the right coronary artery that supplies one large or two smaller branches to this groove, with no contribution from the circumflex artery. This is called right coronary arterial dominance. In the left dominant system, as already described, the converse is true. All three variations

of coronary arterial supply to the inferior interventricular groove and the diaphragmatic surface of the hearts are considered to be normal (Fig. 45-2).

The left and right coronary arteries provide branches superiorly to the atriums, and inferiorly to the ventricles. The major branches remain superficial, and are visible through the epicardium until they terminate in broom-like arborisations that penetrate the myocardium. Over the left ventricle, these penetrating arteries proceed perpendicularly through the wall, being occluded by ventricular contraction. In consequence, the left ventricular myocardium is perfused predominately during diastole.

MORPHOGENESIS

The normal development of the coronary arteries is well proven, and provides the context in which the various anomalies and abnormalities can be understood. When myocardial cells are first observed to contract, there is no defined coronary circulation. The cells are loosely assembled, being bathed in the blood which they pump. The walls of the heart condense in gradual fashion, initially with persistence of an extensive trabeculated luminal meshwork.

Figure 45-1 The cartoon shows the course of the normal coronary arteries as would be seen relative to the cardiac short axis as viewed from the cardiac apex. In the example shown, the inferior interventricular artery is taking origin from the right coronary artery, which then continues to supply the diaphragmatic surface of the left ventricle. This is the so-called right dominant arrangement.

Figure 45-2 The dissection shows the normal origin of the coronary arteries from the aortic root, the heart positioned with the diaphragmatic surface inferior, and with the dissection viewed from the atrial aspect. Note that the coronary arteries arise from the aortic sinuses that are adjacent to the pulmonary trunk.

Early studies⁴ had suggested that the coronary arteries themselves appeared as buds from the developing roots of both the aorta and the pulmonary trunk. It was subsequently shown that the coronary arteries originate specifically from the sinuses adjacent to the pulmonary trunk, which have a particular spatial configuration such that there is a positive transverse and a negative longitudinal curvature.⁵ This has an effect on the wall tension whereby it is increased, perhaps acting as a stimulus for coronary bud development. The distal coronary arteries develop from a network of capillaries originating in the epicardium, with this system then sending major branches into the aortic sinuses.⁶

The numerous anomalies of the coronary arteries can then be well explained on the basis of abnormal patterns of morphogenesis. For example, there can be rudimentary persistence of an embryological coronary arterial structure, failure of normal coronary arterial development, failure of the normal atrophic process of development, or misplacement of connection of an otherwise normal coronary artery.⁷ As a result, anomalies include abnormal origin, abnormal course, abnormal number, abnormal orifices, and abnormal connections or communications. It is these variations, along with their associated pathophysiology, diagnosis and management, which we discuss in the paragraphs which follow.

ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY TRUNK

Incidence

Origin of the left coronary artery from the pulmonary trunk (Fig. 45-3) is one of the more common coronary arterial abnormalities encountered in children. Also referred to as

Figure 45-3 In this specimen, the left coronary artery takes its origin from one of the sinuses of the pulmonary trunk, and then branches to give rise to the anterior interventricular and circumflex arteries in normal fashion.

anomalous left coronary artery from the pulmonary artery, this variation occurs in from 1 in 250 to 1 in 400 of all congenitally malformed hearts, with an overall incidence of approximately 1 in 300,000 children.⁸ This anomaly is seen with greater frequency in boys than it is in girls, with the ratio being 2.3 to 1.⁹

Pathophysiology

In the fetus with the origin of the left coronary artery from the pulmonary trunk, the myocardium, valves, and vessels otherwise develop quite normally. The perfusion pressure for the coronary arteries is the arterial pressure in the arterial trunk supplying these vessels minus the pressure of the chamber receiving the coronary venous flow. As the myocardium is contracting during systole, most flow occurs during diastole. Thus, in the normal situation, the coronary perfusion pressure is the aortic diastolic pressure minus the pressure in the right atrium. During fetal development, the diastolic pressure is nearly identical in the pulmonary arteries and the aorta. Thus, the coronary arterial perfusion in the fetus with the origin of the left coronary artery from the pulmonary trunk is virtually the same as in the normal fetus.

After birth, as long as the pulmonary arterial pressure remains at or near systemic levels, the left ventricular myocardium supplied by the anomalous artery remains well perfused. As the pulmonary vascular resistance, and subsequently the pressure, in the pulmonary trunk falls postnatally, the perfusion of the left ventricle becomes vulnerable, the period during which pressure in the left coronary artery exceeds intramural left ventricular pressure becoming shorter. This circulatory handicap reduces left ventricular function, and raises left ventricular end-diastolic pressure. In time, there may be a reversal of flow through the left coronary artery should the pressure in the

pulmonary arteries fall below that of the left ventricle. This reverse flow leads to the phenomenon referred to as coronary arterial steal, which can lead to further ischaemia of the ventricular myocardium. When the left coronary artery originates from the pulmonary trunk, it is, of course, also perfused with pulmonary blood, which after birth has a much lower content of oxygen than does the blood in the aorta. In some cases, the ischaemic myocardium can be perfused increasingly by a set of developing collateral connections from the right coronary artery, which arises normally (Fig. 45-4). Ideally, a superb set of perfectly distributed collateral arteries could be developed before the pulmonary arterial pressure has fallen sufficiently to result in significant ischaemic damage to the left ventricle. In many circumstances, however, the collateral connections may develop, but be poorly distributed. In consequence, some portions of the left ventricle may be well perfused, while others become ischaemic.

In another pattern of abnormal distribution of the collateral arteries, there are large interconnections proximal to the branches supplying contracting myocardium that act as left-to-right, or aortopulmonary, arterial shunts, requiring extra work from the left ventricle while deviating blood supply from its myocardium. This malformation presents a picture postnatally that may vary enormously from patient to patient, and also from time to time in a given patient.¹⁰ The end result is best evaluated in terms of time of onset of clinically observable myocardial ischaemia. At one extreme, this may never occur, while, at the other, there is disastrous damage to the myocardium in the first weeks of infancy (Fig. 45-5).

Typically, the right coronary artery enlarges at its origin, while the left tends to be small, and relatively thin-walled. The collateral circulation between the right and left systems may be diffusely large, and well distributed. As a result, the left ventricle may remain quite well perfused, allowing the heart to retain its essentially normal form and function. When the collateral connections are poorly developed, the left ventricle becomes ischaemic, dilated, infarcted and

Figure 45-4 The cartoon shows the arrangement when the left coronary artery takes anomalous origin from the pulmonary trunk. The arrows show the direction of collateral circulation from branches of the right coronary artery to those of the left. The dotted lines indicate enlarged collateral connections.

Figure 45-5 The heart, from a patient with origin of the left coronary artery from the pulmonary trunk, has been opened to show the left ventricle. Note the marked ischaemic changes to the myocardium of the inferior wall, and the dilation of the cavity. It is easy to see how such changes could be mistaken during life for dilated cardiomyopathy.

fibrosed (see Fig. 45-5). Often the fibrosis extends into the papillary muscles and the mitral valve itself. Mitral valvar competence may be compromised by these changes, as well as by dilation caused by ischaemia, resulting in stretching of the annulus. The right ventricle, and parts of the left, which are perfused by the right coronary artery, continue to contract well. The left atrium tends to enlarge, as a result of the increasing left ventricular filling pressure, the mitral regurgitation, or both. This will lead to passive congestion of the lungs, an increase in the pulmonary arterial pressure, and subsequently an increase in the pressures in the right heart.

Presentation

The majority of those with origin of the left coronary artery from the pulmonary trunk present during infancy. The infant with myocardial ischaemia tends to have both the classic signs and symptoms of congestive heart failure. Some affected infants will demonstrate a particular type of anginal attack. Brought on usually by the stress of feeding or defaecation, these are episodes in which the infant suddenly appears to be in severe distress, grunting or crying in short gasps, and is dyspnoeic, grey and sweaty. The child who has escaped myocardial ischaemia in infancy may present rather innocuously on a routine examination with an unexplained heart murmur, mild cardiomegaly or an abnormal electrocardiogram. Myocardial ischaemia may first present in adolescence or young adult life when, under the stress of maximally motivated exertion, either anginal pain or arrhythmia may occur. The latter may produce sudden unexplained death, or so-called near-miss death. The patient also may present with progressive mitral regurgitation, which may or may not be accompanied by

electrocardiographic signs of ischaemia. All neonates and infants who present with mitral regurgitation should be evaluated thoroughly for the possibility of origin of the left coronary artery from the pulmonary trunk.

The sick infant may have the general appearance of a baby in chronic congestive heart failure, may have the episodes described above, or may have both. The heart is usually large, and the praecordial impulse is often hyperdynamic. The first heart sound may be loud, normal, or faint, with the second heart sound being loud, and third and fourth heart sounds often present. An apical holosystolic murmur of mitral regurgitation may be heard, and there may be an apical diastolic rumble. The older child with adequate collateral coronary circulation may have completely normal cardiac findings. Sometimes a continuous murmur is heard, resulting from the retrograde flow of blood from the anomalously connected artery into the pulmonary artery. In such patients, the clinical diagnosis may be a small patent arterial duct. In the child with origin of the left coronary artery from the pulmonary trunk, however, there may also be apical murmurs in systole and diastole, resulting from mitral regurgitation and relative mitral stenosis.

Course and Prognosis

It is the extent of collateral vascularisation that dictates the clinical course. Those, likely the minority, with well-developed collateral coronary arteries may have a mild, or even sub-clinical, course with spontaneous improvement. They may present later in childhood, adolescence, or adulthood with progressive mitral regurgitation, congestive heart failure, or myocardial ischaemia with exertion. The overall outlook for the group left untreated, however, is poor. Death may occur suddenly, owing to arrhythmia or to cardiogenic shock from further infarction. In the review of Wesselhoef and colleagues,¹⁰ almost nine-tenths of the infants with angina and/or failure died. Early and accurate diagnosis to guide surgical treatment, therefore, should be the focus of evaluation.

Management

The treatment is surgical, with several approaches being used over recent years. Surgical treatment has evolved dramatically as the transplantation of small coronary arteries during the arterial switch procedure has become commonplace. The specific aim of therapy is to preserve as much myocardium as possible.¹¹ The preferred surgical technique in most cases is surgical reimplantation of the left coronary artery into the aorta, thus re-establishing antegrade flow of oxygenated blood.¹² When technical considerations make this operation difficult or impossible, such as when the orifice of the artery is in an unfavourable position, a transpulmonary baffle can be constructed.¹³ Bypass grafting using the carotid and internal mammary arteries, or saphenous venous grafts, is now performed much less frequently. The procedure of ligating the left coronary artery has, quite correctly, been abandoned, this decision being supported by long-term studies of outcome.¹² In the small subset of patients in whom the cardiac function is profoundly depressed, transplantation may be a more desirable option. Modern surgical techniques make it possible

to support the circulation further by means of devices that assist the left ventricle or provide extracorporeal membrane oxygenation.

ORIGIN OF THE RIGHT CORONARY ARTERY FROM THE PULMONARY TRUNK

This is a far less common anomaly. Though it may occur in isolation, it is associated with other forms of congenital heart disease in up to two-thirds of cases, such as aortopulmonary window, tetralogy of Fallot, or double outlet right ventricle. Like the origin of the left coronary artery from the pulmonary trunk, the anomaly may produce myocardial ischaemia, but often those affected are asymptomatic.¹⁴ Diagnosis is usually made by detailed echocardiography, and may be confirmed by other high-resolution imaging, such as magnetic resonance imaging or computed tomography. The approach to treatment is difficult, since the natural history remains unclear in the asymptomatic patient. In those patients with any evidence of myocardial ischaemia, surgery with re-implantation of the right coronary artery into the aorta is the preferred approach.¹⁵

ANOMALOUS ORIGIN OF A CORONARY ARTERY FROM THE OPPOSITE SINUS OF VALSALVA

Either the right or the left coronary artery can arise from the opposite sinus of Valsalva. Such an anomalous connection may or may not be associated with any symptoms or problems. If the anomalous artery takes an intramural course, or an interarterial course between the pulmonary trunk and the aorta, then significant clinical symptoms may occur. Sudden death may occur, frequently during or soon after competitive sporting events or strenuous exercise. Unfortunately, such sudden death may be the initial presenting event. Although a mechanism for sudden death has not been definitively established, conjecture is that coronary arterial flow is compromised by compression of the coronary artery, so-called interarterial entrapment, restriction at the site of its orifice from the sinus of Valsalva, kinking of the coronary artery itself, or arterial stenosis resulting from the intramural course.¹⁶

Anomalous origin of the left coronary artery from the right aortic sinus carries a higher risk of sudden death than does the anomalous origin of the right coronary artery from the left coronary aortic sinus.¹⁷ The prevalence of the lesion has been estimated at 0.17%.¹⁸ In nine-tenths of cases, there is also an intramural course of the coronary artery.¹⁶ Although the incidence of sudden death in these individuals is unknown, the annual risk of death for the overall population is reported to be 0.24 per 100,000 person-years.¹⁹ Surgical repair is the preferred treatment for symptomatic individuals.¹⁶ There remains, however, considerable discussion as to the best approach to the asymptomatic child known to have this lesion.⁷

OTHER ANOMALIES AND VARIATIONS OF ORIGIN AND COURSE OF THE CORONARY ARTERIES

Most anomalies are extremely rare, and may not present in childhood. They may become important in adolescence

and early adult life, when extremes of physical exertion may cause significant intolerance of malfunction previously well tolerated. They may also become significant with aging, when the additional effects of atherosclerotic changes typically manifest. These malformations are increasingly recognised, albeit still very rarely, in the investigation of syncopal episodes or near-miss sudden death.

Stenosis or Atresia of the Main Stem of the Left Coronary Artery

This lesion has variable presentation, but may be lethal in infancy. The origin, and sometimes a short length of the artery, either fails to canalise or else involutes after formation (Fig. 45-6). Much as when the left coronary artery arises from the pulmonary trunk, the circulation on the left side depends upon collateral blood flow from the branches of the right coronary artery. The severity of symptoms, signs, and laboratory findings are related inversely to the size and distribution of the collateral vessels.²⁰ Some of those affected can survive without symptoms for many years. Infants who present with evidence of myocardial ischaemia are urgently in need of correct diagnosis and treatment. Results obtained by angiography during catheterisation in these infants may be confused with those occurring with origin of the left coronary artery from the pulmonary trunk. Typically, aortic angiography will reveal a large right coronary artery that fills the distribution of the left coronary artery via multiple connections from collateral branches. No contrast material will be seen entering the pulmonary trunk. There may be a slight filling of the left coronary artery from the aorta. There will certainly be no filling of the left coronary circuit from the pulmonary trunk on pulmonary arteriography, thereby excluding the origin of the left coronary artery from the pulmonary trunk as the diagnosis. Cross sectional echocardiography will demonstrate the left coronary artery in its normal location, but it will be diminutive or atretic for a

few millimetres. Surgical treatment should be undertaken in these symptomatic patients.

Other Abnormalities of Coronary Arterial Origin

The orifices of the arteries may be ovoid instead of round. They may be located eccentrically in the sinus of Valsalva, or just above or totally remote from the sinus. In this regard, it should be noted that a significant proportion of the normal population, up to one-fifth, have the coronary arteries arising at or above the level of the sinutubular junction.²¹ In extremely rare circumstances, a coronary artery may originate from an artery other than the aorta or the pulmonary trunk, such as an intercostal or internal thoracic artery. Two orifices within a single sinus usually occur along with anomalous proximal arterial segments.

Anomalies of the Proximal Segments of the Coronary Arteries

A very common normal variation in the proximal segments is a second small orifice in the right sinus of Valsalva that gives rise directly to the infundibular artery (Fig. 45-7). Instead of originating from the main stem, the circumflex artery may arise as a branch of the right coronary artery (Fig. 45-8), or from a separate orifice in the right aortic sinus. It may pass between the front of the aorta and the free-standing subpulmonary infundibulum in such a way as to be compressed between them in systole. Partial intramural course of such arteries through the wall of the aortic sinus has been shown to be significant as a cause of sudden death in juveniles.²²

The Single Coronary Artery

Solitary coronary arteries, whether arising from the right (Fig. 45-9) or the left (Fig. 45-10) sinuses of Valsalva, are large vessels that pass completely around the heart, giving off all the usual normal branches. Such anomalies account

Figure 45-6 In this specimen, the origin of the left main stem of the left coronary artery from the aortic sinus is atretic. Although the orifice of the artery is atretic, the main stem of the left coronary artery is patent. The specimen was obtained from a young adult who died suddenly.

Figure 45-7 The cartoon shows the arrangement of the arteries when the infundibular, or conal, artery takes its origin from an accessory orifice in the right coronary aortic sinus of Valsalva.

Figure 45-8 The cartoon shows the circumflex artery arising as a terminal extension of the right coronary artery. The image is drawn as seen from the cardiac apex looking towards the base (see compass).

Figure 45-9 The cartoon shows the arrangement in which a single coronary artery arises from the right coronary aortic sinus of Valsalva. The image is drawn as seen from the cardiac apex looking towards the base (see compass).

for approximately one-tenth of the total number of coronary arterial anomalies. Such solitary arteries have no pathological implications except in the setting of atherosclerosis, when they take an anomalous course resulting in compression, or when there is an intramural component of the vessel.²² There may, or may not, be an atrophic relic of the opposite artery. This lesion differs from stenosis or atresia of the orifice, in that flow to the side without the orifice is directly through the large single coronary artery with normal branches, as opposed to collateral flow through branches of the arterial bed.

Either a solitary coronary artery, or both coronary arteries arising from the right sinus of Valsalva, achieve pathological significance when the branch or artery that

Figure 45-10 In this cartoon, a solitary coronary artery is shown arising from the left coronary aortic sinus of Valsalva. The image is drawn as seen from the cardiac apex looking towards the base (see compass).

supplies the left coronary arterial distribution courses leftward between the aorta and pulmonary trunk, then being subject to compression.¹⁷ These features are harbingers of sudden unexplained death in adolescents and young adults, and carry a strong relation to death produced by heavy exertion.¹⁷

The single coronary artery from the right sinus of Valsalva can be identified on transthoracic echocardiography performed at the bedside. When found, it is imperative to determine any intramural course. Doppler colour flow confirms the direction of the flow within the coronary artery. In contrast, when the single artery arises from the left sinus of Valsalva (see Fig. 45-10), or both coronary arteries arise from separate orifices in that sinus, with the right coronary artery coursing between aorta and subpulmonary infundibulum, compression can occur, but sudden death may not, probably because of the low perfusion pressure required for the right ventricle.²³

Myocardial Bridges

Rather than running on the surface of the heart, part of any of the epicardial coronary arteries can dip into the muscle, creating a myocardial bridge over the coronary artery. This occurs most frequently in the proximal half of the left coronary artery (Fig. 45-11). Most are not significant, but occasionally longer and thicker bridges can cause ischaemia.²⁴ Although this anomaly is congenital, those affected by it typically do not present with problems during childhood. It can, however, cause myocardial ischaemia, infarction and ventricular dysfunction. The diagnosis is typically made at coronary angiography, but may also be made by high resolution computerised tomographic scanning.²⁵

Coronary Arterial Fistulas

The most distal malformations in the coronary arterial tree are communications between branches of the coronary

Figure 45-11 The specimen has been dissected to show an extensive myocardial bridge across the anterior interventricular artery.

arteries and another large vessel or cardiac chamber.²⁶ The source is most often the right coronary artery, with the left being much less frequently involved, and both coronary arteries less frequently still. The sink may be in any one or several of the superior caval vein, the coronary sinus, the right atrium, the right ventricle, the pulmonary trunk, a pulmonary vein, the left atrium or the left ventricle. Embryologically, these fistulas seem to represent persistent junctions of primordial epicardial vessel with the intramyocardial circulation. They vary from simple direct connections of a coronary artery with the lumen of a chamber or large vessel (Fig. 45-12) to complex, worm-like aneurysmal cavities in which blood may stagnate, clot and calcify (Fig. 45-13). They are as varied pathophysiologically as they are anatomically. In the simple direct connections with large communicating orifices, there may be appreciable

Figure 45-12 The cartoon shows a short, direct, fistula from a coronary artery to the pulmonary trunk. The image is drawn as seen from the cardiac apex looking towards the base (see compass).

Figure 45-13 In this cartoon, a complex and circuitous fistula is shown running from a coronary artery to the pulmonary trunk, a large portion of which is aneurysmal. The image is drawn as seen from the cardiac apex looking towards the base (see compass).

shunts. The increased volume loading begins with the aorta and left ventricle in all cases, and, depending upon where the fistula drains, is reflected farther back into left atrium, pulmonary vascular bed, right ventricle, right atrium or caval veins. The largest shunts tend to be in those that connect to the right side of the heart rather than the left. This is probably because of the greater period of systolic narrowing when the orifice of communication is into the left ventricle, as well as because of the lesser pressure gradient between aorta and left ventricle. Even in those communications ending in the right side of the heart, and contributing to the flow of blood to the lungs, rarely is the ratio between pulmonary and systemic flows greater than 3 to 1.

Some fistulas have been found to be large in the newborn. Further postnatal enlargement does occur. The aneurysmal sections of the fistula, in particular, may gradually dilate over time. If striking cardiac enlargement is noted, it is more likely to be caused by a dilated complex fistula on the surface of the heart than by functional enlargement of the heart from volume overload. Dilation of a complex fistula tends to occur slowly, stretching the pericardium and compressing softer cardiac structures, potentially producing arrhythmias and obstructing veins entering the right or left side of the heart. Other effects and complications include fistulous steal from the neighbouring myocardium, with ischaemia, atherosclerotic changes at points of stress, thrombosis and embolisation, rupture and infective endocarditis.

Over half of patients are clinically asymptomatic with normal exercise tolerance, despite their moderate volume overloads. Symptoms of congestive heart failure may occur, especially when the anomaly presents in infancy. Other symptoms include exercise intolerance with dyspnoea and angina, and occasionally arrhythmia. The presenting physical finding that brings many such patients to the cardiologist is a continuous murmur over the heart. This murmur may resemble that from an arterial duct, except that it is often heard maximally in unusual locations, and may peak in diastole rather than during systolic ejection.

Electrocardiographically, there is no characteristic finding. Radiologically, the heart may be normal in size and shape and moderately enlarged. It may be overactive when there is a short, rapidly flowing, fistula. It may be very large but not overactive when there is a huge cavernous slow-flowing fistula. The cross sectional echocardiogram, especially with Doppler colour flow imaging, has permitted the display of the site of entry of these fistulas.²⁷ The use of Doppler colour flow, accompanied by cross sectional imaging, allows for the recognition of the site of origin, course and site of entry of the fistula. Pulsed and continuous wave Doppler ultrasound confirm the nature of the fistulous flow at the site of entry in most patients, particularly when guided by the colour flow map. Haemodynamic measurements, as well as volume loading of the receiving chamber, can be made with routine echocardiography. Ultimately, however, cardiac catheterisation with aortography provides the definitive diagnosis.

Treatment is now typically accomplished in the catheterisation laboratory. Transoesophageal echocardiography plays an important role in monitoring the success of this procedure.²⁸ Not much is known about the course of these lesions without surgery, because surgical treatment was already available during the years in which accurate diagnosis was feasible. The mortality has been low since the earliest period of surgical treatment, and the tendency has been practically universal to proceed in these patients in order to prevent complications. A small group of patients has been studied prospectively,²⁹ albeit some time ago, with little change noted, and some tendency for spontaneous resolution by thrombosis. The other side of the coin is represented by patients who have come to attention because of infective endocarditis, aggravated atherosclerotic complications, or thrombotic complications. It is rare that embolisation of the fistula with a coil, after appropriate testing for distal ischaemia, cannot be performed at catheterisation. In rare instances when interventional techniques are not successful, surgical treatment may be undertaken. In our discussion, we have purposely avoided reference to the fistulous communications seen in patients with pulmonary or aortic atresia with intact ventricular septum. These are discussed in the appropriate chapters (see Chapters 29 and 30).

Evaluation of Coronary Arterial Structure and Function

All patients with a possible anomaly of the coronary arteries should receive an electrocardiogram as part of their initial evaluation. Beyond that, specific imaging of the coronary arterial circulation may be pursued. In fact, the field of cardiac imaging in children continues to evolve at a remarkable pace. Numerous modalities that are currently available provide detailed anatomical imaging of the coronary arterial structure, course, and in some cases, function. Among these are echocardiography, computed tomographic scanning, magnetic resonance imaging and angiography, positron emission tomographic scanning, and cardiac catheterisation with angiography. The choice of the modality used for imaging should include an analysis based on the availability of expertise for interpretation, the amount of exposure to ionising radiation, and the degree of cooperation,

sedation or anaesthesia required to allow for the proper examination. It is the thoughtful and careful selection of the diagnostic testing that allows for the most accurate and safest diagnosis of the anomalies of the coronary arteries. A detailed explanation of the diagnostic modalities is presented elsewhere in this text, but we provide a brief description here.

Electrocardiography

Those who present with a coronary arterial anomaly that leads to ischaemia or infarction in portions of the ventricular myocardium will almost always have sinus tachycardia in an attempt to maintain cardiac output in the face of diminished myocardial function, and thus decreased stroke volume. Rarely there may be premature ventricular contractions or ventricular tachycardia, pathological Q waves, and abnormalities of the QRS and ST-T segments, compatible with anterior, antero-septal or antero-lateral infarction.¹⁰ Q waves may be present in leads I and aVL in patients with the origin of the left coronary artery from the pulmonary trunk. Alternatively, electrocardiographic changes may be progressive as infarcts evolve. While the electrocardiogram is not likely to be normal in the patient with a coronary artery arising from the pulmonary trunk, it may not show the classic findings for ischaemia or infarction. There are occasions in this disease, therefore, when the electrocardiogram is not diagnostic. The QRS horizontal plane typically reveals a counterclockwise loop pattern, though there is considerable variability. The older child with origin of the left coronary artery from the pulmonary trunk who has survived without symptoms may very well have a normal electrocardiogram.

Echocardiography

In the infant who is suffering from inadequate coronary arterial perfusion, echocardiography demonstrates left atrial and left ventricular enlargement, and depressed ventricular function. Mitral regurgitation is almost invariably present, and brightness of the endocardium may be observed, often associated with endocardial fibroelastosis.³⁰ Definitive imaging of abnormal origin of the left coronary artery from the pulmonary trunk can be achieved using the echocardiographic cut in the sagittal plane (Fig. 45-14). Color flow Doppler mapping is often of great utility. With relatively low Nyquist limits applied to the aorta and the pulmonary trunk in the parasternal short-axis view, the flow in the left coronary artery can be imaged (Fig. 45-15), as can the steal from the coronary circulation into the pulmonary arteries. Pulsed wave Doppler can be used to confirm the flow patterns.

Electrocardiography and echocardiography offer the great advantage of portability, allowing the physician to examine the patient at the bedside. There are now a number of other sophisticated imaging techniques which can provide important information about coronary arterial structure, as well as the viability of the affected myocardium in the patient with coronary arterial anomalies. Magnetic resonance imaging offers concise imaging of the coronary arterial origins (Figure 45-16), and can provide information about myocardial function and scarring. Cardiac computed tomography can also be used to evaluate the origins and course of the coronary arteries in all dimensions, and with gating to the cardiac cycle, also in time. Three-dimensional reconstruction can be performed to further delineate the precise nature of

Figure 45-14 The echocardiogram shows origin of the main stem of the left coronary artery from the pulmonary trunk, with branching to supply the anterior interventricular and circumflex arteries. Ao, aorta; LAD, anterior interventricular artery; LMCA, main stem of the left coronary artery; PA, pulmonary trunk; P Sx, parasternal short-axis section.

Figure 45-15 Colour flow Doppler interrogation demonstrates the abnormal patterns of flow (arrows) in a left coronary artery arising from the pulmonary trunk (PA). Ao, aorta; LAD, anterior interventricular artery; P Sx, parasternal short-axis section.

the coronary artery anomalies (Figs. 45-17 to 45-19). The high resolution of this technique allows for extremely precise diagnosis, albeit consideration must be given to the dose of ionizing radiation. Thallium-201 scintigraphy can yield a cold area in the affected portion of the left ventricle, albeit the same effect has been seen in some patients with cardiomyopathy. More recently, technetium has become the preferred isotope to be used in children, as it has better dosimetry with less gonadal absorption.³¹ Positron emission tomographic scanning may also prove to be useful, particularly in the determination of myocardial viability relative to myocardial perfusion in the patient with the origin of the left coronary artery from the pulmonary trunk.

Figure 45-16 The magnetic resonance image shows the main stem of the left coronary artery (LMCA) arising from the right coronary artery (RCA) and taking a course between the aorta (Ao) and the pulmonary trunk (PA), before branching into the anterior interventricular (LAD) and circumflex (LCx) branches. (Courtesy of Dr. Francis Chan, Lucile Packard Children's Hospital, Division of Radiology and Stanford University, Palo Alto, California.)

Figure 45-17 The computerised tomographic scan shows the course of the normal coronary arteries as seen from the anterior aspect of the heart. Note the location of the right coronary artery (RCA), which courses in the right atrioventricular groove, and the anterior interventricular artery (LAD), which courses in the anterior interventricular groove. (Courtesy of Dr. Francis Chan, Lucile Packard Children's Hospital, Division of Radiology and Stanford University, Palo Alto, California.)

Cardiac Catheterisation

As described previously, any child with an unexplained congestive cardiomyopathy should have detailed echocardiographic imaging, with Doppler colour flow interrogation of the left coronary arterial system. If there is any

Figure 45-18 The computerised tomographic scan shows the right coronary artery (RCA) arising from the left coronary aortic sinus of the aorta, and coursing between the aorta and the pulmonary trunk, posterior to the right ventricular outflow tract (RVOT), to reach the right atrioventricular groove. The left coronary artery, also arising from the left coronary aortic sinus, branches normally into the circumflex and anterior interventricular (LAD) arteries. (Courtesy of Dr. Francis Chan, Lucile Packard Children's Hospital, Division of Radiology and Stanford University, Palo Alto, California.)

Figure 45-19 The computerised tomographic scan shows a large and tortuous coronary arterial fistula, with aneurysmal dilation of the right coronary arterial (RCA) system. doubt about the origins, patency, course or structure of the coronary arteries, the patient should be given the benefit of angiography.

Cardiac catheterisation is performed to measure cardiac output, left ventricular end-diastolic pressure, and pulmonary arterial pressure. The objective of angiocardiology

is to establish the integrity and the source of the coronary arteries. In a very sick infant, the less done the better within the limits of adequate diagnosis. When the left coronary artery arises from the pulmonary trunk, an aortic root injection may be sufficient to show clearly the early filling of the right coronary artery and the delayed passage via collateral vessels into the left coronary arterial distribution and, finally, the pulmonary trunk. If the pulmonary trunk never clearly opacifies, it is desirable next to inject the pulmonary trunk, looking very carefully for small, usually diastolic, phasic filling of the main stem of the left coronary artery and its branches. The finding of coronary arterial filling from the pulmonary trunk should rule out ligation of the main stem of the left coronary artery at its origin as a form of treatment for the patient. Should adequate injections of both the aortic root and the pulmonary trunk still leave no clue as to the origin of the left coronary artery, selective injection of the right coronary artery should be considered.

This elegant study sought to elucidate the mechanism by which the normal coronary arteries develop their connections with the right and left aortic sinuses of Valsalva. Serial sections through embryonic hearts demonstrated that the left and right aortic sinuses develop a positive transverse curvature and a negative longitudinal curvature. The other four sinuses of the great arteries develop positive transverse curvatures and also develop a positive longitudinal curvature. These differences in mural tension may explain the normal connection between the coronary arteries and the sinuses.

This study describes the mode of presentation, the anatomical features, the methods of diagnosis and surgical outcome for patients who have anomalous origin of a coronary artery from an opposite aortic sinus, and discuss the significance of a subsequent interarterial course. The results of 10 patients from one center are

presented. Patients were noted to have frequent intramural course of the coronary artery with the anomalous origin. Surgical repair using an unroofing technique without cardiopulmonary bypass was used in these patients.

- Davis JA, Cecchin F, Jones TK, Portman MA: Major coronary artery anomalies in a pediatric population: Incidence and clinical importance. *J Am Coll Cardiol* 2001;37:593–597.

This prospective study sought to determine the incidence and clinical significance of the major coronary arteries in children by the use of routine, transthoracic echocardiography. Nearly 2400 patients were evaluated, and four were found to have an anomaly of coronary arterial origin. Ischaemia was found to have occurred in those with and without symptoms, and surgical management and close clinical follow-up are recommended.

- Muriago M, Sheppard MN, Ho SY, Anderson RH: The location of the coronary arterial orifices in the normal heart. *Clin Anat* 1997;10:297–302.

In this study, the authors evaluated 23 normal hearts at autopsy to determine the coronary artery orifices in relation to the aortic valve. They determined the position of the zones of apposition between the leaflets, the size of the aortic valvar leaflets, the number, shape and position of the coronary arterial orifices, and their relative position to the sinutubular junction. It was not uncommon for an accessory coronary orifice to be found in the anterior sinus. The coronary arterial orifices were frequently noted to have a non-central position, but were usually below the sinutubular junction.

- Canyigit M, Hazirolan T, Karcaaltincaba M, et al: Myocardial bridging as evaluated by 16 row MDCT. *Eur J Radiol* 2007; 69:156–164.

Using non-invasive advanced computed tomography scanning, this study defines the prevalence and appearance of myocardial bridging and provides a correlation to the clinical presentation. The authors found that this non-invasive technique allowed for the direct visualisation of the myocardial bridge, and could be used to differentiate between complete and incomplete patterns of bridging. They suggest that the technique could be used to avoid invasive, higher risk procedures to image coronary arteries in situations of suspected bridging.

- Velvis H, Schmidt KG, Silverman NH, Turley K: Diagnosis of coronary artery fistula by two-dimensional echocardiography, pulsed Doppler ultrasound and color flow imaging. *J Am Coll Cardiol* 1989;14:968–976.

The authors described the diagnosis and findings using echocardiography with colour flow Doppler mapping in 10 young children with a coronary arterial fistula. Bedside echocardiography accurately describes the origin, course and site of drainage of the coronary arterial fistula, and all anatomical information needed for surgical treatment was consistently obtained by echocardiography with colour flow Doppler mapping.

Aortic Coarctation and Interrupted Aortic Arch

J. ANDREAS HOSCHTITZKY, ROBERT H. ANDERSON, and MARTIN J. ELLIOTT

Coarctation derives from the Latin term *coartatio*, which translated literally means a drawing together. Aortic coarctation, therefore, indicates a narrowing at some point along the course of the aorta. When used in the context of the congenitally malformed heart, coarctation most usually described an area of narrowing of the thoracic aorta in the region of the insertion of the arterial duct, with or without additional abnormalities of the aortic arch. Obstructive lesions can be found more proximally, involving the ascending aorta. These are considered, along with lesions of the aortic valve, in Chapter 44. Those distal to the thoracic aorta, together with acquired lesions, are beyond the remit of this chapter. Within this chapter, however, we will include consideration of patients with interruption of the aortic arch. This condition exists when there is discontinuity between two adjacent segments of the aortic arch, and in haemodynamic terms includes cases with a fibrous cord between the discontinuous segments. In this respect, interruption can be interpreted as the extreme end of the spectrum of obstruction of the aorta (Fig. 46-1).

HISTORICAL CONSIDERATIONS

The first description of aortic coarctation is generally attributed to Johann Freidrich Meckel, the famous Prussian anatomist, who presented the case of an 18-year-old female to the Royal Academy of Sciences of Berlin in 1750. At postmortem, she was found to have an aorta that was 'so narrow that its diameter was smaller by half than that of the pulmonary artery, which it should have exceeded or at least have equalled in calibre'. Some argue, however, that it was Morgagni who should be given priority.¹ As pointed out by Craigie,² nonetheless, a more recognisable description was published in Desault's *Journal de Chirurgie* in 1791. According to Craigie, Monsieur Paris, the Prosector of the Amphitheatre at the Hotel-Dieu described, in the winter of 1789, the postmortem of 'a very emaciated woman about 50 years old'. As well as recognising that the thoracic arteries were thicker and more tortuous than normal, he gave the following description: 'The part of the aorta which is beyond the arch, between the ligamentum arteriosum and the first inferior intercostal, was so greatly narrowed that it had at most the thickness of a goosequill. Hence in taking apart its walls, which had not decreased in this place, there remained only a small lumen. The part of the vessel which was above the constriction was slightly dilated; the distal part was of normal calibre. The most careful dissection did not reveal either in the aorta or in its vicinity any cause to which this extraordinary condition could be attributed'. With regard to interruption of the aortic arch,

as discussed above, this can be considered as the severest end of the spectrum of aortic coarctation (see Fig. 46-1). It was Celoria and Patton³ who classified this lesion into types A, B and C (Fig. 46-2). Interruption at the aortic isthmus had been the first pattern described, being recognised in 1778 by Stiedele in Vienna.⁴ The more common variety, with interruption between the left common carotid and left subclavian arteries, was described some 40 years later by Siedel.⁵ The least frequent variant, with interruption between the brachiocephalic and left common carotid arteries, was not seen until 1948.⁶

PREVALENCE AND AETIOLOGY

Aortic coarctation accounts for 7% of liveborn children with congenitally malformed hearts,⁷ with a higher incidence in stillborn infants.⁸ The overall incidence is in the region of 1 in 12,000, with a slight increased occurrence in males.⁹ Coarctation is generally said to show multi-factorial inheritance, although genetic factors are clearly important in certain groups. The lesion was found in one-tenth of a large Danish series of patients with Turner's syndrome, albeit with a lower incidence in patients with mosaicism, or those with structural anomalies of the X chromosome.¹⁰ Inheritance has also been reported as an autosomal dominant trait.¹¹ It is now known that cells migrating from the neural crest populate the aortic arches, and 22q11 deletion is well recognised as being associated with interruption between the left common carotid and subclavian arteries.¹² The finding of coarctation in an infant with this deletion, therefore, prompted suggestions of a similar association.¹³ There is a reported seasonal incidence, with paucity of males born between April and August, but without any identification of an exogenous aetiological agent.¹⁴

Interruption of the aortic arch accounts for just over 1% of cases of so-called critical congenital cardiac disease.⁹ As already emphasised, there is a known association between deletion of chromosome 22q11, or Di George syndrome, and interruption between the left common carotid and subclavian arteries. This is known to be due to abnormal migration of cells from the neural crest.¹² As many as one third of those with Di George phenotype have interruption of this type, and, conversely, two-thirds of those with interruption between the left common carotid and subclavian arteries have Di George syndrome.¹⁵ Taking those with interruption as a group, interruption between the left common carotid and subclavian arteries is held to account for between half and three-quarters of cases, interruption at the isthmus for two-fifth, and interruption between the carotid arteries is rare.^{16,17} Interruption as an isolated lesion

Figure 46-1 The morphological spectrum of obstruction in the aortic arch.

Figure 46-2 The categorisation of interruption of the aortic arch introduced by Celoria and Patton. The descending component of the aortic arch is supplied through the persistently patent arterial duct.

is also rare.¹⁸ The combination of congenital absence of the aortic isthmus, patency of the arterial duct, and ventricular septal defect is very common and reported to occur in three-quarters of patients with interruption.¹⁹ The incidence is equal between the genders.¹⁶

MORPHOLOGY

The lesions to be considered in this chapter all occur in proximity to the junction of the aortic arch and the arterial duct. This junction is clearly of fundamental importance to their evolution and morphology, although isolated coarctation can also exist proximal to the brachiocephalic arteries, or in the descending thoracic aorta. Aortic coarctation,

however, is not a uniform entity. Rather, it represents a spectrum of lesions, generally encompassing variable degrees of hypoplasia, along with additionally stenotic areas, within the aortic arch. The extreme end of the spectrum is interruption of the aortic arch (see Fig. 46-1). Less severe is the presence of a fibrous cord between the interrupted segments of the arch, so that there is haemodynamic interruption but anatomic continuity. This is also known as atresia of the arch (Fig. 46-3). Tubular hypoplasia is present when there is a uniform narrowing of part of the arch (Fig. 46-4), whereas discrete coarctation is produced by a localised shelf-like lesion within the lumen of the arch, often with a degree of proximal tapering of the arch itself towards the obstructive shelf (Fig. 46-5).

Figure 46-3 In this specimen, the segment of aortic arch between the origin of the left subclavian artery (LSA) and the descending aorta is represented by a fibrous cord (bracket). A dimple can be seen in the lumen of the ascending aorta (arrow), which shows that the arch itself was initially patent. The ascending aorta also supplies the brachiocephalic (BCA) and left common carotid (LCA) arteries, while the patent arterial duct supplies the descending aorta.

Figure 46-4 In this specimen, the segment of arch between the left common carotid artery (LCA) and the descending aorta is uniformly narrow, the anatomic feature described as tubular hypoplasia. Note the origin of the left subclavian artery (LSA) from the descending aorta. BCA, brachiocephalic artery.

The Obstructive Lesions

Presence of a discrete obstructive shelf within the lumen of the arch is much commoner than tubular hypoplasia, and has been the subject of manifold classifications. The most systematic approach was suggested by Edwards,²⁰ who emphasised the need to describe precisely the site of coarctation, irrespective of whether the arterial duct is patent, closed or ligamentous, and irrespective of the presence of additional anomalies. These other features, of course, also require description. In terms of location, nonetheless, when the arterial duct is patent, then the obstructing lesion can be preductal, paraductal, or postductal (Fig. 46-6). The most common site for discrete coarctation is at the junction

Figure 46-5 This image shows the typical features of discrete coarctation as seen in the neonatal heart. The duct is persistently patent, but the ductal tissue surrounds the mouth of the isthmus, with the shelf of ductal tissue producing the major obstruction to flow through the isthmus, albeit with some tapering of the isthmus segment.

of the aortic isthmus, the arterial duct or ligament, and the descending aorta. When the duct is open, there is usually a degree of isthmal hypoplasia, with the isthmus tapering down towards the junction with the duct, and the obstruction is preductal (Fig. 46-7). The obstructive lesion itself takes the form of a discrete waist, associated with infolding of the aortic wall (Fig. 46-8). In the majority of cases, the shelf is formed by ductal tissue, which completely encircles the lumen of the isthmus (see Fig. 46-5). The ductal shelf produces the major obstruction to flow, being the most important factor in coarctation. The waisting of the aortic wall usually accompanies the ductal shelf, but can occur in isolation.²¹ When the arterial duct is closed, then the ductal shelf becomes converted to a fibrous diaphragm, often with a pinhole meatus (Fig. 46-9). Paraductal coarctation occurs directly opposite the mouth of the duct at its insertion to the aorta, and is found in one-tenth of cases (Fig. 46-10). Postductal obstruction is seen distal to the aortic origin of the arterial duct, and again accounts for about one-tenth of cases seen in infancy. The most important consequence of this variant is the lack of improvement of such critically ill infants despite maintenance of ductal patency with prostaglandin. Such postductal coarctation is the norm in adults, although then occurring in postligamentous, rather than postductal, position.

Tubular hypoplasia, describing the presence of a uniformly narrow segment of the aortic arch, frequently coexists with discrete coarctation, but can exist in isolation (see Fig. 46-4). It is distinct from the gradual tapering of the isthmus characteristically seen with discrete coarctation (see Fig. 46-7). Histologically, the wall of an affected segment is normal, in contrast to the ductal and fibrous nature of discrete coarctation. The most frequent sites for tubular hypoplasia are either at the isthmus, or between the common carotid and the left subclavian arteries (see Fig. 46-4). It is rare for the segment between the brachiocephalic

Figure 46-6 The cartoon shows how the obstructive lesion within the aortic arch can best be described as occupying preductal, paraductal, or postductal positions. The distinctions are harder to make when the duct is closed and ligamentous. The arrows show the preferential direction of flow through the arterial duct.

Figure 46-7 The picture shows the external view of a preductal coarctation lesion. Note the tapering of the isthmus, and the direct pathway from the duct to the descending aorta.

Figure 46-8 In this specimen, the junction of isthmus, duct, and descending aorta has been opened to show the shelf-like coarctation lesion, along with the waisting of the arterial walls (arrows). LPA, left pulmonary artery.

and left common carotid arteries to be affected. Atresia of the aortic arch exists when the arch itself is anatomically continuous, but there is no patency within one of its segments. The commonest site for such atresia is the aortic isthmus (see Fig. 46-3), but atresia can also be found between brachiocephalic and left common carotid arteries. Interruption exists when there is anatomic, as well as haemodynamic, discontinuity between segments of the aortic arch (see Fig. 46-2). The commonest site for interruption, accounting for about three-quarters of cases, is between the left common carotid and subclavian arteries (Fig. 46-11), the so-called Type B pattern of Celoria and Patton.³ Most of the remaining cases show interruption at the isthmus, the so-called Type A (Fig. 46-12). As we have already emphasised,

interruption between the brachiocephalic and left common carotid arteries, so-called Type C, is extremely rare.

Associated Malformations

The presence of associated cardiovascular lesions was one of the criterions commonly used to differentiate coarctation found in patients presenting in infancy from those presenting, often in isolation, in later childhood and adulthood. In this respect, the association of aortic coarctation, hypoplasia of the isthmus, patency of the arterial duct, and the presence of an interatrial communication or patency of the oval foramen, is so common as to be referred to sometimes as part of a coarctation complex in neonates. The typical

Figure 46-9 This is the specimen resected by the surgeon prior to an end-to-end anastomosis. It shows the pinhole meatus in the obstructive shelf as typically seen when the arterial duct has become ligamentous.

Figure 46-10 In this heart, the obstructive shelf (red arrow) is in paraductal position, with flow through the open duct possible to both ascending and descending segments of the aorta (white arrows).

associated anomalies are those that tend preferentially to potentiate flow to the pulmonary rather than systemic arterial pathway. Such lesions lead to reduced flow through the aortic isthmus in fetal life. This can be produced first by defects that produce left-to-right flow at either the level of the ventricles or the great arteries. The most common of these lesions is a ventricular septal defect. When found in the presence of coarctation, the ventricular septal defect is similar to the archetypical pattern found in hearts from

Figure 46-11 In this heart, there is interruption of the aortic arch (star) between the left common carotid artery (LCA) and the left subclavian artery (LSA). The right subclavian artery (RSA) has an anomalous retro-oesophageal course, so the ascending aorta gives rise to the right (RCA) and left common carotid arteries.

Figure 46-12 In this heart, the interruption is at the isthmus, between the left subclavian artery (LSA), which together with the left common carotid (LCA) and brachiocephalic (BCA) arteries arises from the ascending aorta, and the descending aorta, which is fed through the persistently patent duct. Note that in this heart there is also an aortopulmonary window (bracket).

patients with interruption of the aortic arch, with posterior deviation of the muscular outlet septum, or its fibrous remnant, into the subaortic area, the deviation leading to subaortic obstruction²² (Figs. 46-13 and 46-14). In the setting of coarctation, however, the defects are more frequently perimembranous, and associated with postero-inferior

Figure 46-13 The heart has been sectioned in parasternal long-axis fashion, showing the morphology of the defect typically associated with interruption of the aortic arch, and with some cases of coarctation. There is posterior deviation of the muscular outlet septum, narrowing the subaortic outflow tract.

Figure 46-14 In this heart, also sectioned in parasternal long-axis fashion, there is a variation on the morphology shown in Figure 46-13. In this heart, the outlet septum is represented by its fibrous remnant, so that the defect is doubly committed and juxta-arterial. The deviated fibrous raphe, nonetheless, still obstructs the subaortic outflow from the left ventricle.

overriding of the aortic valve²² (Fig. 46-15). Interruption of the aortic arch can be found with an aortopulmonary window rather than a ventricular septal defect (see Fig. 46-12). It, and coarctation, of course, can be found in the setting of discordant ventriculo-arterial connections, or double outlet ventricle, or common arterial trunk. The coarctation or interruption is then considered the associated lesion, and these are dealt with in the appropriate chapters of our book. Very rarely, interruption can be found in the absence of associated lesions, and with a closed arterial duct.^{18,22} The supply to the lower half of the body is then dependent on collateral circulation.

The second mechanism underscoring the existence of associated lesions is one producing obstruction to the outflow from the left ventricle both pre- and postnatally. Lesions falling into this second category include valvar and subvalvar aortic stenosis, and potentially the aortic valve with two leaflets. Congenital stenotic lesions of the mitral valve will also lead to decreased flow through the aortic arch, as will supravalar mitral shelf, stenosing left atrial ring, and divided left atrium. The presence of several such lesions in combination presents a particularly poor prognosis, with the heart itself in such settings overlapping with the hypoplastic left heart syndrome. The best known combination involves co-existence of parachute mitral valve, supravalar left atrial ring, subaortic stenosis, and aortic coarctation. It is known as Shone's syndrome.²³

The aortic valve with two leaflets is usually haemodynamically insignificant in early postnatal life. It is, nonetheless, a common finding in patients with aortic coarctation. In

Figure 46-15 The ventricular septal defect in this heart associated with aortic coarctation is perimembranous, and overridden by the aortic valve. The entrance to the aorta from the left ventricle is narrowed by hypertrophy of the antero-lateral muscle bundle of the left ventricle, while tissue tags narrow the right ventricular origin of the aorta. These lesions presumably reduced aortic flow during fetal life.

later life, the malformation of the aortic valve predisposes to calcific stenosis, regurgitation, and infective endocarditis. When found in association with coarctation, however, the morphology of the bifoliate valve is significantly different from that seen as an isolated lesion.²⁰ When found

in patients with coarctation, the valve typically has two equally sized leaflets, whereas bifoliate aortic valves seen in isolation usually have leaflets of unequal size. Irrespective of the valvar morphology, there is a known association between the bifoliate valve and weakness in the aortic wall, this accounting for the long-term incidence of dilation, and subsequent dissection of the aortic root and ascending aorta.²⁴ Whether this association will produce problems in the long-term follow-up of patients with coarctation has still to be established.

Anomalies of the subclavian arteries can accompany either discrete coarctation or interruption of the aortic arch. They are important both clinically and surgically, being seen more frequently in association with interruption. The most common anomaly is origin of the right subclavian from the aorta distal to the site of the ductal insertion (see Fig. 46-11). The anomalous artery then pursues a retro-oesophageal course, often arising from the expanded segment of aorta called the diverticulum of Kommerell. The left subclavian artery can also be anomalous, arising paradoxically (see Fig. 46-4). In this setting, the isthmus itself is exceedingly short or non-existent. The mouth of the subclavian artery can be incorporated in the ductal sling, and has a tendency to be stenosed at its origin.

As might be anticipated, coarctation, atresia, or interruption can also occur when the aortic arch is right sided. Coarctation can also be found in the setting of a double aortic arch, while interruption of part or parts of the hypothetical double aortic arch is an essential part of the understanding of vascular rings (see Chapter 47). Abnormal ventriculo-arterial connections are also described with interruption, including discordant ones, double outlet right ventricle with subpulmonary defect, or the Taussig-Bing malformation,²⁵ aortopulmonary window with intact septum,^{26,27} and congenitally corrected transposition.²⁸

Collateral Circulation

Although rarely present in infants, collateral circulation gradually develops throughout childhood in those with subcritical coarctation. Such collateral arteries bypass the obstruction and augment perfusion to the lower body. The most common pattern involves a large aberrant artery arising from the right subclavian artery, and supplying the aorta below the coarctation, together with various branches of the left subclavian artery, including the thyrocervical trunk, the left intercostal arteries via the left internal thoracic artery, this leading to notching of the ribs, and the anterior spinal artery through the left vertebral artery. One particular vessel in this circulation has achieved recognition as the artery of Abbott. This anomalous vessel (Fig. 46-16) arises from the posterior aspect of the isthmus, and passes medially behind the carotid artery and transverse arch.²⁹

Secondary Pathology

Secondary pathology can be divided into local effects, effects on the myocardium and distant effects, the last in general caused by hypertension. The local changes tend to be characteristic. In older children and adults, fibrous intimal thickening is superimposed on the site of coarctation. The thickened layer is composed of concentric layers of collagen, with varying degrees of elastin and smooth

Figure 46-16 This photograph shows Abbott's artery arising from the posterior aspect of the aortic isthmus. Photograph taken in the operating room through a left thoracotomy in a patient with aortic coarctation. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

muscle cells. The characteristic depletion and disarray of elastic tissue seen with cystic medial necrosis have also been observed.³⁰ The intimal proliferation, together with superimposed thrombus, can lead to near or complete obliteration of the lumen. In such instances, all distal perfusion becomes dependent on the collateral circulation. The distal aortic wall often shows post-stenotic dilatation and is somewhat thinner than normal. The abdominal aorta may, however, be somewhat hypoplastic owing to diminished flow. The combination of these local changes accounts for the occasional development of aortic dissection in patients with advanced disease without treatment. Pregnancy imposes an increased haemodynamic strain on the aortic wall owing to the physiological changes that occur, particularly in the last trimester and peripartum. Aortic dissection, and even rupture, can initially be misdiagnosed as pre-eclampsia. Such complications can also follow an apparently successful repair. Whether earlier surgical intervention decreases the occurrence of the changes in the aortic wall is not yet known.

The direct effect on the myocardium of obstruction to the left ventricular ejection depends on the rapidity of the onset, as well as the degree of the increase in afterload, the left ventricle having numerous compensatory mechanisms. In the neonate undergoing rapid decompensation with ductal closure, left ventricular systolic and diastolic dysfunction rapidly lead to congestive heart failure. Diastolic flow in the coronary arteries decreases as left ventricular wall stress increases. This leads to ischaemia, especially of the subendocardium. The resultant decrease in cardiac output causes, and then perpetuates, a metabolic acidosis, which further depresses the left ventricular contractility. In part, in infancy, this is a consequence of the inability of the myocardium to mount the usual adaptive responses to increased impedance to outflow. These will be discussed below under pathophysiology. Unless intervention is performed, death

can be rapid. Of those who survive the initial insult, some develop marked subendocardial fibrosis. If the onset of obstruction is less abrupt, compensatory adaptations can occur, primarily in the form of left ventricular hypertrophy. Ischaemic heart disease eventually occurs in many, even in the absence of proximal coronary arterial occlusion. Distant complications include the well-recognised and classic berry, or saccular, aneurysm of the circle of Willis. All the organs in the upper body can sustain pathology secondary to hypertension. These changes are not entirely ameliorated by the initial relief of obstruction. This will also be discussed at greater length in the sections to follow.

Morphogenesis

There are three main aberrations in embryological development proposed to explain abnormalities of the aortic arch. The first, abnormal embryogenesis of the vessels of the arch, and the second, abnormal development of the arterial duct, are closely interlinked. The third implicates changes in the ratio of flow between the pulmonary and systemic arterial pathways.

In the usual situation, with a left-sided arch, it is the left fourth branchial arch that becomes the definitive aortic arch. The arterial duct is the persisting artery of the left sixth branchial arch, connecting to the dorsal aorta. The left subclavian artery, in contrast, forms from the seventh segmental artery. This must undergo a cephalad migration through differential growth before it assumes its definitive position proximal to the aortic isthmus. In its migration, it must cross many structures. Derangements in this process are suggested to be of importance in the pathogenesis of coarctation. The hypothesis implicating the arterial duct is based on the presence of the ductal sling around the entire circumference of the aortic isthmus in the setting of coarctation. Unequivocal evidence of such a ductal sling (Fig. 46-17) was provided initially by Wielenga and Dankmeijer,³¹ and subsequently confirmed by others.^{32,33}

The third proposal is that the patterns of flow of blood in the fetal circulation influences embryogenesis, specifically that a reduction in the volume of blood passing through the ascending aorta in fetal life leads postnatally to the development of coarctation.³⁴ Such a hypothesis is strongly supported by the common association of coarctation with other obstructive lesions in the left side of the heart, along with those malformations that result in decreased flow in the fetal ascending aorta.

No single hypothesis can explain the morphogenesis of all obstructive lesions in the aortic arch. It is most likely that there is interplay between the various mechanisms. It is highly likely, for example, that decreased flow to the aorta in some way influences the distribution of ductal tissue in the aortic arch. These basic mechanisms certainly help in the understanding of the clinical presentation, early management, and even successful treatment of the various obstructive lesions to be described below.

Presentation and Clinical Symptomatology

Neonates and Infants

Most infants with coarctation or interruption present with varying degrees of heart failure in infancy. When seen immediately, this is manifested by collapse, or later

Figure 46-17 The cartoons show the differing extent of ductal tissue (yellow) relative to the aortic arch in the normal situation, and in the setting of aortic coarctation. The ductal tissue lassos the lumen of the isthmus (bracket) when there is coarctation.

by poor feeding, sweating, breathlessness and failure to thrive. The group that survives infancy without symptoms will be discussed below. The onset of cardiac failure is commonly within the first 3 months of life, but a significant number present within the first week of life, who uniformly will have critical narrowing of the aorta. They present when the supplementary effect of blood flow through the duct from the right ventricle to the descending aorta is interrupted by its closure, critically limiting the blood flow to the lower body. The situation, therefore, is often described as a duct-dependent systemic circulation. This process causes them to become acutely unwell with metabolic acidosis, shock, renal failure and necrotising enterocolitis. Similarly, interrupted aortic arch tends to present with cardiac heart failure of acute onset occurring simultaneously with closure of the arterial duct within the first few days of life. Four-fifths are admitted to a specialist hospital within 2 weeks.³⁵

The secondary effects of acidosis on the myocardium, will then lead to additional global reduction in cardiac output. The coarctation itself may only be recognised as the infant is resuscitated. With the introduction of prostaglandin E_1 in the 1970s, it was possible to temporarily maintain ductal patency, and this revolutionised the management of these infants. This will be discussed below.

In the most common situation, where interruption is associated with a patent arterial duct and ventricular septal defect, the infant will initially be well because the pulmonary vascular resistance is high and blood will, therefore, pass through the arterial duct to the systemic circulation. One of two events will precipitate collapse in these infants. First, ductal closure will lead to a critical reduction in lower body perfusion and rapid development of acidosis and shock. Second, a falling pulmonary vascular resistance in the presence of a widely patent duct will lead to preferential flow of blood to the pulmonary circulation to the detriment of the systemic circulation. More slowly progressive, but potentially equally important, tissue acidosis leading

to collapse may also occur. In those with the rarer variant of interruption occurring in isolation, there must be a collateral circulation, usually via the head and neck vessels, which can develop very rapidly.³⁶

Physical Findings

The signs on presentation in infancy include tachypnea, with intercostal recession. If markedly low cardiac output is present, they will often show profound skin mottling, slow capillary refill, and peripheral cyanosis. Central cyanosis will occur only in the presence of an associated cyanotic congenital cardiac lesion, or when there is persistence of the fetal circulation. The presence of palpable femoral pulses in the first day or two of life does not exclude the diagnosis of coarctation or interruption, since flow of blood to the lower body may be maintained antegradely through the persistently patent arterial duct. Once symptoms occur, the femoral pulses are usually weaker, or absent. If the patient has severe low output and no pulses are felt, resuscitation usually causes the pulses in the right arm to return. The praecordium is often active, unless myocardial function is depressed. On auscultation, there is usually a summation gallop rhythm. There is often a systolic murmur found along the left sternal edge, from the site of coarctation, and this may also be audible posteriorly. The continuous murmur classically ascribed to coarctation is unusual in infancy. Associated cardiac or central vascular defects, such as the persistently patent arterial duct, can produce additional murmurs. An ejection systolic murmur may indicate an associated bicuspid aortic valve. Signs of congestive heart failure, such as hepatomegaly and crepitations on auscultation, are commonly found. Auscultation in patients with interrupted aortic arch is usually unhelpful. Often a gallop rhythm is present, and the heart sounds are usually easily audible, the second being split. An ejection click may indicate the presence of associated bicuspid aortic valve, but this is non-specific. If a murmur is present, it is often pan- or mid-systolic and of low intensity, indicating the non-restrictive nature of the ventricular septal defect.

Measurements of the blood pressure in all four limbs reveal a gradient between the upper and lower limbs irrespective of the method used to measure it, although Doppler appears preferable.³⁷ It should be remembered that differences in pressure of up to 20 mm Hg may be revealed by Doppler interrogation in the normal neonate, presumably owing to the isthmal narrowing that is normal at this stage.³⁸ It is sometimes necessary to measure blood pressures serially if the diagnosis remains unclear. Paradoxically, the diagnosis of coarctation can be made more difficult by the administration of prostaglandin. Although greatly improving the physical condition, the manoeuvre leads to the pressure difference between the arms and legs becoming significantly diminished, making the clinical diagnostic process less clear. Indeed, in the presence of a marked run-off between the right subclavian and the iliac arteries as occurs with a large arterial duct or a cerebral arteriovenous malformation, for example, it may be possible to detect a large difference between systolic blood pressures measured in the arms and legs and yet the femoral pulses will remain easily palpable. The combination of weak or absent femoral pulses together with a gradient in pressure between the limbs is therefore virtually pathognomonic of aortic coarctation.

Older Children and Adults

Frequently patients with coarctation go beyond infancy without detection, either because initially the coarctation was not severe enough to become critical following closure of the arterial duct, or because of a significant early collateral circulation. The diagnosis then usually follows a routine medical examination, where the murmur is discovered, femoral pulses are found to be weak, or unexplained systemic hypertension is found. Headaches, nosebleeds, cold feet, or calf pain on exercise are often experienced.³⁹ Sometimes patients present with end-stage systemic hypertensive disease, such as subarachnoid haemorrhage or hypertensive retinopathy. Very occasionally, the lesion is detected during investigations for coronary arterial disease in later life.

Physical Findings

The physical findings in older patients usually rest upon the appreciation of diminished or delayed femoral pulses compared with the pulses in either arm. The femoral pulse is normally fractionally earlier than the radial, with a similar character, waveform and volume. If this is not the case, then the patient should be further investigated. More reliable than the delay of the femoral pulse to exclude coarctation is measurement of blood pressures in all limbs.⁴⁰ Further signs include a normal jugular venous pressure, and normal sized liver. Indirect signs of left ventricular hypertrophy, such as a displaced apical beat and heave, are often found on palpation of the praecordium. On auscultation, the first and second heart sounds are usually normal, but may be accompanied by an apical fourth heart sound if the left ventricle is becoming non-compliant. The murmur of coarctation is best heard in the left infraclavicular fossa and radiates to the back over the left scapula. It is continuous, peaks late in systole, and continues into early diastole, corresponding with the diastolic tail seen on Doppler echocardiography. Additional continuous murmurs may be generated by larger collateral arteries, which can restore adequate flow of blood to the lower body, resulting in palpable femoral pulses, albeit usually reduced and delayed. If surgery is considered, this feature will be crucial, as it determines if partial cardiopulmonary bypass is required or not to maintain adequate perfusion of the lower body and spinal cord whilst the coarcted segment is excluded with clamps for the repair. In the patients beyond infancy, the physical findings of associated abnormalities, such as an ejection click with bicuspid aortic valve, or a murmur owing to a small ventricular septal defect, will be typical of those lesions. A search for disease caused by hypertension is often unrewarding in childhood, although fundoscopic changes with a unique corkscrew appearance to the retinal arteries has been described. These changes are different from the usual hypertensive change.⁴¹

Investigations

Chest Radiography

In infants, cardiomegaly and increased pulmonary vascular markings can be seen on the radiograph. In older children, the heart size is often normal, but if cardiomegaly is present, it is usually caused by left ventricular enlargement. There are two pathognomonic signs on the plain chest radiograph in older children. The first is the figure 3 sign, which appears to the left of the mediastinum and is

caused by pre- and post-stenotic dilation of the aorta (Fig. 46-18). The second sign is rib notching, which is usually not seen until 4 years of age, although appearance in the first year has been described.⁴² By adulthood, around three-quarters of untreated patients have rib notching. It is best seen posteriorly in the medial third of the lower borders of the fourth to eighth ribs, where the intercostal artery crosses the rib (see Fig. 46-18). The notching in coarctation is classically bilateral, to be differentiated from the unilateral notching seen after a classical Blalock–Taussig shunt, although unilateral notching can also occur with coarctation when a subclavian artery arises aberrantly distal to the site of obstruction.

In those with interruption the heart is usually left sided with normal abdominal and bronchial arrangement. Cardiomegaly, particularly enlargement of the left atrium, is present in nine-tenths of neonates.⁴³ Increased pulmonary vascular markings with pulmonary oedema are also the norm. In the rare patients who survive infancy untreated, more specific signs can be seen,⁴⁴ including absence of the aortic knob, a midline trachea, absence of an aortic impression on the barium swallow, and termination of the descending aorta at the level of the pulmonary trunk. Rib notching can also be seen on the side of the subclavian arteries arising from the ascending aorta in the presence of a restrictive or closed arterial duct. A narrow mediastinum may suggest absence of the thymus gland, a feature of Di George syndrome.

Electrocardiography

The majority of young infants presenting with coarctation will have normal right ventricular dominance, with extreme right-axis deviation. Later, left ventricular hypertrophy supervenes. There are early electrocardiographic signs of left ventricular dominance and strain in some infants. This has been linked to subendocardial ischaemia⁴⁵ or co-existing aortic stenosis. There are no specific features that are diagnostic for interruption. As with coarctation the findings are strongly influenced by associated abnormalities, the tracings may show any combination of ventricular hypertrophy, right, left or both, or they may be normal. Occasionally, a prolonged QT interval may be seen secondary to the hypocalcaemia of Di George syndrome.

Magnetic Resonance Imaging

Although echocardiography is a superior modality for the diagnosis of congenital cardiac disease in infants and young children, and magnetic resonance imaging is limited in smaller children because of the need for sedation or anaesthesia, the latter technique combined with phase velocity mapping can be used as a complete diagnostic tool in obtaining both morphological and physiological information in coarctation.⁴⁶ It is also an excellent tool in the assessment of postoperative repair. It can reveal not only the primary pathology and the collateral flow, but also assess secondary pathology, for example, the aortic root for dilation if a bicuspid aortic valve is present, aortic valvar incompetence and stenosis, and provide details of left ventricular mass and function. Magnetic resonance, therefore, is rapidly establishing itself as the method of choice in the evaluation of treatment and complications of aortic coarctation, most notably of aortic gradients and recoarctation. The gradient in blood pressure between the arms and legs is not a reliable indicator of haemodynamic significance of restenosis in patients with prior repair of coarctation. Direct visualisation of collateral vessels by magnetic resonance angiography, and proportional increases in flow from proximal to distal descending thoracic aorta, in contrast, are reliable indicators of haemodynamic significance.⁴⁷ Changes in the collateral circulation after stenting of coarctation segments have also been successfully demonstrated using phase-contrast magnetic resonance.⁴⁸ The combination of anatomic and flow data obtained by magnetic resonance provides a sensitive and specific test for predicting catheterisation gradient greater than 20 mm Hg in native and recurrent coarctations.⁴⁹ Contrast-enhanced magnetic resonance angiography provides additional diagnostic information compared to fast-spin echo magnetic resonance.⁵⁰

When magnetic resonance, magnetic resonance angiography, and Doppler echocardiography are compared in relation to surgical repair of coarctation, it has been shown that magnetic resonance is superior to Doppler echocardiography in the evaluation of the aorta, and that the internal measurement of the narrowing does not correspond to the external aspect of the surgical narrowing.⁵¹ Helical computer tomography and magnetic resonance do not

Figure 46-18 These chest radiographs show evidence of coarctation, with (A) rib notching (arrows) and (B) the figure 3 sign.

seem to differ when used for follow-up assessment of adults with treated coarctations. There can be a substantial variation in two subsequent measurements, without an overall substantial bias towards larger diameter in one of the two methods.⁵² In those with interruption of the arch, magnetic resonance can also be a useful tool to assess the length of the interruption and any associated anomalies, most notably with three-dimensional gadolinium-enhanced magnetic resonance angiography.⁵³

Echocardiography

Echocardiography has become the diagnostic method of choice in infancy. The aortic arch is best visualised from the suprasternal notch in the superior paracoronal view, revealing details of the entire arch (Fig. 46-19). In those with coarctation, there is most commonly a short narrowed segment just distal to the left subclavian artery caused by the obstructive shelf projecting into the aorta posteriorly. More rarely, there is a longer segment of narrowing involving the isthmus (Fig. 46-20). It must be remembered that the apparent anterior shelf often seen on the anterior wall of the aorta is not part of the coarctation, but the overlapping point of entry of the duct.⁵⁴ It is important, especially in infants, to assess the size of the transverse aortic arch. It can often be hypoplastic (Fig. 46-21) or stenotic, and can result in residual obstruction after distal repair. In the absence of an arterial duct, the haemodynamic severity of coarctation can readily be assessed by Doppler echocardiography.

The spectral recording shows an extension of antegrade flow, and a persisting gradient into diastole, the so-called diastolic tail. There is rarely any doubt to its significance, but if uncertainty does exist, the spectral recording can be

Figure 46-19 These echocardiographic images obtained from the suprasternal approach show severe discrete coarctation in a neonate. AAO, ascending aorta; DAO, descending aorta.

Figure 46-20 This suprasternal paracoronal section shows long segment isthmal tubular hypoplasia (arrows). Ao, aorta; RPA, right pulmonary artery.

analysed further⁵⁵ according to the peak velocity and the half-time of diastolic velocity decay. This predicts accurately the severity of anatomical coarctation (Fig. 46-22). Another useful feature is the carotid-subclavian arterial index, which is the ratio of the diameter of the aortic arch at the left subclavian artery to the distance between the left carotid artery and the left subclavian artery, with a ratio of less than 1.5 being both sensitive and specific for coarctation in infants and neonates.⁵⁶ In neonates with a patent arterial duct, measurements of ratio of diameters of the isthmus and descending aorta, along with the delineation of the posterior shelf and a discrepancy in blood pressure between the limbs, has been shown satisfactorily to identify those with coarctation.⁵⁷ In isolated coarctation, the peak instantaneous pressure drop across the obstruction can be calculated from the peak velocity of the jet by using the simplified Bernoulli equation. In the presence of

Figure 46-22 The image shows typical spectral Doppler recordings from a patient with severe aortic coarctation before (A) and after (B) balloon angioplasty. The peak velocity is 3 m/sec, but more importantly there is a prolonged diastolic tail, which is abolished immediately after balloon angioplasty.

a significant associated obstructive lesion in the left heart, it is necessary to quantify the peak velocity of the jet proximal to the site of coarctation. This can often be significantly raised and, if not taken into account by using the expanded Bernoulli equation, there can be a significant overestimation of the gradient.⁵⁸ The remaining examination must be focused on the potential associated malformations, with care taken to assess the mitral and aortic valves accurately. Left ventricular mass should be measured and an M-mode assessment of left ventricular shortening fraction should be made. It must always be remembered that, in the presence of coarctation severe enough to cause low cardiac output, the severity of associated obstructive lesions in the left heart can be underestimated. All of these observations must be modified in the presence of an arterial duct. When large, any gradient across the site of coarctation will be obviated, and the pattern of flow altered. Under these circumstances, much more reliance is placed upon adequate imaging of the stenotic area. In experienced hands, the diagnosis of coarctation using echo Doppler can be made with 95% sensitivity and 99% specificity.⁵⁹

When the arch is interrupted in patients with Di George syndrome, echocardiography is more difficult because of absence of the thymic window. The examination must focus on the intracardiac anatomy, as well as on the aortic arch. Subcostal views will demonstrate the discrepancy in size between aorta and pulmonary arteries. Suprasternally, a relatively small ascending aortic arch is seen to follow an obviously straight course, leading to at least one arterial branch, while the much larger pulmonary trunk leads, via the arterial duct, to the proximal end of a much larger descending aorta.⁶⁰ If approached in this fashion, it is possible to show the entirety of the aorta, despite the interruption, permitting accurate diagnosis in almost all neonates (Fig. 46-23). The parasternal long-axis view will demonstrate the ventricular septal defect, along with the degree of obstruction of the left ventricular outflow tract. Particular care is needed to exclude an aberrant right subclavian artery, or right-sided arterial duct, in the usual setting of a left-sided aortic arch.

Fetal Echocardiography

Significant advantages accrue when congenitally malformed hearts are diagnosed accurately during fetal life, especially those lesions that can be deemed duct

Figure 46-23 This suprasternal echocardiographic section shows the typical appearances of interruption of the aortic arch distal to the subclavian artery. Ao, aorta; BC, brachiocephalic artery; DAo, descending aorta; LC, left carotid artery; LS, left subclavian artery.

dependent, as intervention electively with prostaglandin can prevent shock and acidosis. For those with coarctation, antenatal diagnosis has been shown to permit presentation in a better condition, with less consequent mortality.⁶¹ There are difficulties, nonetheless, in prenatal diagnosis of coarctation. Although a certain combination of features is strongly suggestive of abnormalities in the aortic arch, there is a significant rate of false-positive diagnosis, particularly in late pregnancy.^{62,63} Severe coarctation is certainly associated with relative hypoplasia of the components of the left heart when compared with the right, and this is visible in early pregnancy, but this can also be a feature of the normal fetus later in pregnancy. Milder forms of coarctation, furthermore, are compatible with an entirely normal fetal echocardiogram, especially in the last trimester.

Cardiac Catheterisation and Angiography

In most cases, sufficient information can be obtained from clinical and non-invasive examination to decide on an appropriate plan for management. Cardiac catheterisation is of limited value in delineating further the anatomy in the neonate, and it is associated with significant

Figure 46-24 The echocardiographic images show interruption of the aortic arch between the left carotid artery and left subclavian artery (LSA), the latter arising from the descending aorta (DAO), opposite the arterial duct (D). AAO, ascending aorta; PA, pulmonary trunk; R, right pulmonary artery.

morbidity. It is rarely necessary for the assessment of associated anomalies. Indeed, even if significant mitral obstruction, mitral regurgitation or aortic stenosis is present, the baby is often better assessed after repair of the coarctation, when cardiac output, the effects of the arterial duct and other abnormalities of ventricular performance, have resolved. One potential indication for invasive assessment, nonetheless, is for intervention in the setting of coarctation. Controversy has surrounded the use of balloon angioplasty as the primary treatment for patients of various ages with coarctation since its first use in 1982.⁶⁴ This will be discussed in more detail below.

On the rare occasion that aortography is performed in the setting of interrupted arch, an injection into the ascending aorta will demonstrate, in three-fifths of cases, the classic V sign as seen in the frontal projection of the brachiocephalic and left common carotid arteries, as also seen in the echocardiogram (Fig. 46-24).⁴³ Occasionally, the V more resembles a U or W if all three arteries take origin proximal to the interruption. The appearance is still characteristic in that the aortic arch continues smoothly into its most distal branch proximal to the interruption, regardless of whether this is the brachiocephalic, left common carotid, or subclavian artery. If the aortic arch continues beyond its last branch, and appears to taper down to apparent complete obstruction, the diagnosis is either aortic atresia, or else severe coarctation with distal wash-in from the arterial duct and not interruption.⁶⁵

COURSE AND PROGNOSIS

The quoted mean length of survival is 31 years for those with coarctation surviving the first year without an operation, three-quarters being dead by the age of 46 years. This information was derived from clinical records and postmortem studies.⁶⁶ In a natural history study in which infants who died in their first year of life were excluded,⁶⁶ it was suggested that those presenting with congestive heart failure might have had a survival rate at 1 year as low as 16%, this figure taking no account of associated lesions.

In older patients, the cause of death was often related to systemic hypertension, the two most common findings being congestive cardiac failure and aortic dissection or rupture. Bacterial endocarditis was also common. An additional significant group died as a result of ruptured berry or saccular aneurysms causing intracranial bleeding, a feature more commonly found in coarctation.⁶⁷ Hypertension secondary to coarctation is not, however, thought to be the only pathogenetic factor. Abnormalities of the vessel wall are important, certainly in intracerebral catastrophes, but also with the other causes of death such as aortic dissection or rupture. Cystic medial necrosis and new structural abnormalities are seen in areas remote from the coarcted segment itself and may be unrelated to the type and age at surgery.

When considering interruption of the arch, the natural history is poor. Without surgery, three-quarters die in the first month of life, the majority in the first 10 days. Less than one-tenth survive without correction beyond the first year of life if there is co-existing ductal patency.^{16,68,69} With the evolution of prostaglandin therapy and surgical intervention over the past decades, the impact of the associated cardiac and extracardiac defects has become of greater relevance in interruption, although little long-term follow up is available.

The mortality from bacterial endocarditis has fallen markedly in recent years through improved diagnostic techniques, especially cross sectional echocardiography, and aggressive early treatment with antibiotics. If present, the site of endocarditis is often in the aorta, distal to the site of coarctation or interruption, or on an associated bicuspid aortic valve. At present, nonetheless, it is usually recommended that children with coarctation or interruption receive prophylactic antibiotics against endocarditis, even after definitive surgical repair, during dental, colonic and genitourinary procedures.

MANAGEMENT

Stabilisation of Neonates and Infants

Clinical management of infants with coarctation and interruption was dramatically changed in the 1980s by the advent of pharmacological means to maintain patency and reopen the arterial duct. This now enables the majority of infants with either preductal coarctation or interruption, who present with heart failure, shock and deteriorating renal function, to perfuse their lower body, albeit with systemic venous blood. This will, nonetheless, reverse the tissue ischaemia as long as ductal patency and flow is maintained. The beneficial effects of prostaglandin E_1 in maintaining ductal patency under both aerobic and anaerobic conditions⁷⁰ did not lead immediately to its use, but a decade later it was commonly used in patients with obstructive lesions such as coarctation and interruption.⁷¹ Prostaglandin E_1 is given initially at a dose of 0.05 to 0.1 $\mu\text{g}/\text{min}/\text{kg}$ body weight. This can be increased to 0.4 $\mu\text{g}/\text{min}/\text{kg}$ if required, although lower initial doses have been shown to be equally therapeutic and less likely to cause apnoea.⁷² The maximal response occurs between 15 minutes and 4 hours.⁷³ Occasional improvement has been documented in infants as old as 5 weeks, but treatment is generally less impressive in older neonates, and in those whose ducts are closed at presentation.^{73,74} Positive effects

have also been found on the diameter of the coarcted segment of the aorta without any reopening of the arterial duct, suggesting the presence of reactive ductal tissue in the aorta.^{75,76} Side effects can include a decreased respiratory drive leading to apnoea, occasionally requiring ventilation. There can also be hypotension with cutaneous vasodilation; jitteriness, which can lead to seizures; fever; susceptibility to infections; diarrhoea; and, more rarely, coagulopathy. For the neonates, management depends on timing of diagnosis. If the diagnosis has been made, or is strongly suspected, antenatally, then there is little to be lost from starting prostaglandin E_1 at birth. Certain centres advocate antenatal transfer and delivery in or close to the cardiac centre. If a neonate is found to have weak or absent femoral pulses, and remains well, it is justifiable to arrange transfer to a tertiary centre, having commenced prostaglandin E_1 to avoid the catastrophe of an acute closure of the duct during transfer.

In any infant becoming shocked within the first few weeks of life in the absence of pulses in the lower limbs, it should be mandatory to start prostaglandin along with the normal resuscitatory manoeuvres while expert assistance is sought. Ventilation with positive pressure will reduce the systemic demand for oxygen, and may improve cardiac failure. During ventilation, manoeuvres to increase pulmonary vascular resistance, and hence reduce the ratio of pulmonary to systemic blood flow, will lead to increased right-to-left flow through the arterial duct, thus improving perfusion of the lower body. The management is similar to that adopted in the pre- and post-operative care of the infant with hypoplastic left heart syndrome (see Chapter 29). This will include minimising the fraction of inspired oxygen, maintaining arterial partial pressure of carbon dioxide at 6 kPa or more, and the judicious use of volume and ionotropes. The outcome in these children with multi-organ failure is much more favourable if time is taken medically to stabilise them before carrying out definitive intervention.⁷⁷ If prostaglandin E_1 produces no effect of augmenting distal aortic flow, which occurs in a small proportion of patients, then immediate definitive treatment is required.⁷⁸

During the preoperative workup, patients require chromosomal analysis for 22q11 deletion using fluorescent in situ hybridisation. Levels of calcium need to be measured to exclude hypocalcaemia, and to anticipate it before clinical sequels, such as convulsions, develop. Infusions of calcium are useful in the acute phase. Subsequently, the management is identical to that of isolated hypoparathyroidism, involving oral supplementation of calcium and administration of vitamin D. Documentation of decreased levels of parathormone in the setting of low levels of calcium are diagnostically important before embarking on treatment, which should ideally be conducted with advice from a paediatric endocrinologist. Abnormalities can occur in the function of the T cells, and it is important to assay their number and function. In the acute phase, infants with interruption should be presumed to have defects of the T cells. Transfusion, including cardiopulmonary bypass, should be performed using irradiated blood to avoid the possibility of transfused lymphocytes causing graft-versus-host disease. Later on, the susceptibility to infection may lead to the need for rotational antibiotics or other immune manipulation. These children often have developmental

delay and problems with feeding, both of which need a significant amount of medical input after repair.

Definitive Treatment

As yet, there is no single cost-effective technique with clearly demonstrable superior outcomes in the short-term and long-term, and without significant side-effects, for all types of coarctation and interruption. The pursuit of a single ideal form of therapy for all forms of coarctation is almost certainly misguided, as the obstructive lesions show great variability in their morphology, even before ductal patency and associated intracardiac lesions are considered.⁷⁹ Furthermore, a significant proportion of the literature is now of only historical value, as over the past 50 years both surgical and cardiological techniques and medical resuscitation have improved greatly, and prostaglandin has been introduced. Many studies exist, but are based on different groups of patients from different periods of time, and treated with different techniques.⁷⁹ Large multi-centric randomised controlled trials of the various forms of surgical and interventional cardiological techniques for various types of coarctation, therefore, are long overdue.

Non-elective Surgical Repair

The majority of infants with duct-dependent circulations can be stabilised medically, and will benefit from an interlude before definitive treatment while metabolic derangements are corrected. These infants, nonetheless, will need relief of their aortic obstruction within 1 or 2 days of presentation. There have been reports that minimally symptomatic infants with isolated coarctation can be managed medically for a period of time.^{80,81} Nowadays, even those born with coarctation and very low weight, less than 2 kg, can undergo corrective surgery with a low mortality, but will be at a higher risk of recoarctation.⁸² The majority of symptomatic infants undergo surgery with little delay. There is a subgroup of patients who present in cardiogenic shock and cannot easily be stabilised medically. Timely intervention, with the therapeutic strategy individualised to the anatomy, has been shown to give excellent outcomes in neonates with coarctation.⁸³ There is ongoing debate, nonetheless, about the procedure of choice, and whether the associated defects should be addressed at the same time as resection of the coarctation, or at a second procedure.

The major concern remains the significant incidence of recoarctation. Difficulties arise in the interpretation of the data, as some papers cite residual gradients from arm to leg, others measure differences between the arms, whereas still others measure the difference in the pressure between the arms and legs as exposed by exercise. Furthermore, many cases that are termed recoarctation represent residual coarctations. In order to try to standardise these features, four patterns of gradients have been described between the arms and legs after initial surgery.⁸⁴ The first pattern results in complete and permanent abolition of the gradient after surgery, the second leads to an initial abolition followed by late recurrence. The third group has initial residual obstruction followed by late resolution, whereas the last group has persistent residual obstruction. Defining rates of recoarctation as the percentage of patients undergoing surgery who are known to have recoarctation at the time of reporting,

is very dependent on the period over which progress has been monitored, and therefore actuarial rates of recoarctation should be used.^{85,86}

Management of Associated Lesions in Infancy

The management of associated lesions is tailored according to clinical needs and pathology. An arterial duct, if patent, should be ligated during surgery. Controversy surrounds the management of concomitant ventricular septal defects when treating coarctation in neonates and infants. Some opt for repair of the coarctation through a lateral thoracotomy, with subsequent assessment of progress. In this approach, inability to wean from the ventilator, or failure to thrive, would indicate the need for surgical closure of the ventricular septal defect. Its advantages include allowing improvement in ventricular performance, pulmonary oedema, and the general condition of the infant. It may even buy time for spontaneous closure of small defects. More frequently, especially if there is a single defect and the child is not small, the option nowadays is to proceed with complete repair in one stage. This involves closing the defect, together with repair of coarctation, via a midline sternotomy. In earlier times, this was associated with higher mortalities, but contemporary reviews suggest this is no longer the case.⁸⁷ Another alternative is to use only one operation, but to repair the coarctation through a left thoracotomy, using a subsequent sternotomy to correct the intracardiac defect.⁸⁸ This approach has the downside of multiple incisions but will lead to shorter periods on bypass, and avoids any circulatory arrest. It also reportedly decreases the time spent in both intensive care and hospital.⁸⁸ The least fashionable option nowadays is to repair the coarctation and band the pulmonary trunk. This option remains valid for those with multiple ventricular septal defects, or for those in whom the defects are judged inaccessible. It is rarely recommended for the management of single large defects. The presence of a left-to-right shunt prior to repair of the coarctation, and extension of the defect into the right ventricular inlet or outlet, nonetheless, are two situations in which the ventricular septal defect is less likely to close spontaneously.⁸⁹ In addition more complicated associated defects, such as transposition, double outlet right ventricle, tricuspid atresia or double inlet ventricle, also need to be taken into consideration and addressed at the time of repair of coarctation.

In those infants at the extreme end of the spectrum with multiple obstructive lesions in the left heart, such as Shone's complex, the prognosis is more guarded with a significant early mortality, although there possibly is some benefit from aggressive reconstructive surgery with early attention paid to the mitral valve.^{90,91} The late functional outcome can be favourable compared with more conservative approaches.⁹¹

Elective Repair

There has also been much debate regarding optimal age for surgical treatment in asymptomatic patients with coarctation. Various issues need to be considered. Generally, overall operative mortality is greatest in those under 1 year of age for most conditions, although this has improved greatly in recent years through a combination of improved medical and intensive care management and better surgical techniques. Furthermore, the likelihood of recoarctation is

related not only to the type of repair, but also to the timing of repair, being more common in those undergoing surgery under 1 year of age.^{92,93} Age at operation is also important with regard to the incidence of late hypertension. This was reported in one-tenth of patients after neonatal and early repair, but increased mortality was found in children undergoing repair over the age of 5 years.⁹² It had already been demonstrated that patients undergoing repair of coarctation in their late teens had an excessively high mortality from cardiovascular causes in later life.⁹⁴ There is an age, therefore, beyond which operative repair may not change the natural history of the disease.⁹⁴ These findings were subsequently confirmed by others, who also showed that residual hypertension was a poor prognostic factor.⁹⁵ Still others have since shown that hypertension can occur late after repair,⁹⁶ while a much higher incidence of permanent hypertension not caused by recoarctation is found in patients undergoing surgery above 4 years of age.⁹⁷ The break-point in another cohort was 1 year of age, with this group making recommendation some time ago for elective repair during the second 6 months of life.⁹⁸ Since then, scattered reports have appeared of permanent hypertension occurring in patients undergoing repair of coarctation in infancy, or even the neonatal period.^{99–101} The problem should, nonetheless, be kept in perspective, since one analysis found no patient with permanent hypertension without recoarctation among 118 survivors of repair of coarctation in infancy.¹⁰² In young asymptomatic children without duct dependent circulations, a more recent report has suggested that the timing of surgical repair does not seem to be a predictor of morbidity or mortality. It also does not predict residual hypertension, any residual gradient, persistent cardiomegaly, post-operative neurological sequelae, the requirement for a second surgery, or the need for balloon dilation for residual post-operative coarctation and the need for antihypertensive medications within five years after surgery within a follow-up of up to 20 years.¹⁰³ In hypertensive adults with coarctation, the hypertension was abolished without requirement for medication in two-thirds of the patients, although one-third of these were hypertensive on exercise.¹⁰⁴ Most adults with significant coarctation that has not been treated die before the age of 50 years from cardiovascular complications. A subset of patients can survive beyond this age, and for these the benefits of surgery are unclear. Surgery for such hypertensive patients can be undertaken with low morbidity and mortality, and most are symptomatically improved, with some normotensive at rest, although a majority remains hypertensive on exercise.¹⁰⁵ Some patients are found, nonetheless, in whom permanent hypertension will ensue irrespective of the age of repair. To some extent, all of this discussion has become irrelevant to contemporary management. Elective surgery is performed nowadays in most centres at, or shortly after, presentation at any age. The above discussion serves as a reminder of the potential long-term implications for those with the disease, no matter when, or how, it is repaired.

The risk of paraplegia is important. Pre-operative evaluation by magnetic resonance imaging to show the presence or absence of collateral circulation is now considered to be valuable in identifying the need for pre-emptive protective actions. Options include using a temporary bypass with a polytetrafluoroethylene tube from the ascending to the descending aorta,¹⁰⁶ or partial bypass from the left atrium to the descending aorta.¹⁰⁷

STRATEGIES FOR SURGICAL TREATMENT

Resection and End-to-End Repair

The era of repair of coarctation started during the second world war, when Blalock performed the first experimental repairs using either the turned-down left subclavian artery or the carotid artery to bypass the induced stenosis.¹⁰⁸ Gross, in Boston, had also demonstrated experimentally that resection with end-to-end anastomosis was feasible.¹⁰⁹ The first operation to resect congenital coarctation was performed by Crafoord in Stockholm.¹¹⁰ The coarctation was resected, and the aortic segments were anastomosed in end-to-end fashion. To this day, this remains the most common surgical procedure in older patients with discrete narrowing. Modifications of the technique have been suggested, including the combination of resection and end-to-end repair with a subclavian flap angioplasty. Recent reports suggest this to be a safe technique when used in infants, producing no mortality and very good resolution of the gradients.¹¹¹

As discussed earlier, there are, as yet, no proper randomised controlled trials comparing the many techniques used for surgical repair. Because of this, retrospective studies are used to provide the evidence required to guide optimal treatment. One such study compared end-to-end anastomosis to use of a subclavian flap for repair in infants younger than 3 months of age.¹¹² The outcomes were similar, with a similar risk of recoarctation, albeit due to different mechanisms. The expertise of the surgeon was deemed to be the primary determinant of outcome.

Interposition Grafts

Although the first use of a graft¹¹³ ended in failure, Gross a year later interposed an aortic homograft across the coarcted segment.¹¹⁴ For a time, this was considered the treatment of choice for infants with coarctation, with successful repairs being reported in a 10-week-old infant,¹¹⁵ and in a neonate.¹¹⁶ A similar approach, but using prosthetic conduits, was introduced later.¹¹⁷ This remained useful in older patients with aneurysms, in those with complex anatomy, or for those in whom approximation of the cut ends could not be accomplished during attempted end-to-end anastomoses.¹¹⁸ Disadvantages include use of prosthetic material, and hence increased risk of infection, lack of potential for growth, and obviously the need for two anastomoses.

Extra-anatomical Bypass Grafts

The extra-anatomical bypass of complex coarctation through a sternotomy, used mainly in adults, has been promoted as a safe alternative to the alternative approach through a thoracotomy.¹¹⁹ The technique yielded good results in the mid to long term, with no graft-related deaths or complications, and significant decrease of systolic blood pressures. The technique can be accomplished without the use of cardiopulmonary bypass when using a heart-lifting device.^{120,121}

Patch Aortoplasty

Because of initially poor results using end-to-end anastomosis, with recoarctation reported in up to three-fifths of patients,^{122,123,124} different mechanisms of repair were

Figure 46-25 The post-operative ascending aortogram shows obvious aneurysmal dilatation of the aorta at the site of previous patch aortoplasty.

sought. Plasty of the aortic isthmus had already been introduced in 1957,¹²⁵ and from this developed the technique of patch aortoplasty. An elliptical patch of Dacron, or polytetrafluoroethylene, was placed over the site of coarctation opposite the site of ductal insertion, with claims made for reduction in rates of recoarctation.¹²⁶ Differences in pressure between arms and legs induced by exercise were also shown by two independent groups to be less after patch angioplasty than after resection followed by end-to-end anastomosis.^{127,128} The very high frequency of true aneurysms (Fig. 46-25) developing late and opposite the site of repair, nonetheless, has now led many centres to use this technique only if no alternative is available. The pathogenesis of aneurysms is not fully elucidated. It has been suggested that excessive resection of the ductal shelf weakens the aortic media.¹²⁹ Others have implicated deviations in haemodynamic patterns caused by differing tensile strength between the prosthetic patch and the posterior aortic wall,¹³⁰ with intensification of the pulse wave at the native wall. Use of polytetrafluoroethylene as material for the patch, but without resection of ductal tissue, promised improved results.¹³¹ A further retrospective comparison of end-to-end anastomosis with polytetrafluoroethylene patch aortoplasty accompanied by resection of the coarctation shelf revealed a similar rate of recoarctation for the two techniques, but with development of aneurysms after patch repair, and more late hypertension.¹³² This technique, therefore, is nowadays rarely used.

Subclavian Flap Repair

The initially reported high incidence of recoarctation with the techniques available for repair caused surgeons to develop still other approaches, amongst which was subclavian flap aortoplasty.¹³³ This technique (Fig. 46-26) consists of mobilisation of the subclavian artery through a standard left thoracotomy, and ligation of the subclavian artery at its first branch, attempting to preserve the thyrocervical trunk and the internal thoracic artery in order to improve perfusion to the left arm.¹³⁴ A longitudinal incision is made across the coarctation from the subclavian artery to the

Figure 46-26 The cartoon shows the technique of subclavian flap aortoplasty. The dotted lines show the site of the initial surgical incisions into the narrowed arterial pathways.

Figure 46-27 This cartoon shows the technique of reversed subclavian flap aortoplasty. The dotted lines show the site of the initial surgical incisions into the narrowed arterial pathways.

area of post-stenotic dilation. The proximal stump of the subclavian artery is then opened anteriorly, turned down over the incision, and the edges closed. The vertebral artery is ligated to prevent any subsequent subclavian steal leading to cerebral ischaemia. The reported benefits using this technique over others include the use of exclusively native material, with consequent decreased risk of infection, and improved potential for growth,¹³⁴ no circumferential anastomosis, less extensive dissection, and less tension on the suture lines compared with the end-to-end repair. The obvious disadvantage is the loss of the main arterial supply to the left arm, and deleterious effects on growth of the arm have been reported. These range from mild discrepancy in length of the arm, similar to that following a Blalock-Taussig shunt, to rare reports of gangrene.^{135,136,137} Aneurysms have also been described,¹³⁸ but are less common than after patch aortoplasty.

Despite early studies suggesting a much lower incidence of recoarctation compared with other types of repair, some centres have moved away again from this technique after reports of unfavourable or equivocal results.^{137,139–143} Other centres have continued to use subclavian flap angioplasty as their preferred technique in infants and neonates, producing an acceptable incidence of recoarctation, varying between 3% and 13% depending on the age, low early morbidity and mortality, and an overall low incidence of late hypertension.^{144,145} A direct comparison between end-to-end resection and repair using a subclavian flap revealed a similar risk of recoarctation between the techniques, and as already emphasised, highlighted the experience of the surgeon as the major determinant of outcome.¹¹² Modifications of the subclavian flap technique itself have also been described. The most commonly used is the reversed

subclavian flap for obstructive lesions proximal to the left subclavian artery,^{133,146} or coarctations associated with tubular hypoplasia of the aortic arch,¹⁴⁷ where the reversal of the flap produces excellent relief of hypoplastic arches, and low rates of recoarctation (Fig. 46-27).

Attempts have also been made to address the loss of the subclavian artery, using techniques involving reimplantation^{148,149} or by using the internal thoracic artery to preserve the arterial supply to the arm.¹⁵⁰ Further variants have been described to deal with rare anatomical variants, such as anomalous origin of the right subclavian artery, involvement of the left subclavian artery in the obstructive lesion, and hypoplasia of the arch.^{151–153} The last technique consists of side-to-side transverse aortic anastomosis at the level of the coarctation, widening the coarctation segment and shortening the isthmus, pulling the distal end of the aortotomy more proximal, thus allowing creation of a tension-free aortoplasty. This is reported to provide very low rates of recoarctation, less than 5%, along with low morbidity and mortality even when used in neonates and infants.

Extended End-to-End Repair

The frequent finding of recoarctation by those using the subclavian flap for repair, particularly in very young infants, led to the introduction of the extended end-to-end repair.¹⁵⁴ Many now use this technique, or one of its modifications, electively, especially if there is associated tubular hypoplasia of the transverse arch or isthmus (Fig. 46-28). Whether tubular hypoplasia needs to be so specifically addressed is itself a contentious point. Proponents of the use of the subclavian flap argue that, in most patients, subsequent

Figure 46-28 The cartoon shows the technique of extended end-to-end repair of coarctation with or without associated arch hypoplasia.

growth of the arch is sufficient once the obstruction has been relieved.¹⁵⁵ They suggest that recoarctation is related to the original ductal shelf,¹⁵⁶ and not to hypoplasia of the arch. Some evidence certainly suggests that the hypoplastic arch does have significant potential for growth after repair.¹⁵⁷ Correction, nonetheless, must address hypoplasia of the isthmus and distal arch. Various modifications of the original procedure were therefore introduced, varying the position of the proximal clamp. The position of the distal clamp has not changed. Initially it was placed just proximal to the left subclavian artery, with the site of proximal anastomosis being the longitudinally cut underside of the aortic arch, the distal end being the obliquely cut descending aorta. The technique was modified further by moving the proximal clamp further proximally and being more aggressive with dissection of the aortic branches and the mobilisation of the arch.^{158,159} This allowed the surgeon better to address hypoplasia of the arch, placing the proximal clamp across the left subclavian, left common carotid and part of the brachiocephalic arteries, the tip being well down the left wall of the ascending aorta. This has reportedly led to a reduction in recoarctation,¹⁵⁹⁻¹⁶¹ but consensus is lacking due to variations in the reported experience of different surgeons.

Surgical Management of Interrupted Aortic Arch

Since the first repair of an interrupted arch using an end-to-end anastomosis was reported in 1955,¹⁶² various techniques have emerged, from repair using a flap combined with banding of the pulmonary trunk,¹⁶³ to eventual repair in one stage in 1972.¹⁶⁴ The first repair using direct anastomosis was reported 5 years later.¹⁶⁵ The introduction of prostaglandin revolutionised the preoperative management of these critically ill children. Furthermore, in recent years it has become more common place to perform the repair using one rather than two procedures.¹⁶⁶⁻¹⁶⁸ An area of debate has remained the material used to restore continuity of the aortic arch, either by end-to-side direct anastomosis, or by interposition of a tube graft, the latter being less favourable because of anatomical distortion and somatic outgrowth of the graft. Our current policy, mirroring practice in most large centres, is to avoid insertion of prosthetic material whenever possible, and to perform an end-to-side anastomosis of the distal segment to the ascending aorta in the same procedure as used to close the ventricular septal defect¹⁶⁹⁻¹⁷¹ (Fig. 46-29). Analysis of large cohorts has demonstrated that risk factors for death include low weight at

birth, younger age, interruption between the left common carotid and subclavian arteries, and presence of major associated cardiac anomalies.^{172,173} In the largest series, however, one-third of the patients had died after 16 years follow-up, and a repeated intervention on the arch had been needed in three-tenths.¹⁷² In a smaller series, nonetheless, survival of 83% had been reported at 5 years.¹⁷⁴ Reinterventions are more likely in those patients who did not have a direct anastomosis with patch augmentation. Patients with initial associated procedures to relieve obstruction in the left ventricular outflow tract had similar rates of survival and reoperation at 16 years. Reoperation for left ventricular obstruction is often related to development of new and discrete subaortic shelves or valvar stenosis.¹⁷⁵

Should the anatomy not be suitable for a biventricular strategy, such as with substantial subaortic obstruction and hypoplastic left heart syndrome, then reconstruction is feasible following the Norwood protocol.²⁷ This approach is indicated if the subaortic diameter measures less than 3 mm.^{176,177} It is also possible to baffle the left ventricular

Figure 46-29 This cartoon shows the technique of end-to-side anastomosis as used in repair of interruption of the aortic arch.

Figure 46-30 These ascending aortic angiograms are from a neonate before (A) and after (B) balloon dilation. The Doppler tracings show the initial gradient (C) across the narrowed aorta (Ao) and confirm (D) the excellent early haemodynamic result, showing abolition of the initial gradient. Severe recoarctation, however, occurred within 4 weeks. CoA, aortic coarctation; DAo, descending aorta; LV left ventricle.

outflow to the pulmonary trunk through the ventricular septal defect, creating a Damus-Kaye-Stansel anastomosis, and placing a conduit between the right ventricle and the pulmonary arteries.¹⁷⁸ Whenever possible, nonetheless, it is preferable to perform an anatomical correction, with resection of the subaortic lesions.^{179,180}

Balloon and Stent Angioplasty

A percutaneous approach to coarctation (Fig. 46-30) was initiated clinically because surgical treatment of recoarctation carried increased morbidity and mortality.^{181–184} Balloon angioplasty had been assessed in animal studies^{185,186} and at a postmortem in a neonate who had died with a coarctation.¹⁸⁷ Initial results with balloon dilation of native coarctation were disappointing.¹⁸³ Of particular concern was the occasional incidence of aneurysms developing at the site of dilation (Fig. 46-31),^{188–190} comparing unfavourably in neonates and infants at the time with contemporary results of surgical repair. Rates of recoarctation of 83% for the former, and 40% for the latter, with complications involving the femoral artery in 20% and 10%, respectively, have been quoted by the most ardent proponents of angioplasty for native coarctation.¹⁹¹ These poor outcomes need to be placed in the context of continually improving

surgical results, and this is supported by prospective randomised studies and non-randomised studies.^{192,193} A small randomised study, for example, showed that balloon angioplasty, when used to treat children with coarctation, was associated with a higher incidence of formation of aneurysms and iliofemoral arterial injury than surgery.¹⁹⁴ The results of balloon angioplasty for native coarctation in selected older children and adults, nonetheless, are excellent in the mid term.^{195,196} Longer-term data, albeit from non-randomised studies, is also now becoming available to suggest that primary balloon dilation for discrete coarctation in adolescents and young adults has excellent results.^{197,198} This has to be placed in the light of surgery for a similar subset of patients, which also achieves a very high rate of success without the need for further pharmacological control of blood pressure.¹⁹⁹

Balloon angioplasty can be performed retrogradely via a femoral or umbilical arterial catheter,^{200,201} or antegradely via a patent oval fossa, the left ventricle and ascending aorta.^{202,203} Although no consensus exists regarding the size of the balloon, most choose a balloon that does not exceed the diameter of any part of the aorta outside the coarcted segment, which includes areas of associated tubular hypoplasia. Angiography should be repeated after dilation to assess the degree of damage to the arterial wall.

Figure 46-31 The ascending aortic angiogram is taken immediately after balloon dilation of severe aortic coarctation. There is early aneurysmal formation, with an obvious intimal flap posteriorly.

The recently dilated site should not be crossed with catheter tips or guide-wires to minimise the risk of aortic dissection, or even rupture.¹⁸² A successful balloon angioplasty requires tearing of the intimal and medial walls of the aorta,^{186,204} the extent of dissection produced being well illustrated by intravascular ultrasound, be the lesion native or residual.²⁰⁵ Even though the majority of the tears remain clinically unimportant, dissection requiring surgical intervention has been reported.^{206–208} Local problems include residual coarctation and development of aneurysms. Other serious complications occur at the site of vascular access. It is worth noting that balloon dilation is not entirely free from neurological sequelae, particularly if associated with anomalies in cerebral vasculature.²⁰⁹

Stent angioplasty can also produce good and safe results in children with native and recurrent coarctation, with excellent relief of the gradient in children, even in patients below 20 kg.^{210–213} Stenting has also been used in infants who could not undergo surgery for various reasons, as a bridge to a later definitive operation.²¹⁴ In older children and adults with native coarctation, balloon angioplasty with stenting has been shown to result in sustained reduction in gradients at early- and intermediate-term follow-up,^{215–219} but aortic aneurysm was detected in almost one-fifth of patients in one of these series. In selected adults, covered stents are useful, but aneurysms can still occur in patients with markers of aortic mural weakness. Refinements in the technique of deployment and design of the stent are needed to eliminate this risk.²²⁰ The stents can be deployed using magnetic resonance guidance.²²¹ A recent controversial paper by Wong and colleagues,²²² and its accompanying

editorial,²²³ highlighted again that, when it comes to comparing results of treatments for coarctation, we have little good quality head-to-head comparative evidence on which to base our decisions. Less robust evidence, and the preference of the individual physician, is used to formulate some of these decisions, and may bias inappropriately the process of informed consent.

Recurrent coarctations are now frequently being treated with success in children by angioplasty and stenting.^{195,210,224–227} Hypoplasia of the transverse arch appears to be the primary predictor for the need to reintervene. Generally, the results of balloon angioplasty are more successful for recurrent as opposed to native coarctation, with a lower incidence of formation of aneurysms,^{228,229} perhaps because of the surrounding scar tissue. In one analysis of results from a registry, nonetheless, acute angioplasty for native coarctation proved marginally superior to the same technique used for recurrent coarctation.²³⁰ Stenting of mild gradients, less than 20 mm Hg, has also shown to benefit some patients insofar that a proportion of them will not require medication for persistent hypertension.²³¹

EARLY COMPLICATIONS

Coarctation

Local complications after surgery can result from the lateral thoracotomy, or dissection of tissues around the coarcted site, or from cardiopulmonary bypass should there have been the need to repair associated defects. Severe complications after surgery include significant bleeding from suture lines, suggested by significant losses from the chest drains or worsening haemodynamics. This should prompt immediate re-exploration. Concomitant paradoxical hypertension, often seen after coarctectomy, should be aggressively controlled in order to take away pressure on suture lines. Patients with Turner's syndrome are at significant risk for this complication, possibly due to their abnormal connective tissue.²³² Damage to the thoracic duct can result in persistent chylous effusions.

Neurological complications are occasionally seen, including palsy of the recurrent laryngeal nerve or phrenic nerves, and Horner's syndrome. The most feared surgical complication is injury to the spinal cord with subsequent paraplegia. The risk for this complication is higher if there has been poor formation of collateral arteries around the site of coarctation, and low distal pressure of perfusion.²³³ Suggested interventions to minimise these risks have included minimising the period of aortic clamping, and pharmacological intervention when the pressure in the distal arch falls below 50 mm Hg in older patients.^{234,235} Other less frequently employed techniques include measuring somatosensory potentials,²³⁶ and drainage of cerebrospinal fluid.²³⁷ The distal pressure of perfusion is particularly important. If this drops too much, a temporary extra-anatomical shunt^{238,239} or partial bypass of the left heart, can be used to increase the distal perfusion, a technique that improves the margins of safety and maintains adequate perfusion of the anterior spinal artery.²⁴⁰ Occasionally, subclavian steal from the circle of Willis can result if the vertebral artery is left open during subclavian flap aortoplasty. It is also important to recognise an aberrant right subclavian originating from below the site of coarctation, as theoretically this can reduce the supply of blood to the spinal artery.²⁴¹

As already discussed, paradoxical hypertension is commonly seen after repair of coarctation, and tends to occur in two periods of time. The initial period is caused by a noradrenergic storm due to reduced stretch of the baroreceptors in the aortic arch and carotid arteries,^{242,243} and tends to subside after 24 to 72 hours. The second period produces the so-called post-coarctectomy syndrome, and occurs around the second or third postoperative day. It is associated with pan-arteritis distal to the site of repair, and is possibly due to sudden exposure of the distal vascular bed to much higher pressures after repair, causing intense arterial vasospasm and subsequent endothelial ischaemia.²⁴³ Renin has also been implicated, with normal levels found in the plasma prior to surgery, and paradoxically elevated levels afterwards.^{244–247} This post-coarctectomy syndrome can be abated by pharmacological manipulation, which includes smooth muscular relaxation, inhibition of angiotensin-converting enzyme, and β -blockade. The latter, if started prior to surgery, reduces both post-operative blood pressures and activity of rennin without affecting the usual rise in post-operative concentrations of noradrenaline in the plasma, suggesting a major role for the sympathetic nervous system.²⁴⁸ No clear relationship has yet emerged between these transient changes in blood pressure and long-term hypertension.^{249,250}

Interrupted Aortic Arch

Apart from the above mentioned complications, all of which can also occur after repair of an interrupted arch, it is important to exclude residual gradients across the repair, and incomplete resolution of intracardiac pathology, such as residual intracardiac shunts or stenosis of the outflow tracts. This should be achieved whilst the patient remains in the operating room, or if any deviation is noted from a routine post-operative recovery. This is most commonly achieved with echocardiography

LATE COMPLICATIONS

Coarctation

As we have discussed, there remains confusion regarding the definition of recoarctation. Most symptomatic patients require an intervention. Gradients measured using echodoppler assessment, and measurement of blood pressure in the limbs, tend to be reliable only in younger children, and magnetic resonance imaging with reconstruction and assessment of collateral flow is rapidly becoming the investigation of choice in most centres for assessment of recoarctation in older children and adults.²⁵¹ It has proven to be useful in assessing local and cardiac anatomy, particularly for assessing aneurysmal change, and estimation of gradients and severity of stenosis.^{252–254} As far as medium-term follow-up after repair of coarctation is concerned, it is evident that, left untreated, almost half the patients will develop hypoplasia of the aortic arch. Such hypoplasia, therefore, should be addressed at the same time as the coarctation itself.²⁵⁵ Very long-term data on survival and morbidity is sparse, but it appears that with the early techniques used to repair coarctation, there is an excess cardiovascular mortality and morbidity, and often a need for reintervention.²⁵⁶ These patients, therefore, need careful long-term follow-up.

Abnormal physiological responses after repair are found even in infancy. In the long term, these patients have also been shown to have impaired function of the conduit arteries, with abnormal responses to flow and nitroglycerin, and increased vascular stiffness in the pre-coarctation vascular bed.²⁵⁷ The elastic properties can be preserved with an early repair, but the reduced reactivity will remain. Cardiovascular complications secondary to hypertension have been shown to lead to reduced life expectancy, even after anatomically relieved obstruction in late childhood.^{258,259} In pre-school children after initial return to normotension and normal exercise capacity and function, a tendency develops for later abnormal physiological responses to exercise,²⁶⁰ with the appearance of upper body hypertension, and sometimes gradients across the vascular bed. Upper body hypertension is also seen without resting gradients across the repair, suggesting that pre-operative hypertension causes irreversible changes in the arteriolar walls with chronic baroreceptor dysfunction.^{261,262} This finding is underpinned by abnormal endothelial responses in the pre-coarctation vascular bed in adults after otherwise successful surgical repair in childhood.²⁶³ The exercise-induced hypertension appears unrelated to anatomical narrowing, but rather due to interaction between an enhanced sympathetic nervous system and structural and functional abnormalities of the pre-coarctation vessels.²⁶⁴ Another factor that may play in the aetiology is the shape of the arch after the repair, with an angulated gothic arch independently associated with abnormal responses of blood pressure, highlighting a subgroup of patients at risk for development of hypertension in young adult life.²⁶⁵ Long-term follow-up of patients after surgical correction shows that, despite a minority having a gradient greater than 20 mm Hg, a significant proportion have hypertension.²⁶⁶

These children also have abnormal left ventricular mass and diastolic dysfunction, thought to be due by some to occult gradients.^{267,268,269} The beneficial effects of relieving the burden of long-term cardiovascular complications by pharmacological intervention remains to be proven when the gradient does not produce symptoms. When comparing the use of a subclavian flap to end-to-end anastomosis, patients were shown to have a higher incidence of late hypertension, both during exercise and ambulatory monitoring, after the former procedure.²⁷⁰ Furthermore, there appeared to be lower residual aortic stiffness after an end-to-end anastomosis. These children can be encouraged to participate in sports 6 months after intervention if any residual gradient at rest is less than 20 mm Hg, and systolic pressure is normal on exercise. Should there be evidence of aortic dilation, mural thinning, or formation of aneurysms, participation should be restricted to low-impact sports.²⁷¹

Interrupted Aortic Arch

The anastomosis requires close observation. Those in whom a patch or conduit was used will, at some stage, require replacement due to somatic outgrowth. If a gradient develops across a direct anastomosis, then balloon dilation can successfully be used to provide relief.^{180,272,273} Intracardiac anatomy also requires repeated analysis, as ongoing obstruction in the left ventricular outflow tract may require surgical intervention.^{273,274} The size of the outflow tract, the site of interruption, and an aberrant course of the right

subclavian artery have been shown to be significant risk factors for future obstruction in the outflow tract.²⁷⁵

The outcome of repair of interrupted aortic arch is, to a large degree, dependent on the pre-operative state of the infant, this determining late neurological outcome in these children.²⁷⁶ Thus, neurodevelopmental delay has been found in those patients who have 22q11 deletion.²⁷⁷ Furthermore, pre-operative renal function, intracerebral haemorrhages, the number of cardioplegic injections, and age at operation all play an important role in outcome,¹⁷¹ but the overall survival, of around 70% at 5 years, is mostly determined by the associated lesions.^{171,272,278,279}

This retrospective study compares two different strategies within one institution over the past decade, demonstrating that completion of repair is achieved at an earlier age, with fewer operations and fewer incisions, when using single staged repair. This does not result in any increase in complications or in-hospital mortality.

- Kanter KR, Mahle WT, Kogon BE, Kirshbom PM: What is the optimal management of infants with coarctation and ventricular septal defect? *Ann Thorac Surg* 2007;84:612–618.

This important retrospective study compares various strategies and outcomes in a single high-volume institution of treatment of patients with either single-stage, two incisions but single-stage, or two-stage approach to coarctation and ventricular septal defect. It demonstrates that primary repair using a one-stage approach through separate incisions affords excellent clinical results, avoiding prolonged aortic cross-clamping, cardiopulmonary bypass and circulatory arrest. Furthermore, in comparison with a single-stage sternotomy-only approach, intensive care and hospital stay were significantly decreased.

- Cobanoglu A, Thyagarajan GK, Dobbs JL: Surgery for coarctation of the aorta in infants younger than 3 months: End-to-end repair versus subclavian flap angioplasty: Is either operation better? *Eur J Cardiothorac Surg* 1998;14:19–25.

This retrospective single centre study compared the end-to-end resection versus the subclavian flap technique, in the same centre in infants younger than 3 months of age. It reported a similar incidence of late recoarctation in both techniques, demonstrating that outcomes are mostly determined by a surgeon's expertise at the procedure.

- Kanter KR, Vincent RN, Fyfe DA: Reverse subclavian flap repair of hypoplastic transverse aorta in infancy. *Ann Thorac Surg* 2001;71:1530–1536.

Dealing with arch hypoplasia in the setting of coarctation can be challenging, and this study demonstrates nicely how a reversed subclavian flap offers excellent relief of arch hypoplasia and coarctation in infants with low rates of recoarctation, and acceptable operative and intermediate results, without the need for foreign material or cardiopulmonary bypass.

- Elliott MJ: Coarctation of the aorta with arch hypoplasia: Improvements on a new technique. *Ann Thorac Surg* 1987;44:321–323.

This modification of the extended end-to-end anastomosis for coarctation in the setting of arch hypoplasia, with extensive aortic arch branch dissection and descending aortic dissection up to the diaphragm, allows for a wide open anastomosis with low residual gradients.

- Jonas RA, Quaegebeur JM, Kirklin JW, et al: Outcomes in patients with interrupted aortic arch and ventricular septal defect: A multiinstitutional study. *Congenital Heart Surgeons Society. J Thorac Cardiovasc Surg* 1994;107:1099–1109.

This large multi-institutional study from the Congenital Heart Surgeons Society in North America looked at a large cohort of patients with interrupted aortic arch and ventricular septal defect. Risk factors for death included low birth weight, younger age at repair, interrupted arch type B, outlet and trabecular ventricular septal defects, smaller size of the ventricular septal defect, and subaortic narrowing.

- McCordle BW, Tchervenkov CI, Konstantinov IE, et al: Risk factors associated with mortality and interventions in 472 neonates with interrupted aortic arch: A Congenital Heart Surgeons Society study. *J Thorac Cardiovasc Surg* 2005;129:343–350.

This further study, also originating from the Congenital Heart Surgeons Society, and incorporating a few more years of this large cohort of patients and a long follow-up time up to 16 years, showed that after 16 years 33% of the patients had died and 28% had required reintervention on the aortic arch. A reintervention was more likely for those who had repair of common arterial trunk, repair of the interrupted arch by a method other than direct anastomosis with patch augmentation, and the use of polytetrafluoroethylene as either an interposition graft or a patch. Among those who had undergone an initial left ventricular outflow tract procedure, after 16 years 37% had died and 28% had undergone a second procedure.

- Cowley CG, Orsmond GS, Feola P, et al: Long-term, randomized comparison of balloon angioplasty and surgery for native coarctation of the aorta in childhood. *Circulation* 2005;111:3453–3456.

This important paper is a randomised study of balloon angioplasty and surgery for native coarctation in children between the ages of 3 to 10 years. Blood pressure, residual aortic obstruction, and exercise performance were evaluated. Median follow-up time was between 10 and 11 years after the initial intervention. There was no difference in resting blood pressure, coarctation gradient, exercise performance, magnetic resonance analysis of the aortic arch, or need for repeat interventions. There was a much higher incidence of early and late formation of aneurysms in patients undergoing balloon angioplasty.

- Rodés-Cabau J, Miró J, Dancea A, et al: Comparison of surgical and transcatheter treatment for native coarctation of the aorta in patients > or = 1 year old: The Quebec Native Coarctation of the Aorta study. *Am Heart J* 2007;154:186–192.

This is a contemporary multi-centric non-randomised series of children older than 1 year of age with native coarctation treated either with balloon, balloon and stenting or surgery, demonstrating again a comparable immediate haemodynamic result to surgery, and less morbidity and length of stay in hospital with angioplasty. Angioplasty was associated with a higher rate of reintervention and aneurysmal formation at a mean follow-up of 3 years.

- Hager A, Kanz S, Kaemmerer H, et al: Coarctation Long-term Assessment (COALA): Significance of arterial hypertension in a cohort of 404 patients up to 27 years after surgical repair of isolated coarctation of the aorta, even in the absence of restenosis and prosthetic material. *J Thorac Cardiovasc Surg* 2007;134:738–745.

This large cohort study with long-term follow-up up to 27 years after repair of coarctation demonstrates that a large proportion of patients remain hypertensive at long-term follow-up, but this is only caused in a small proportion by recoarctation. Even in those without prosthetic material or minimal-grade restenosis, there is a substantial incidence of arterial hypertension.

Vascular Rings, Pulmonary Arterial Sling, and Related Conditions

SHI-JOON YOO and TIMOTHY J. BRADLEY

The aortic arch, the arterial duct, and the right and left pulmonary arteries have close spatial relationships with the major airways and the oesophagus. Due to this close proximity, abnormalities in the size, position, and/or pattern of branching pattern of these structures may cause obstruction to the trachea, the bronchuses, or the oesophagus. Many of the abnormalities of position and branching, along with the so-called pulmonary arterial sling, are characterised by a complete or partial encirclement of the trachea and oesophagus, or the trachea in isolation, by a composite vascular structure. Although the terms ring and sling have been used somewhat loosely, we use vascular ring to denote a complete encirclement, and vascular sling an encirclement which is incomplete. Vascular rings and slings are the classic anomalies that cause symptoms and signs of obstruction to the airways and oesophageal compression. Not all rings and slings, however, result in clinically recognisable symptoms and signs. Conversely, there are other vascular abnormalities that do not form a ring or sling, and yet may produce significant obstruction of the airways and oesophagus. In this chapter, we discuss these various anomalies of the aortic arch and pulmonary arteries that may cause obstruction to the central airways.

ANOMALIES OF THE AORTIC ARCH

In this section, we discuss the abnormalities in position and/or branching of the aortic arch. The obstructive lesions within the arch, such as coarctation or interruption, are not generally included in this category. They are addressed in Chapter 46. Insight into the mode of development of the arterial trunks, and their pattern in the fetal circulation, is tremendously helpful in understanding the prenatal and postnatal features of the various malformations which involve the aortic arch.

Hypothetical Model of the Double Aortic Arch

The normal and abnormal development of the components of the aortic arch can best be understood by making reference to the model introduced by the pioneer pathologist, Jesse E. Edwards, in 1948 (Fig. 47-1).^{1,2} The model illustrates a relatively late stage of development, in that the distal intrapericardial outflow tract has been divided into the ascending aorta and pulmonary arterial trunk, and the descending aorta occupies a neutral position. The earlier stages of development will not be discussed here, in part because the precise morphogenesis of the outflow tracts has still to be clarified, but also because most of the

congenital malformations involving the aortic arch can be understood without knowledge of these earlier events, which are reviewed in Chapter 3.

In the hypothetical model, symmetrical aortic arches connect the ascending and descending aorta on each side, forming a complete vascular ring around the trachea and oesophagus. Each aortic arch gives rise superiorly to a common carotid artery and a subclavian artery. On each side, right-sided and left-sided arterial ducts pass between the pulmonary arteries and the distal part of the aortic arches, forming an additional vascular ring around the trachea and oesophagus. The hypothetical model, therefore, is made up of two vascular rings joined together at the descending aorta.

With normal development, it is the left aortic arch and left-sided arterial duct which persist, while the right aortic arch distal to the origin of the right subclavian artery, along with the right-sided arterial duct, regress (Fig. 47-2). As a result, the proximal part of the embryological right aortic arch remains as the brachiocephalic artery, which bifurcates into the right common carotid and right subclavian arteries. The brachiocephalic artery, of course, is also known as the

Figure 47-1 The hypothetical model for the perfect double aortic arch proposed by Jesse E. Edwards. As we will show, all malformations involving the arch can be understood on the basis of this model. LAA, left aortic arch; LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; PT, pulmonary trunk; RAA, right aortic arch; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery. (Modified from Edwards JE: Anomalies of the derivatives of the aortic arch system. *Med Clin N Am* 1948;32:925-948; and Edwards JE: Vascular rings and slings. In Moller JH, Neal AN [eds]: *Fetal, Neonatal, and Infant Cardiac Disease*. Norwalk, CT: Appleton & Lange, 1990, pp 745-754.)

Figure 47-2 This panel of cartoons illustrates the steps involved in normal formation of a left-sided aortic arch, with a left arterial duct. In the model of the hypothetical double arch as shown in the left hand diagram, the red bars indicate the segments that regress. In the normal left-sided aortic arch, shown in the right hand diagram, this results in disappearance of the right aortic arch distal to the origin of the right subclavian artery (RSA), along with right-sided arterial ducts. In the fetal circulation, as shown in the middle diagram, the aortic arch (red arrow), and the left arterial duct (blue arrow), make a V-shaped confluence at the descending aorta. In the postnatal circulation, the left arterial duct closes, becoming the arterial ligament, or as we will describe it, the ligamentous arterial duct. LAA, left aortic arch; LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; PT, pulmonary trunk; RAA, right aortic arch; RBA, right brachiocephalic artery; RCCA, right common carotid artery; RPA, right pulmonary artery. The red and blue arrows are used in comparable fashion in Figures 47-6, 47-9, 47-11, 47-13, 47-14, and 47-16.

Figure 47-3 The fetal echocardiogram across the upper mediastinum shows the normal left aortic arch and left-sided arterial duct, forming a V-shaped confluence at their union to form the descending aorta. PT, pulmonary trunk; SCV, superior caval vein.

innominate artery. It seems particularly perverse, however, to continue to designate an artery supplying vessels to the head and arms as being unnamed! The left-sided aortic arch, in sequence, gives rise to the brachiocephalic, left common carotid, and left subclavian arteries (Figs. 47-3 and 47-4). Anomalies can be positional, or reflect abnormal branching due to persistence of part or parts of the double arch that normally should have regressed. In exceptional cases, nonetheless, it still remains difficult to predict the embryological mechanism, even using the concept of the double arch.

Classification

Anomalies can be classified into four groups, depending on the position of the aortic arch relative to the trachea, and the pattern of branching of the brachiocephalic arteries:

- Left aortic arch with aberrant right subclavian or brachiocephalic artery
- Right aortic arch with aberrant left subclavian or brachiocephalic artery
- Right aortic arch with mirror-image branching
- Double aortic arch

Figure 47-4 The volume rendered magnetic resonance angiogram seen from the front (left panel), and the computed tomographic angiogram seen from above (right panel), show the normal arrangement of the left-sided aortic arch, which gives rise sequentially to the brachiocephalic, left common carotid, and left subclavian arteries (LCCA, LSA). LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RBA, right brachiocephalic artery; RCCA, right common carotid artery; RV, right ventricle; SCV, superior caval vein.

Most of the major anomalies produce a vascular ring, or else a sling, around the trachea and oesophagus. The only exception is the classic form of right aortic arch with mirror-image branching. Aberrant origin of a subclavian or brachiocephalic branch of the aortic arch produces encirclement of the trachea and oesophagus, since the anomalous artery takes a retro-oesophageal course. The arterial duct, regardless of whether it is patent or ligamentous, may also contribute to encirclement of the trachea and oesophagus. Occasionally the distal aortic arch itself has a retro-oesophageal course that causes oesophageal and tracheal compression. The assessment and description of the anomalies, therefore, should include description of:

- The position of the aortic arch relative to the trachea
- The location of the most proximal part of the descending aorta in relation to the spine
- The presence or absence of an aberrant branch
- The origin and insertion of the patent or ligamentous arterial duct, or rarely ducts

The anomalies producing a vascular ring or sling around the trachea and oesophagus are:

- Aortic arch anomalies forming a vascular ring:
 - Double aortic arch
 - Right aortic arch with aberrant left subclavian or brachiocephalic artery and left-sided arterial duct
 - Left aortic arch with aberrant right subclavian or brachiocephalic artery and right-sided arterial duct
 - Right aortic arch with mirror-image branching and retro-oesophageal left arterial duct between right-sided descending aorta and left pulmonary artery
 - Circumflex retro-oesophageal aortic arch
- Aortic arch anomalies forming a vascular sling or incomplete ring:
 - Left aortic arch with aberrant right subclavian or brachiocephalic artery and left-sided arterial duct
 - Right aortic arch with aberrant left subclavian or brachiocephalic artery and right-sided arterial duct
 - Circumflex retro-oesophageal aortic arch

Other anomalies that may have clinical significance include the cervical aortic arch, isolated origin of the left

or right subclavian artery from a pulmonary artery, and double-barreled, or double lumen, aortic arch.

Morphology and Morphogenesis of Individual Anomalies

Double aortic arch is the tightest and most commonly recognised form of vascular ring.¹⁻¹⁰ It refers to the presence of two aortic arches, one on each side of the trachea and oesophagus (Fig. 47-5). Both the left and right aortic arches of the hypothetical model persist, without regression of any segment. An arterial duct, more frequently the left than the right, persists, although cases with bilateral ducts have rarely been described.¹¹ During fetal life, when the arterial duct is patent, the composite arrangement of the two arches and a patent arterial duct produces a figure of 9 or 6 configuration at fetal echocardiography.^{12,13} Each aortic arch gives rise to common carotid and subclavian arteries. In the majority of the cases with double aortic arch, both arches are patent. Usually the right arch is larger than the left arch, or less commonly the two arches are equally sized. The left arch is dominant in less than one-fifth of cases. In general, the apex of the larger arch is higher than the smaller arch. Occasionally, a segment of one arch may be atretic, mostly on the left. The atretic segment is almost always distal to the subclavian artery, although an atretic strand may also be found between the common carotid and subclavian arteries. The atretic segment cannot be visualised by any imaging modality. It is difficult, therefore, to differentiate a double aortic arch with an atretic segment distal to the origin of the left subclavian artery from a right aortic arch with mirror-image branching. Similarly, the double aortic arch with an atretic segment between the origins of the left common carotid and left subclavian arteries is difficult to differentiate from the right aortic arch with aberrant left subclavian artery and left arterial duct. In the setting of a double aortic arch, the subclavian and common carotid arteries that arise from the patent and atretic arches almost always show a symmetrical arrangement.¹⁴ The patent part of the atretic left aortic arch tends to have a more posterior position than the left brachiocephalic artery arising from the right aortic arch. An inferior kink of the

Figure 47-5 These computed tomograms, showing a complete double arch, are seen from behind and above (*left panel*), and from below (*middle panel*). The double arch encircles the trachea and oesophagus, with the right arch dominant. The reformatted image in the coronal plane (*right panel*) shows narrowing of the trachea due to compression by the dominant right aortic arch. The trachea is slightly bent to the left. LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

Figure 47-6 The cartoons show the mode of formation of a right aortic arch with aberrant origin of the left subclavian artery (LSA) and a left-sided arterial duct. In this, and the subsequent panels formatted in this fashion, the hypothetical model of the double arch is shown in the left hand diagram, with the red bars indicating the segments that will regress. The middle diagram shows the situation in the fetal circulation. In this variant, the right aortic arch (RAA), along with the remnant of the distal left aortic arch (LAA), the left-sided arterial duct, and the pulmonary trunk (PT), produce a U-shaped vascular loop around the trachea and oesophagus. As the two limbs of the U-shaped loop are attached to the heart, this produces a complete vascular ring. In the postnatal circulation, shown in the right hand panel, consequent to closure of the arterial duct, the proximal part of the aberrant LSA, representing the distal remnant of the left aortic arch usually persists as the so-called diverticulum of Kommerell. Note that the flow of blood in this distal remnant of the left aortic arch reverses direction after birth. LCCA, left common carotid artery; LPA, left pulmonary artery; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

proximal part of the common trunk for the subclavian and common carotid arteries in the presence of a diverticular outpouching from the descending aorta is a telltale sign of the presence of an atretic segment between the kink and the apex of the diverticulum.¹⁵ The proximal descending aorta is left-sided in just over two-thirds of patients with double aortic arch, being right-sided in almost all the rest, and only rarely occupying a neutral midline position.

Right aortic arch with aberrant left subclavian artery results from abnormal persistence of the right aortic arch, and abnormal regression of the left arch between the origins of the left common carotid and left subclavian arteries, the left subclavian artery taking its origin from the distal part of the left aortic arch (see Figs. 47-6 through 47-10). The distal remnant of the left aortic arch, along with the aberrant left subclavian artery, produces the retro-oesophageal component of the ring. It has previously been described that the aberrant artery may course either between the trachea and oesophagus, or in front of the aorta.¹ It is now usually believed that arteries that do not take a retro-oesophageal course are collateral arteries.² The persistent arterial duct is usually left-sided, connecting the left pulmonary artery to the distal remnant

of the left aortic arch (Fig. 47-6).^{1-7,10,16} This combination is the second commonest type of ring reported in most series. During fetal life, when the arterial duct is widely patent, this combination is characterised by a U-shaped vascular loop that encircles the trachea and oesophagus from behind (Figs. 47-6 and 47-7).^{12,17-20} This U-shaped loop consists of the ascending aorta, the right aortic arch, the distal remnant of the left aortic arch, the left-sided arterial duct, and the pulmonary trunk. Although the vascular loop looks open anteriorly, a vascular ring is completed by the underlying heart. This configuration changes dramatically with closure of the arterial duct after birth. The left limb of the U-shaped loop disappears with ductal closure, while the distal remnant of the left aortic arch persists as a diverticular outpouching, with the left subclavian artery arising from its apex. The diverticular outpouching is called the diverticulum of Kommerell (Figs. 47-7 and 47-8).²¹⁻²⁴ Flow through this distal remnant, is from the left-sided arterial duct into the descending aorta in the fetal circulation, but switches its direction with ductal closure so that the aberrant left subclavian artery is supplied from the descending aorta in postnatal circulation (see Fig. 47-6, right panel). Postnatally, therefore, the presence

Figure 47-7 These fetal echocardiograms illustrating the situation diagrammed in Figure 47-6 show a U-shaped vascular loop around the trachea. Note the extent of the gap between the ascending aorta and the pulmonary trunk (PT). SCV, superior caval vein.

Figure 47-8 These computed tomograms, from a different patient than the image shown in Figure 47-7, but illustrating the same anomaly, show a right aortic arch with an aberrant left subclavian artery (LSA) arising from a diverticulum of Kommerell. In the right panel, the expected location of the ligamentous arterial duct is marked with a red bar. Note the mild compression of the distal trachea. LCCA, left common carotid artery; LPA, left pulmonary artery; PT, pulmonary trunk; RCCA, right common carotid artery; RSA, right subclavian artery; SCV, superior caval vein.

of a diverticulum of Kommerell is indicative of presence of an arterial ligament between the apex of the diverticulum and the left pulmonary artery. This vascular ring is usually not as tight as that produced by the double aortic arch. The severity of the oesophageal and, to a certain extent, the tracheal, compression varies with the size of the diverticulum. When this type of anomaly is associated with significant

obstruction of the pulmonary outflow tract, as in tetralogy of Fallot, the diverticulum of Kommerell may be absent or inconspicuous (Figs. 47-9 and 47-10). This is because the flow of blood through the left arterial duct was reduced, or even reversed, during fetal life. The distal remnant of the left aortic arch, therefore, does not persist as a diverticular outpouching after ductal closure.¹² Postnatally, an arterial

Figure 47-9 The cartoons show the mode of formation of the right aortic arch (RAA) with aberrant left subclavian artery (LSA) and right-sided arterial duct, the pattern following the same format as for Figures 47-2 and 47-6. In the fetal and postnatal circulations, this arrangement produces a vascular sling on the right side of the trachea and oesophagus. This is a rare combination. LAA, left aortic arch; LCCA, left common carotid artery; LPA, left pulmonary artery; PT, pulmonary trunk; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

Figure 47-10 These computed tomograms show a right aortic arch with aberrant origin of the left subclavian artery (LSA), but no arterial duct, in a newborn with tetralogy of Fallot and pulmonary atresia. The computed tomograms in axial and coronal planes show that the right aortic arch gives rise to the aberrant left subclavian artery with no intervening diverticulum of Kommerell. The pulmonary arteries were non-confluent, with the pulmonary circulation supplied by major aortopulmonary collateral arteries (MAPCA), with congenital absence of both arterial ducts. LCCA, left common carotid artery; SCV, superior caval vein.

ligament is suspected when the proximal left subclavian artery is tethered inferiorly toward the left pulmonary artery. The right-sided aortic arch with aberrant origin of the left subclavian artery is occasionally associated with persistence of the right arterial duct, or even absence of arterial ducts bilaterally (see Fig. 47-9). The latter combination is typically seen in tetralogy of Fallot with pulmonary atresia and pulmonary arterial supply via major aortopulmonary collateral arteries (see Fig. 47-10). This combination forms an incomplete encirclement or a vascular sling around the right side of the trachea and oesophagus. The right aortic arch with aberrant origin of the left brachiocephalic artery is rare.^{25,26} It results from abnormal regression of the left aortic arch proximal to the origin of the left common carotid artery. The persisting arterial duct is usually left-sided, completing a vascular ring.

Left aortic arch with aberrant right subclavian artery is the most common anomaly involving the aortic arch, but is usually asymptomatic.^{1,2,24,27,28} It results from abnormal regression of the right arch between the origins of the right common carotid and right subclavian arteries, leaving the right subclavian artery attached to the distal remnant

of the right-sided aortic arch (Figs. 47-11 to 47-13). As a consequence, the distal remnant of the right aortic arch and the right subclavian artery together constitute the aberrant segments. In most cases, it is the left arterial duct which persists. This combination forms a vascular sling around the left side of the trachea and oesophagus (see Fig. 47-12). Typically the aberrant left subclavian artery courses behind the oesophagus, but has been described to course between the trachea and oesophagus, although again these vessels may have been collateral arteries.^{1,2} When there is a right-sided arterial duct between the aberrant artery and the right pulmonary artery, there is a complete vascular ring (see Fig. 47-13). The ring consists of the ascending aorta, the left aortic arch, the descending aorta, the distal remnant of the right aortic arch, the right arterial duct, the right pulmonary artery, and the pulmonary trunk, with the heart itself completing the ring. In fetal life, when the arterial duct is a wide channel that connects the pulmonary artery to the descending aorta (see Fig. 47-13, middle panel), an ℓ -shaped loop is formed around the trachea and oesophagus. With closure of the right-sided arterial duct after birth,

Figure 47-11 The cartoons show the morphogenesis (*left panel*), fetal arrangement (*middle panel*), and postnatal structure of left aortic arch (LAA) with aberrant origin of the right subclavian artery (RSA) and left-sided arterial duct. In the hypothetical model, the *red bars* again indicate the segments that regress. In the fetal and postnatal circulations, a vascular sling is formed on the left side of the trachea and oesophagus. LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; PT, pulmonary trunk; RAA, right aortic arch; RCCA, right common carotid artery; RPA, right pulmonary artery.

Figure 47-12 The computed tomograms show a left aortic arch (LAA) and aberrant right subclavian artery (RSA) arising from the descending aorta, with no intervening diverticulum of Kommerell. The posterior wall of the trachea shows a shallow indentation from the aberrant right subclavian artery (*right panel*). LCCA, left common carotid artery; LSA, left subclavian artery; RCCA, right common carotid artery.

Figure 47-13 These cartoons, as with previous ones, show the derivation and structures of left aortic arch (LAA) with aberrant right subclavian artery (RSA) when the arterial duct is right-sided. In the hypothetical model, the red bars again indicate the segments that regress. In the fetal circulation (*middle panel*), the left aortic arch, the distal remnant of the right aortic arch (RAA), the right-sided arterial duct, and the pulmonary trunk (PT) produce an ℓ -shaped vascular loop around the trachea and oesophagus. As the two limbs of the ℓ -shaped loop are attached to the heart, there is a complete vascular ring. In the postnatal circulation (*right panel*), subsequent to closure of the arterial duct, the proximal part of the aberrant right subclavian artery, representing the distal remnant of the right aortic arch; persists as a diverticulum of Kommerell. Note that, as with the previous situation (see Fig. 47-6), the flow in the distal remnant of the right aortic arch switches its direction after birth. LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery; RCCA, right common carotid artery; RPA, right pulmonary artery.

the distal remnant of the right aortic arch persists as the diverticulum of Kommerell (see Fig. 47-13, right panel). It is theoretically possible for a left-sided aortic arch to be associated with aberrant origin of the right brachiocephalic artery, but thus far, as far as we are aware, this has not been reported. Aberrant subclavian or brachiocephalic arteries co-existing with either right-sided or left-sided aortic arches are often associated with other anomalies, including a common carotid arterial trunk, anomalous origin of the vertebral artery from the common carotid artery on the same side, anomalous point of entrance of the vertebral artery into the cervical spine, and an abnormal drainage site of the thoracic duct.¹⁶ Although these anomalies are clinically silent, they may be of practical importance to the surgeon.

A right-sided aortic arch with a mirror-image branching results from abnormal regression of the left aortic arch distal to the origin of the left subclavian artery (Figs. 47-14 and 47-15). This is the only anomaly of the aortic arch that does not constitute a vascular ring or sling, regardless of the presence of a left-sided or right-sided arterial duct. In this pattern, the persisting arterial duct is usually on the left, connecting the base of the left brachiocephalic artery to the left pulmonary artery.²⁹ Less commonly, the arterial duct is either on the right, or bilateral. Rarely, the arterial duct arises from the descending aorta on the right side, and takes a retro-oesophageal course to connect to the left pulmonary artery (Fig. 47-16).^{3,6,29-32} This is the only combination that constitutes a complete vascular ring in the presence of mirror-image branching. The anomaly results

Figure 47-14 The cartoons show the morphogenesis, fetal arrangement, and postnatal structure of a right aortic arch (RAA) with mirror-image branching, the red bars in the hypothetical model indicating the segments that regress. In the majority of cases, it is the arterial duct on the left side that persists, with regression of the left aortic arch (LAA) distal to the origins of the left subclavian artery (LSA) and the left arterial duct, along with the right-sided arterial duct. In the postnatal circulation, the left-sided arterial ligament connects the base of the left brachiocephalic or subclavian artery to the left pulmonary artery (LPA). Persistence of the right-sided arterial duct is uncommon. LCCA, left common carotid artery; PT, pulmonary trunk; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

Figure 47-15 The computed tomograms, seen from above and the front, show the aortic arch on the right side of the trachea. The aortic arch gives rise to the left brachiocephalic artery (LBA), the right common carotid artery (RCCA), and the right subclavian artery (RSA) in sequence. The expected location of the ligamentous arterial duct is marked by a red bar (right panel). Note that the left subclavian artery (LSA) kinks inferiorly, and the left pulmonary artery (LPA) is mildly stenotic, both highly suggestive of the presence of a left-sided arterial ligament. LCCA, left common carotid artery; MPA, pulmonary trunk; RPA, right pulmonary artery; SCV, superior caval vein.

Figure 47-16 The cartoons show the mode of formation of a right aortic arch (RAA) with mirror-image branching, and retro-oesophageal course of the left-sided arterial duct between the right-sided descending aorta and the left pulmonary artery (LPA). In the hypothetical model (left panel), the red bars indicate the regression of the left aortic arch (LAA) between the origins of the left subclavian artery (LSA) and the left arterial duct, along with the right arterial duct. In the fetal circulation (middle panel), a U-shaped vascular loop is formed around the posterior aspect of the trachea and oesophagus. In postnatal circulation (right panel), the left-sided arterial duct arises from the right-sided descending aorta via a diverticulum of Kommerell, extending to the LPA, to produce a complete vascular ring in this rare anomaly. LBA, left brachiocephalic artery; LCCA, left common carotid artery; PT, pulmonary trunk; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

from abnormal regression of the left aortic arch distal to the origin of the left subclavian artery and proximal to the insertion of the persisting left arterial duct, with regression of the right arterial duct. The distal left aortic arch remnant persists as a diverticulum of Kommerell.

Circumflex retro-oesophageal aortic arch is a rare form of aortic arch anomaly in which the aortic arch and the proximal descending aorta are placed on opposite sides of the spine (Figs. 47-17 to 47-19).^{33,34} This combination requires the aortic arch to make an additional arc to the

Figure 47-17 The computed tomograms show a circumflex and retro-oesophageal right-sided aortic arch. The aortic arch is located on the right side of the trachea, and makes a sharp oblique leftward and downward turn to course behind the oesophagus so as to connect to the left-sided descending aorta. The left subclavian artery (LSA) arises from the top of the descending aorta, with the presence of a diverticulum suggesting that a left-sided arterial ligament is present between the apex of the diverticulum and the proximal left pulmonary artery. LCCA, left common carotid artery; PT, pulmonary trunk; RCCA, right common carotid artery; RSA, right subclavian artery.

Figure 47-18 The cartoon shows the situation illustrated in Figure 47-17. LCCA, left common carotid artery; LSA, left subclavian artery; LVA, left vertebral artery; PT, pulmonary trunk; RCCA, right common carotid artery; RSA, right subclavian artery; RVA, right vertebral artery.

other side behind the trachea and oesophagus, thus reaching the descending aorta on the opposite side. The patterns of branching of the brachiocephalic arteries are variable. It is hard to explain this rare malformation. It occurs much more frequently with a right-sided than with a left aortic arch. When it occurs with a right aortic arch, the arch gives rise to the left common carotid, right common carotid and right subclavian artery from its segment on the right side of the trachea (see Fig. 47-17, left panel). Then the aortic arch makes a sharp oblique leftward and usually downward turn to connect to the left-sided descending aorta. The left subclavian artery arises from the transitional point of the retro-oesophageal part of the arch to the descending aorta. It can be named as an aberrant artery in the sense that it is the last, instead of the first, branch of the right aortic arch. It is not retro-oesophageal in location, but the aortic arch itself is behind the oesophagus. In most cases, the left subclavian artery arises from the aorta through a diverticulum of Kommerell. The apex of the diverticulum connects to the left pulmonary artery through a left arterial ligament, thus forming a complete vascular ring around the trachea and oesophagus. A circumflex retro-oesophageal aortic arch is rarely seen without aberrant origin of a subclavian artery, but does exist (see Fig. 47-19).²⁹ Hypoplasia of the retro-oesophageal segment of the aortic arch is common.³⁴

Figure 47-19 The magnetic resonance angiogram seen from behind (left panel) shows a normal left aortic arch with normal brachiocephalic branching, but the descending aorta takes an unusual oblique course to the right side. The transverse axial T1-weighted images (right panel) obtained at the levels marked on the angiogram clearly show the normal left aortic arch, but illustrate that the left main bronchus is compressed between the descending aorta and the right pulmonary artery (RPA) as the former takes its oblique retro-oesophageal course. LPA, left pulmonary artery; PT, pulmonary trunk.

Figure 47-20 The magnetic resonance angiogram shows a so-called cervical right aortic arch, which reaches to the apex of the right lung, where it makes a hair-pin turn. It shows mirror-image branching, but the branches are tortuous, and the origin of the right subclavian artery (RSA) is aneurysmally dilated. LBA, left brachiocephalic artery; LCCA, left common carotid artery; LSA, left subclavian artery; RCCA, right common carotid artery.

The aortic arch is described as being cervical when its apex reaches the upper mediastinum above the level of the clavicles (Figs. 47-20 and 47-21).³⁵⁻³⁷ It may be recognised as a pulsatile mass in the supraclavicular fossa or lower neck. A cervical arch is slightly more common on the right, often taking a circumflex retro-oesophageal course to form a vascular ring. A double aortic arch can also adopt a cervical position. The branching of the brachiocephalic arteries is abnormal in the majority of cases. In addition, it is common to find unusual tortuosity, obstruction and aneurysm of the aortic arch, and obstruction of a brachiocephalic branch or branches (see Figs. 47-20 and 47-21). A cervical aortic arch is often associated with tracheal obstruction because of crowding of vascular structures and airway in a confined small space of the upper mediastinum, especially when the aortic arch is right-sided and takes a hairpin turn.³⁸

Isolated origin of the subclavian artery from the pulmonary artery through the arterial duct is a rare type of anomaly in which the subclavian artery is disconnected from the aorta, instead taking its origin from the pulmonary artery

Figure 47-21 These magnetic resonance angiograms show that the severely hypoplastic cervical aortic arch, left-sided in this instance, reaches to the lower neck. It shows normal branching. Interrupted of the aortic arch has been suspected in this patient. LCCA, left common carotid artery; LSA, left subclavian artery; RBA, right brachiocephalic artery.

Figure 47-22 The hypothetical model for the double arch is used to explain isolated origin of the left subclavian artery (LSA) from the left pulmonary artery (LPA) through the left arterial duct (left panel). The red bars show regression of the left aortic arch (LAA) in two locations, both proximal and distal to the origin of the left subclavian artery. As the distal interruption is distal to the insertion of the left arterial duct, the LSA becomes isolated from the aortic arch, instead retaining its connection with the left pulmonary artery. The right arterial duct also persists. The middle and right panels show the arrangements in the fetal and postnatal circulations. LBA, left brachiocephalic artery; LCCA, left common carotid artery; PT, pulmonary trunk; RAA, right aortic arch; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery.

Figure 47-23 These contrast-enhanced magnetic resonance angiograms reformatted in right anterior oblique (*left panel*), left anterior oblique (*middle panel*), and frontal (*right panel*) planes show that there is a right aortic arch that gives rise to the left common carotid, right common carotid, and right subclavian arteries (LCCA, RCCA, RSA) in sequence. The left subclavian artery (LSA) arises from the proximal left pulmonary artery (LPA) through the left-sided arterial duct. The right arterial duct is patent between the right pulmonary artery (RPA) and the descending aorta. Note that the right arterial duct has an ampullary dilatation (*asterisk*) at its pulmonary arterial end. LV, left ventricle; LVA, left vertebral artery; MPA, pulmonary trunk; RA, right atrium; RV, right ventricle; RVA, right vertebral artery. (Reprinted with permission from Sun AM, Alhabshan F, Branson H, Freedom RM, Yoo SJ: MRI diagnosis of isolated origin of the left subclavian artery from the left pulmonary artery. *Pediatr Radiol* 2005;35:1259–1262.)

on that side through the persistently patent arterial duct (Figs. 47-22 and 47-23).^{39–41} It is explained on the basis of abnormal regression at two locations in the hypothetical double arch (Fig. 47-22, left panel), one proximal and the other distal to the origin of the affected subclavian artery. Such isolation occurs more commonly when the aortic arch is right-sided, with the left subclavian artery being the isolated artery in the majority of cases. Flow to the isolated artery varies according to the size of the persistently patent arterial duct, and the patency of the pulmonary outflow tract. When the arterial duct is wide open, and there is no pulmonary obstruction, the left subclavian artery is supplied through the pulmonary arteries. If associated with significant pulmonary obstruction, the flow through the arterial duct may be reversed. Postnatally, when the arterial duct closes, the anomalous artery may lose its primary supply of blood, and can result in vertebral steal on the side of the isolated artery. Brachiocephalic or carotid arteries can also be isolated in comparable fashion.⁴²

Double-barreled, or double lumen, aorta is a rare anomaly in which the ascending and descending components of the aorta are connected by two aortic arches on the same side of the trachea (Fig. 47-24).^{42–44} It should not

be confused with the double aortic arch, in which each arch is to the opposite sides of the trachea. In the past, this anomaly has been interpreted as persistence of the embryological fifth aortic arch.⁴³ The existence of the fifth aortic arch in human and mammalian embryos, however, remains controversial, never having been encountered during normal development.⁴⁵

Incidence, Genetics and Association with Anomalies

The overall incidence of anomalies involving the aortic arch is difficult to estimate, since an unknown but significant number of individuals having such anomalies do not present with symptoms, and thus remain undiagnosed. The reported incidences of individual anomalies, therefore, vary significantly according to the population studied. A left aortic arch with aberrant origin of the right subclavian artery, which is usually found as an incidental and isolated anomaly, has been reported as the most common condition, being found in 0.5% of a large autopsy series.² In patients with other cardiac defects, a right aortic arch with mirror-image branching is the most common malformation.²⁹

Figure 47-24 The computed tomograms show a double-barreled aortic arch in a patient with tetralogy of Fallot and pulmonary atresia. LPA, left pulmonary artery. (Reprinted with permission from Bernasconi A, Goo HW, Yoo SJ: Double-barreled aorta with tetralogy of Fallot and pulmonary atresia. *Cardiol Young* 2006;17:98–101.)

Association with congenitally malformed hearts varies according to the individual lesions. A right aortic arch with mirror-imaged branching is almost always associated with congenital cardiac disease.²⁹ A right aortic arch is common in tetralogy of Fallot and common arterial trunk, with the incidence ranging from one-sixth to over one-third for both lesions. When tetralogy is associated with pulmonary atresia, the incidence is high at one-third. A mirror-imaged right aortic arch is less frequently seen in transposition, tricuspid atresia, and isolated ventricular septal defect. When not associated with intracardiac anomalies, the mirror-imaged right aortic arch is commonly associated with absence or stenosis of the proximal left pulmonary artery.²⁹ The rare mirror-imaged right aortic arch with retro-oesophageal left-sided arterial duct is uncommonly associated with other cardiovascular anomalies. Right aortic arch with aberrant left subclavian artery is also less commonly associated with congenital cardiac disease, with the reported incidence ranging from less than one-fifth to over three-fifths.^{4,6,7} The most commonly associated malformations are ventricular and atrial septal defects, tetralogy of Fallot, and transposition. Left aortic arch with aberrant right subclavian artery is much less commonly associated with other malformations, and therefore is usually found as an incidental finding. Double aortic arch is associated with other cardiovascular anomalies in up to one-fifth of cases, the most common being atrial and ventricular septal defects, tetralogy of Fallot and patency of the arterial duct.⁴⁻⁹ Circumflex retro-oesophageal aortic arch is associated with congenitally malformed hearts in up to half of cases.³³ Although uncommon, a right aortic arch with or without an aberrant left subclavian or brachiocephalic artery may be associated with an obstructive lesion of the aortic arch, especially when the arch forms a circumflex retro-oesophageal or high cervical course, or both (see Fig. 47-21).⁴⁶⁻⁴⁸ Rarely, interruption can be found in a right aortic arch.^{47,49}

Non-cardiac anomalies are infrequently associated with anomalies of the aortic arch. The most important non-cardiac anomaly is the oesophageal atresia with or without the VACTERL (vertebral, anal, cardiac, tracheal, oesophageal, renal, and limb anomalies) association.^{8,50,51} It has been reported that oesophageal atresia seen in association with such anomalies of the aortic arch tends to have a long gap.⁵⁰

Chromosome 22q11 deletion syndrome is common.⁵²⁻⁵⁴ This deletion is considered to affect migration of cells from the neural crest that contribute to development of the ventricular outflow tracts and pharyngeal arches in the embryo. The precise mechanisms of abnormal development of the aortic arches, however, remain speculative. A fetal series showed an 8% incidence of 22q11 deletion in fetuses with a right aortic arch as an isolated abnormality, and 46% in those with right aortic arch and intracardiac abnormality.¹⁹ Postnatal series showed higher incidences of 22q11 deletion, this being found in up to one-quarter of cases with an isolated anomaly of the aortic arch.^{52,53} The higher incidence of 22q11 deletion in postnatal series is explained by selection bias, as these patients are more likely to be referred to a cardiologist.¹⁹ More than half of the patients with an intracardiac anomaly and 22q11 deletion have an anomaly of the aortic arch.⁵⁴ In patients with anomalies of the ventricular outflow tracts, anomalies of the subclavian arteries

function as an important anatomical marker for chromosome 22q11 deletion, independent of the laterality of the aortic arch.⁵⁵ The subclavian arterial anomalies encompass aberrant origin from the descending aorta, isolated origin, distal ductal origin from the pulmonary artery, and cervical origin. Chromosome 22q11 deletion was present in greater than three-quarters of such patients with abnormalities of the ventricular outflow tracts and abnormal subclavian arteries, while it was present in less than three-tenths when there was no subclavian arterial anomaly. The patients with tetralogy of Fallot with chromosome 22q11 deletion show higher incidence of cervical aortic arch.⁵⁶ Down syndrome has also been shown to be associated with an increased risk for aberrant right subclavian artery.^{5,57,58} In the presence of an anomaly of the aortic arch, therefore, fetal karyotyping is recommended, especially when it is associated with intracardiac anomalies, extracardiac malformations, or an increased nuchal translucency.¹⁹

Clinical Findings

Patients with a vascular ring or sling may develop symptoms and signs of airway obstruction and/or oesophageal compression.³⁻¹⁰ Clinical manifestations vary with the severity of encroachment on the trachea, bronchus or oesophagus by the abnormal artery or arteries. The severity of compression of the trachea and oesophagus not only depends on the type of anomaly, but is also affected by the size and shape of the thoracic cage enclosing the vascular structures and airway. For instance, a chest cage with diminished anteroposterior diameter, as in stove chest or straight-back syndrome, is associated with more severe compression than a normally shaped chest cage. In addition, dilation of a vascular component of the anomalous aorta or its neighbouring vessel, and hyperinflation of the lungs, may further compromise the patency of the airway and oesophagus.

Patients with a vascular ring are more frequently symptomatic than those with a vascular sling. Tighter vascular rings usually present early in life with respiratory symptoms, while looser rings or slings may present later with symptoms of oesophageal compression. Patients with a double aortic arch tend to have the earliest onset of symptoms. Common presenting symptoms are respiratory, including stridor, wheezing, and cough. Study of a large cohort showed that symptomatic patients have significantly altered tracheal geometry, with smaller diameters and cross sectional areas compared to asymptomatic patients.⁵⁹ The characteristic stridor is inspiratory, but it may be both inspiratory and expiratory. Stridor may not be obvious during sleep or quiet play and is exacerbated by exertion or crying. The severity and pattern of stridor or noisy breathing can change with position. There may be a history of recurrent respiratory infections requiring medical attention, and some patients have been referred for an evaluation of suspected asthma or bronchiolitis. Infants with a tight vascular ring may show life-threatening reflex apnea with feeding. Some infants show opisthotonic posture, with hyperextension of the neck to relieve tracheal compression.⁶ Respiratory symptoms seen in infancy or early childhood may disappear with conservative medical treatment as the thoracic cage becomes more spacious as the patient grows.⁶⁰

Symptoms of oesophageal compression, including dysphagia or choking, usually develop later when the patient commences to take solid foods. Dysphagia is often the first symptom in older patients.^{16,23} This late onset of dysphagia may be related to the elongation of the aorta, or be secondary to aneurysmal changes of an existing diverticulum of Kommerell or the adjacent descending aorta.^{16,24,28} Dysphagia may be associated with frequent aspiration. A vascular ring is occasionally diagnosed at the time of removal of foreign bodies, such as chicken bones and coins. When a diverticulum of Kommerell develops aneurysmal change, it may be complicated by dissection and frank rupture.^{16,21,24,28}

The majority of patients with isolated abnormalities grow adequately. Uncommonly there may be failure to thrive and poor physical development due to frequent pulmonary infections, and/or difficulties with feeding. Rarely, the patient may present with the symptoms of compression of a nerve plexus by an abnormally positioned aorta or its branch.³² Incidental discovery of an anomaly is not uncommon following imaging for other medical problems.

Diagnostic Investigations

The chest radiograph is a simple and logical starting point for the imaging algorithm (Fig. 47-25). It provides information regarding not only the position of the aortic arch, but also the pulmonary complications of the anomaly, if present. The laterality of the aortic arch relative to the trachea is usually readily apparent. The trachea is bent to the other side of the aortic arch. The tracheal air column usually shows a subtle indentation caused by the aortic arch. In most cases, the position of the arch can be traced back from the descending aorta, which can be identified as a vertical linear stripe along the bony spinal column. When the aortic arch and the vertical linear stripe of the proximal descending aorta are seen on the opposite sides, a double aortic arch, or a circumflex retro-oesophageal aortic arch with the descending aorta on the other side, should be suspected. A double aortic arch may cause a concentric narrowing, with bilateral indentation in the lower trachea, but more frequently, the narrowing is asymmetric

and the indentation is unilateral. Bilateral indentation by other types of vascular ring is rare. The lateral view may show anterior bowing of the distal trachea when there is a large retro-oesophageal component (Fig. 47-26). A dilated proximal oesophagus containing air may suggest the presence of retro-oesophageal component. The superior mediastinum is wide when there is a cervical aortic arch, and a mediastinal mass can be mistakenly suspected. The superior mediastinum in young children, however, is normally wide because of a large thymus. Atelectasis or pneumonic consolidation involving various lung regions may be present and mask the underlying malformation. In some cases, hyperinflation of the lungs or parts of the lungs may be the predominant radiographic feature.

Although the barium oesophagogram was previously used as a valuable adjunct, its use is almost abandoned now because it does not provide a definitive diagnosis while exposing the patient to radiation.⁶

The definitive diagnosis can be made by using echocardiography, X-ray angiography, computed tomography or magnetic resonance imaging. Echocardiography is always indicated with aortic arch anomalies to exclude any associated intracardiac anomaly. A standardised echocardiographic approach to locate the position of the aortic arch, and its pattern of branching, is always an essential component of the evaluation of suspected congenital cardiac disease.⁶¹ For this purpose, the transducer is positioned transversely in the suprasternal notch and starting with downward angulation, a gentle sweep upward allows identification of the aortic arch position relative to the trachea and the origins and branching pattern of the head and neck branches. In the normal left aortic arch, the first branch heads rightward and bifurcates into the right common carotid and subclavian arteries. Whereas, in the right aortic arch with mirror-image branching, the first branch heads leftward and bifurcates into the left common carotid and subclavian arteries (Fig. 47-27). If the first branch does not bifurcate, then an aberrant subclavian artery should be suspected (Fig. 47-28). Alternatively, a common origin of the right brachiocephalic and left carotid arteries, or a separate origin of the left vertebral artery proximal to the left subclavian artery, can both occur in approximately

Figure 47-25 The frontal chest radiographs show a normal left aortic arch (*left panel*) and a right aortic arch (*middle panel*). The trachea shows slight indentation on the same side of the aortic arch and is bent slightly to the other side when there is a left or right aortic arch. The aortic arch can be traced downward to the vertical linear stripe of the descending aorta on the same side (*arrows*). In the setting of a double aortic arch (*right panel*), the distal trachea shows narrowing on both sides. In this case, the descending aorta can be traced down the left side (*arrows*) and pneumonic consolidation is seen in the right middle lobe (*right panel*).

Figure 47-26 These lateral chest radiographs correspond to those shown in Figure 47-25. The left panel shows a normal left aortic arch and a normal trachea, which takes a straight course without narrowing. When the aortic arch is right-sided, and an aberrant left subclavian artery arises from a diverticulum of Kommerell, as in the middle panel, the trachea is bowed forward by the diverticulum (*arrows*). In the setting of a double aortic arch, as shown in the right panel, the distal trachea in this case shows diffuse narrowing (*arrow*), and pneumonic consolidation is seen in the right middle lobe.

one-tenth of otherwise normal left aortic arches. In a double aortic arch, if both are patent, both can be identified in this transverse suprasternal view. Echocardiography has the advantage that it can often be performed with no or minimal sedation at the bedside, and a complete diagnosis can be reached with echocardiography alone when the vascular anatomy is simple, as in classic form of double aortic arch.⁸ Often the information provided by echocardiography is incomplete, and the assessment of the anatomy of the airways is not possible with ultrasound.

Although catheterisation with angiography was once the gold standard for the diagnosis, this has almost been completely replaced by computed tomography and magnetic resonance imaging. Both computed tomography and magnetic resonance imaging provide a clear road map allowing the construction of a precise preoperative strategy.^{6,62,63}

Computed tomography is perfectly suited for the simultaneous evaluation of the anatomy of the vascular structures and the airways.^{62–65} Recent introduction and development of the multi-detector technology in computed tomography has allowed high-resolution acquisition of data from the whole chest within a few seconds. Sedation or general anaesthesia, therefore, is rarely required, even in uncooperative children. Although computed tomography uses a large amount of radiation, the dose can be significantly reduced by carefully adjusting the imaging parameters, scan direction and the volume of coverage.⁶⁶ As the vessels in question are rather large structures, artifacts associated with using a low kilo-voltage and low milliamperage technique do not significantly reduce the diagnostic accuracy. The volume of tissue covered by computed tomography can be minimised by referring to the already available information. Every effort should be made to reduce the dose of radiation when computed tomography is performed. In performing a diagnostic procedure using radiation, taking beautiful pictures should not be regarded as a virtue. The real virtue is to take images of diagnostic quality, using the lowest possible dose of radiation. The axial images are reviewed by scrolling up and down in the workstation.

Three-dimensional reconstruction in various planes is mandatory. Three-dimensional reconstruction is useful, not only for demonstration of the anatomy, but also for more accurate diagnosis. Both maximum-intensity projection and volume-rendering algorithms are useful for the assessment of the vascular structures. Minimum-intensity projection with volume rendering algorithm is used for three-dimensional reconstruction of the airway. The volume rendered images of the vascular structures and airways can be merged to show spatial relationships. Endoluminal volume rendering also allows virtual tracheobronchoscopic demonstration of the airway.⁶⁷ The severity of the narrowing seen in the airways at routine computed tomography does not always correlate with symptoms and signs. In addition, a significant discrepancy in severity is often found between bronchoscopic and computed tomographic findings. This is because routine computed tomography has limitations in detecting dynamic airway narrowing. Dynamic narrowing can be assessed by scanning the airway in both inspiratory and expiratory phases when the patient can follow the imaging instructions.^{68,69} In infants and uncooperative patients, the suspected pathological region can be repeatedly scanned throughout the respiratory cycle to assess the dynamic nature of the obstruction (*Fig. 47-29*).⁷⁰ It does, however, require significant additional radiation.

Magnetic resonance imaging is also an excellent tool for the assessment of the vascular anatomy.^{62,63,71,72} Contrast-enhanced magnetic resonance angiography has been used for the assessment of the vascular structures. Three-dimensional volume data acquisition of the cardiovascular anatomy can be acquired without injection of contrast medium, by using an electrocardiographically gated balanced steady-state free precession sequence and respiratory navigation.⁷³ Double-inversion recovery sequence is a technique that can be used for the assessment of the airway. Real-time cine magnetic resonance imaging is a future direction for a dynamic airway assessment.⁷⁴ Magnetic resonance imaging is the preferred technique in cooperative children because it does not use radiation.

Figure 47-27 The panel of illustrations shows the standardised echocardiographic approach to show the anatomy of the aortic arch in a patient with right aortic arch and mirror-image branching. A, The position of the aortic arch relative to the trachea is identified in a downward tilted transverse view from a suprasternal approach. B, Sweeping upward with the transducer permits ascertainment of the origins of the brachiocephalic arteries. The first branch in this case is the left brachiocephalic artery (LBA), which bifurcates into the left common carotid and subclavian arteries. C, With a further sweep upward, the carotid and subclavian arteries can be imaged in an almost symmetric arrangement in the lower neck. D, Then, the transducer is rotated clockwise or counterclockwise to align the ascending and descending aorta with the aortic arch. In this instance, the sonographer has mirror-imaged the transducer clearly to demonstrate that there is a right aortic arch. LBV, left brachiocephalic vein; LCCA, left common carotid artery; LIV, left innominate vein; LSA, left subclavian artery; RCCA, right common carotid artery; RPA, right pulmonary artery; RSA, right subclavian artery; SCV, superior caval vein.

Pre-operative or intra-operative bronchoscopy is still performed in all patients with vascular rings in some institutions.^{6,8} Bronchoscopy allows proper positioning of the endotracheal tube, and diagnosis of unrecognised tracheomalacia or bronchomalacia.

It should be noted that none of the currently available imaging modalities is able to visualise of a vascular structure, such as an arterial ligament or an atretic segment of the aortic arch. The presence of such fibrous strands can only be suspected when an arterial branch shows an otherwise unexplainable kinked course or a diverticular outpouching.¹⁵ Presence of a diverticulum of Kommerell indicates that a ligamentous arterial duct extends from the

apex of the diverticulum to either the pulmonary artery or an atretic arch on the same side.

Management of Anomalies Causing Tracheal and Oesophageal Compression

The simple existence of a vascular ring is not an indication for surgical intervention. Symptoms of borderline severity may disappear as the child grows. It is generally accepted, however, that surgical intervention should be undertaken whenever the patient is symptomatic, and there is significant compromise to the airways. Unnecessary delay may cause irreversible tracheobronchial damage, leading to

Figure 47-28 This panel of echocardiographic images shows a left aortic arch with an aberrant right subclavian artery. A, In the downward transverse view a left aortic arch is displayed with the trachea to the right. B, The upward sweep of the transducer reveals the first branch arising from a left aortic arch does not bifurcate, but instead continues forward, upward and rightward, this being characteristic for the right common carotid artery (RCCA). C, Inferior angulation of the transducer reveals the aberrant right subclavian artery (RSA) arising more distally from the descending aorta on the left side of the midline. SCV, superior caval vein.

Figure 47-29 The dynamic computed tomographic axial images obtained in inspiration and expiration phases show that the trachea is collapsed during expiration. As shown in the right panel, the patient has an aberrant right subclavian artery (RSA).

chronic compromise of the airways, even after surgical repair of the anomalous arch. In addition, prolonged intubation should be avoided because it may result in erosions into the trachea, aorta, or oesophagus.¹⁰

When surgical treatment is planned, a judicious decision should be made based on the anatomical information provided by echocardiography, magnetic resonance imaging or computed tomography for the best surgical approach that will allow successful relief of compression of the airway and oesophagus.⁶ A left lateral thoracotomy is the most often used surgical approach, but a right thoracotomy or a median sternotomy can be desirable in certain situations. Surgical approaches used for similar conditions vary among surgeons and institutions, often because of the institutional or personal preference and experience.^{3–10,16,21–24,27,28,35,36} A muscle sparing thoracotomy is advised as it is associated with less chest discomfort and fast postoperative recovery.⁷ Recently, video-assisted thoracoscopic surgery with or without robotic assistance has successfully been performed for division of some vascular rings.^{75–77} When there is no

associated cardiac defect, the surgery is performed without cardiopulmonary bypass.

A double aortic arch usually requires surgery in early infancy. The smaller of the two arches, or the atretic arch, should be divided. In most cases of double aortic arch, the left arch is the smaller one, or is atretic. The smaller arch is ligated and divided between the subclavian artery and descending aorta through a thoracotomy on that side. The arterial duct is also ligated and divided. Occasionally, aortopexy of either the ascending or descending aorta to the sternum or prevertebral fascia is required for further relief of tracheal or oesophageal compression.

The surgical approach to right aortic arch with aberrant left subclavian artery varies according to the preference of the individual surgeon or the institution. It may be treated by simple division of the ligamentous arterial duct without resection of the diverticulum of Kommerell, but this may be associated with persistent or recurrent symptoms necessitating reoperation. Preferable to this is resection of the diverticulum and reimplantation of the aberrant left subclavian artery to the left common carotid artery, the

procedure being performed through a left thoracotomy.⁶ Reasons for resection of a diverticulum of Kommerell are to avoid persistent oesophageal compression, and to prevent later development of an aneurysm that may rupture. In symptomatic adults with aberrant left or right subclavian arteries arising directly from the descending aorta without a diverticulum of Kommerell, reimplantation of the aberrant artery to the common carotid artery or ascending aorta on the same side can be performed through a supraclavicular approach.²⁷ Left aortic arch with aberrant right subclavian artery can be approached through a right thoracotomy. In cases with occlusion or aneurysmal dilation of the aberrant artery, a combined endovascular approach can be considered with endoluminal implantation of a stent.²⁸

Circumflex retro-oesophageal aortic arch can be approached through left thoracotomy, but often requires median sternotomy.³⁴ The retro-oesophageal part of the aortic arch is divided, and the mobilised aortic arch is translocated to the other side of the trachea and anastomosed to the descending aorta.

High cervical arch with tracheal compression requires aortopexy or aortic division, as well as division of the ligamentous arterial duct, resection of a diverticulum of Kommerell, and reimplantation of the aberrant subclavian artery if present.^{35–38} The redundant ascending aorta, as well as the aortic arch, should be sutured to the sternum. Relief of obstruction without compression of the airways may require interposition of a prosthetic graft between the ascending and descending aorta.³⁸

Operative mortality for relief of vascular rings is now almost zero.⁶ Rarely, the surgery is complicated by development of a chylothorax, an aorto-oesophageal fistula, or paralysis of the vocal cords as a result of damage to the recurrent laryngeal nerve. Most patients show immediate symptomatic improvement after surgery. Symptoms related to the airways persist in up to half of patients, and difficulties with feeding in a lesser percentage.^{7–9,78} Tracheomalacia is the major determinant for incomplete improvement of the symptoms. Chronic post-operative symptoms are related to age at operation. Symptoms persist most frequently in patients repaired in early infancy, because these patients present early, and therefore tend to have worse pathology. The patients who present later in childhood may also show moderately increased risk of persistent tracheobronchomalacia.

Figure 47-31 The diagram showing a pulmonary arterial sling also illustrates a left-sided arterial ligament connecting the distal left pulmonary artery (LPA) to the descending aorta. PT, pulmonary trunk; RPA, right pulmonary artery.

PULMONARY ARTERIAL SLING

This is a rare congenital anomaly in which the left pulmonary artery does not arise intrapericardially from the pulmonary trunk, but takes its origin extrapericardially from the posterior aspect of the right pulmonary artery, to the right side of the trachea (Figs. 47-30 and 47-31).^{79–82} The left pulmonary artery then makes a hairpin turn to the left, and courses toward the hilum of the left lung through the space between the lower trachea and oesophagus. As a consequence, a vascular sling is formed around the right side of the trachea. The arterial duct, or its ligament, connects the pulmonary trunk to the descending aorta on the left side of the trachea. The sling is almost always associated with an abnormality of the airways. The anomalous course of the left pulmonary artery may cause direct mechanical compression of an otherwise normal trachea, resulting in tracheomalacia. An abnormality of the airways, however, occurs far more commonly as an associated lesion. An abnormal branching pattern of the tracheobronchial tree is seen in up to four-fifths of patients with a pulmonary arterial sling.^{79–81} Typically the trachea bifurcates into the bronchuses to the right and left lungs at a lower level than normal, with a wide angle between the right and left bronchuses,

Figure 47-30 The volume rendered computed tomographic angiograms seen from the front and above (left panel) and from behind and above (right panel) show a pulmonary arterial sling with abnormal tracheobronchial branching and stenosis. The left pulmonary artery (LPA) arises from the proximal right pulmonary artery (RPA), makes a hairpin turn around the airway in the mediastinum and courses to the hilum of the left lung. The airway has two bifurcations in the mediastinum, with a narrow intermediary segment, characteristic of congenital stenosis due to complete cartilaginous rings. PT, pulmonary trunk.

producing an inverted T appearance. In approximately one-third of the cases with a low inverted T bifurcation of the airways, the right upper lobar bronchus arises from the trachea slightly above the level of normal tracheal bifurcation. The left pulmonary artery then forms a sling on the right side of the airway immediately above the lower bifurcation. The low inverted T pattern of bifurcation has previously been described as a bridging bronchus.⁸⁰ In this rather confusing concept, it has been considered that this part of the airway between the supposedly normal level of bifurcation and the lower bifurcation into the right and left bronchi is erroneously assumed to be the left main bronchus, and that the bronchus to the entire right lung, or to the right middle and lower lobes, arises abnormally from the left main bronchus. This bronchus, therefore, was thought to create a bridge between the right and left lungs. Almost all cases with the low inverted T bifurcation of the airways, with or without a separate origin of the right upper lobe bronchus, are associated with narrowing of a long segment of the lower airways above the bifurcation. The narrowing is due to complete cartilaginous rings, with absence of the membranous part of the trachea posteriorly. The narrowing may also extend into the main bronchuses. In addition, the right and, less frequently, the left bronchus may show bronchomalacia.¹⁰ One-third of patients with tracheal stenosis due to complete cartilaginous rings have an associated pulmonary arterial sling. The presence of complete rings, however, does not necessarily imply important stenosis, although the trachea is narrower than normal. Imperforate anus is seen in one-sixth of cases with a low inverted T bifurcation, but not in cases with a tracheal bifurcation at normal level.⁸⁰

The left pulmonary artery is often relatively hypoplastic, being considerably smaller than the right pulmonary artery. Stenosis of the right pulmonary artery, with hypoplasia of the right lung, has also been reported.⁸³ Rarely, the sling is associated with agenesis of the right lung.⁸⁴ Also rarely the pulmonary artery to the left upper lobe may arise anomalously from the proximal right pulmonary artery, with normal pulmonary arterial supply to the left lower lobe. In addition, the right upper lobe may have an aberrant supply from the anomalous left pulmonary artery.

The sling is reported to be associated with congenital cardiac disease in from one-third to four-fifths of cases.^{81,83,85,86} The most common reported defects are atrial septal defect, patency of the arterial duct, ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, and persistence of the left superior caval vein. The anomaly has also been reported in association with imperforate anus, congenital megacolon, biliary atresia, and genitourinary anomalies. Rarely, an aberrant left pulmonary artery arising distally from the right pulmonary artery does not form a vascular sling but is associated with tracheal stenosis.^{87,88} A sling involving the right pulmonary artery has been reported in a case with tetralogy of Fallot and pulmonary atresia when the aortic arch is right-sided.⁸⁹ A vascular course similar to the sling has been described involving the arterial duct.⁹⁰ In this instance, the duct arose from the right pulmonary artery, and coursed leftward through the space between the distal trachea and oesophagus to connect to the descending aorta on the left side. It is also suggested that an aberrant left subclavian artery can arise from the descending aorta and course through the space between the trachea and oesophagus,¹ but in this instance it is more likely that the artery is a collateral vessel rather than the left subclavian artery itself.²

Clinical Manifestations

Pulmonary arterial sling usually presents in the first year of life, although asymptomatic older children and adults have been reported.⁸¹ There is a slight male preponderance.⁸¹ The dominant clinical manifestations are due to obstruction of the airways, and include stridor, wheeze, and cough. Stridor is often expiratory, but can be inspiratory or biphasic. Less commonly, patients present with symptoms from oesophageal compression, such as dysphagia and vomiting. Rarely, the sling is found as an incidental lesion during cardiac or pulmonary investigations for other reasons.

Diagnostic Investigation

The chest radiograph sometimes provides clues to the diagnosis (Fig. 47-32). When present, abnormal branching of the airway can be appreciated in a well-taken frontal image.

Figure 47-32 The chest radiographs are shown together with computed tomographic correlation of a pulmonary arterial sling. The diagnosis can be entertained when careful observation shows the abnormality seen in the chest radiograph. The arrows indicate the narrowed vertical segment of trachea between its upper and lower bifurcations.

The inverted T appearance of the tracheal bifurcation at a level lower than normal is an important sign. Narrowing of long or short tracheal and bronchial segments can also be recognised. The lungs may show various combinations of hyperinflation and/or atelectasis, according to the associated tracheobronchial narrowing and retention of secretions. The pulmonary vascularity may be asymmetric, with the left lung, or less commonly, the right lung, showing less prominent vascularity than its partner. Barium oesophagography is diagnostic.⁸¹ On the lateral view, the left pulmonary artery is seen as a round structure between the air-filled distal trachea and barium-filled oesophagus, causing an anterior indentation in the oesophagus. Barium oesophagography, nonetheless, should be avoided in critically ill neonates, especially if they are ventilator dependent.⁸²

Echocardiography reveals continuation of the pulmonary trunk to the right, without origin of the normal

left pulmonary artery, a feature which may suggest unilateral absence of the left pulmonary artery, or aberrant origin of the left pulmonary artery from the ascending aorta. The origin of the left pulmonary artery from the right pulmonary artery is appreciated when the pulmonary trunk is followed to the right (Fig. 47-33). Echocardiography is always essential when assessing patients with a sling, since associated congenital cardiac disease is common.

Both computed tomography and magnetic resonance imaging are diagnostic (Fig. 47-34; see also Fig. 47-30).^{83,91,92} Contrast-enhanced computed tomography is preferred, not only because of its ability to visualise the pulmonary vessels and airway with great precision, but also because the short time required for scanning obviates the need for general anaesthesia or deep sedation in critically ill patients. Three-dimensional reconstruction of the airways and the contrast-enhanced vascular structures provides complete

Figure 47-33 The echocardiographic images show a left pulmonary arterial sling. High left parasternal short-axis views of the pulmonary arteries reveal that the pulmonary trunk (PT) continues as the right pulmonary artery (RPA), without giving rise to a normal left pulmonary artery (LPA). The left pulmonary artery arises from the right pulmonary artery behind the ascending aorta. The left pulmonary artery then makes a hairpin turn to course to the left side, encircling the trachea from the right side. This anatomy can be appreciated when the pulmonary trunk is followed as it moves to the right. Note that the proximal part of the LPA is not clearly shown in the cross sectional images because of sonic shadowing from the air-filled trachea. SCV, superior caval vein.

Figure 47-34 These computed tomographic angiograms reformatted in transverse axial and coronal planes show origin of the left pulmonary artery (LPA) from the proximal right pulmonary artery (RPA). The left artery encircles the right side of the distal trachea and courses between the trachea and oesophagus to reach the left hilum. The left pulmonary artery shows mild narrowing in front of the descending aorta. Tracheal branching is at the usual level, but is unusually symmetric. There is no tracheal or bronchial narrowing. PT, pulmonary trunk; SCV, superior caval vein.

information for the subsequent surgical procedure. When the narrowing of the airways is considered dynamic, a few selected slices can be scanned repeatedly for cine-display during respiration.^{68,69} Complications such as hyperinflation, collapse, or consolidation of the pulmonary parenchyma due to pneumonia should also be evaluated. Although magnetic resonance imaging can provide comparable information, the time required for scanning is long, and the anatomical detail, especially of the airways and lungs, is not as good as that of computed tomography. Bronchoscopy is recommended when dynamic narrowing due to tracheomalacia or bronchomalacia is suspected. Routine intraoperative bronchoscopy can be useful as the right and left bronchuses distal to the complete cartilaginous rings may also show malacic changes.¹⁰

Management

Early recognition is important. General supportive respiratory care should be given before proceeding to surgery. Respiratory infection may be difficult to clear completely before surgery because of persistent retention of secretions. Symptomatic patients should undergo surgical intervention without delay.^{82,85,86,93–95} The optimal surgical approach is median sternotomy with cardiopulmonary bypass, dividing and mobilising the left pulmonary artery at its origin from the right pulmonary artery, with reimplantation to the pulmonary trunk after complete resection of all ductal tissue. At the same time, associated problems of the airways should be inspected and treated surgically when necessary. Mild tracheal stenosis may not require tracheoplasty. Bronchoscopy after cardiopulmonary bypass can be beneficial because the extent of tracheal stenosis is not always apparent when viewing the trachea externally. Various techniques have been utilised for repairing tracheal stenosis, the length of the stenotic segment dictating the type of reconstruction. Stenosis of a short segment may require simple resection and end-to-end anastomosis. This procedure may obviate the need for division and reanastomosis of the left pulmonary artery, because the undivided left pulmonary artery can be translocated at the time of tracheal resection.⁹⁶ This procedure, however, may result in compression of the trachea or left main bronchus. A longer segment of narrowing requires tracheoplasty using a piece of rib cartilage, or more preferably a pericardial patch. In the majority of cases, an excessively long trachea allows resection of a part of the narrowed segment. The resected tracheal piece can also be used to augment the size of the tracheal lumen. This tracheal autograft technique is considered advantageous over other autologous patch materials. Sliding tracheoplasty is also used, transecting the stenotic segment at its midpoint, incising the proximal and distal stenotic segments in vertical direction, anteriorly in one segment and posteriorly in the other. The two spliced extremities are then slid over each other and anastomosed. The optimal surgical technique should be chosen not only according to the extent and nature of the tracheal stenosis, but also according to the institutional expertise. Tracheal repair is not always necessary.⁸²

Mortality is variable, with relatively high rates in earlier studies. The postoperative mortality is mainly related to

the associated tracheal and bronchial abnormalities, while vascular reconstruction is relatively free of symptomatic complication. Early recognition and surgical intervention may minimise morbidity and mortality. Survivors usually show prompt symptomatic improvement, and are free of significant symptoms at long-term follow-up. Some degree of airway obstruction with granulation tissue often persists, and narrowing of the reimplanted left pulmonary artery is not uncommon.

VASCULAR COMPRESSION OF THE AIRWAY WITHOUT VASCULAR RING OR SLING

As discussed earlier in this chapter, the shape of the thoracic cage is an important factor that contributes to compression of the airway and oesophagus in patients with an anomalous aortic arch or pulmonary arterial sling. In addition, abnormal position or dilation of the otherwise normally formed vessels may cause compression of the airway or oesophagus.

The brachiocephalic arterial compression syndrome refers to a condition in which the brachiocephalic artery arises too far to the left side of the aortic arch, compressing the anterior wall of the trachea as it courses from left to right (Fig. 47-35).^{4,97} Such tracheal compression by the brachiocephalic artery is reputed to cause respiratory symptoms, including stridor and bouts of apnoea that may progress to cyanosis, bradycardia, and even death. There has been controversy, nonetheless, regarding its clinical significance. The brachiocephalic artery arises at least partly to the left of the trachea in most normal individuals, and mild indentation of the trachea by the artery is not uncommon.⁹⁸ In addition, the majority of individuals with anterior tracheal compression fail to exhibit respiratory symptoms. In congenitally corrected transposition with a left aortic arch, the brachiocephalic artery crosses the midline in front of the trachea because the ascending aorta is typically on the left side. The syndrome is more likely to arise in patients with a crowded superior mediastinum, such as in those patients with cardiomegaly and dilated vessels in the mediastinum or narrow depth of the thoracic cage.⁹⁷ Symptomatic compression of the trachea is rare in patients over 2 years of age. In patients with severe symptoms, the artery has been suspended by sutures to the sternal periosteum with or without reimplantation to the more proximal ascending aorta.

An elongated aortic arch may also compress the anterior wall of the trachea significantly, compromising the luminal patency.⁹⁹ A classic example is the right aortic arch in congenitally corrected transposition (Fig. 47-36). In this setting, the aorta ascends on the left and takes a long transverse course in front of the trachea to connect to the descending aorta in the right posterior mediastinum. Once the lungs are hyperinflated, they extend to the midline behind the sternum, pushing the mediastinal structures and heart backward, further compromising the tracheal and bronchial patency.

A posteriorly displaced ascending aorta may cause significant compression of the airways (Fig. 47-37).^{71,100} The ascending aorta may directly compress the right side of the trachea. In addition, the left main bronchus,

Figure 47-35 The computed tomograms reformatted in transverse axial and coronal planes show the brachiocephalic artery arising from the aorta on the left side of midline and coursing rightward in front of the trachea. The trachea is mildly compressed. Note that the anteroposterior dimension of the thorax is narrow in this case. LCCA, left common carotid artery; LSA, left subclavian artery; RBA, right brachiocephalic artery.

Figure 47-36 In this patient with congenitally corrected transposition and a right aortic arch, an elongated aortic arch compresses the distal trachea. The frontal chest radiograph (*left panel*) shows a right aortic arch. The ascending aorta occupies a far leftward position in the upper mediastinum. Magnetic resonance image in axial transverse plane (*right panel*) shows posterior displacement and narrowing of the distal trachea. Note that the right aortic arch is unusually elongated as it connects the far leftward ascending aorta to the descending aorta on the right side. SCV, superior caval vein.

and less commonly, the right main bronchus, are compressed by the right pulmonary artery which is also displaced backward by the posteriorly displaced ascending aorta.

Absent pulmonary valve syndrome, also associated with bronchial compression, is characterised by severe dilation of the pulmonary arteries in the mediastinum and the hila of the lungs (Fig. 47-38).^{101,102} It is most typically associated with tetralogy of Fallot, and in most cases the arterial duct is absent. Most patients present early in life with

severe respiratory distress due to the bronchial compression and tracheobronchomalacia. The lungs are typically hyperinflated, with or without scattered areas of segmental or lobar collapse.

As in vascular rings and slings, all these related conditions need a tailored surgical approach and procedure. Contrast-enhanced computed tomography is best suited for investigation of critically ill patients, while magnetic resonance imaging can be used in older and less symptomatic patients.

Figure 47-37 In this patient, posterior displacement of the ascending aorta and the right and left pulmonary arteries compresses the left main bronchus. Transverse axial images of computed tomographic angiography (*left column*) show that the superior mediastinum is crowded with normal vascular structures. The ascending aorta has an unusual posterior location, and the right and left pulmonary arteries are consequently in direct contact with the left main bronchus, compressing it against the spine (*middle and lower panels*). The left main bronchus is squashed in an antero-posterior direction and therefore its vertical dimension is increased (*right column, upper panel*). The diminished antero-posterior diameter of the left main bronchus is well shown in the curved reformatted image seen from below (*right column, lower panel*). LPA, left pulmonary artery; PT, pulmonary trunk; RPA, right pulmonary artery.

Figure 47-38 These computed tomograms show mild narrowing of the right ventricular outflow (RVO) tract by the anteriorly deviated outlet septum, a ventricular septal defect (VSD; *left panel*), and markedly dilated central pulmonary arteries, consistent with tetralogy of Fallot and absent pulmonary valve syndrome. The left and right bronchi are compressed by the right and left pulmonary arteries (*middle panel*). Reformatted images of the airway in the coronal plane (*right panel*) show severe narrowing of the left main bronchus, with trapping of air in the left lung. LPA, left pulmonary artery; LV, left ventricle; OS, outlet septum; PT, pulmonary trunk; RPA, right pulmonary artery; RV, right ventricle.

ACKNOWLEDGEMENTS

We are very grateful to Dr Eoghan Laffan for valuable comments and corrections on the final manuscript. We thank Ms Jennifer Russell for help with coordination of the references, and Mrs Eul Kyung Kim for making the cartoons which illustrate the hypothetical double arch and its consequence for the fetal and postnatal circulations.

These papers assess the mechanism of compression of the airways by an aorta that does not form a vascular ring or sling. The authors emphasise that the trachea can be significantly compressed by the elongated and enlarged aortic arch, when the ascending aorta connects to the descending aorta on the opposite side, and that the main bronchus can be squeezed between the ascending and descending aorta when the ascending aorta has an unusually posterior position.

Abnormal Positions and Relationships of the Heart

ROBERT H. ANDERSON and SHI-JOON YOO

An abnormally positioned heart is not in itself a malformation of major significance. The exceptions are the extreme examples of exteriorisation of the heart, usually described as *ectopia cordis*, or union of parts of the heart in the setting of conjoined twins. A heart unusually positioned within the chest, an abnormal orientation of the cardiac apex, or the finding of unexpected relationships of structures within the heart, nonetheless, can all lead to considerable diagnostic problems. In the past, such situations created significant confusion. Our philosophy and approach to these situations has been outlined in Chapter 1. Those who have not studied this chapter in detail should, perhaps, return for refreshment concerning our ground rules. In this chapter, we seek to synthesise the value of our concepts in the setting of abnormally positioned hearts, and unexpected intracardiac relationships. We start by discussing the major problems produced by an extrathoracic position of the heart, or *ectopia cordis*, in its various degrees, following this with a brief account of congenital absence of the pericardium. We then summarise the cardiac problems encountered in the setting of conjoined twins. The location of the heart in an unexpected part of the thoracic cavity, or the orientation of its apex in a disharmonious fashion, the next topics for consideration, are best dealt with simply by description. Having suggested such simple descriptions, we then discuss the problems produced by, and the anomalies associated with, juxtaposition of the atrial appendages, before concluding with a consideration of the arrangements variously described as criss-cross hearts, superoinferior ventricles, or the topsy-turvy arrangement.

EXTERIORISATION OF THE HEART (ECTOPIA CORDIS)

It is maintained that the famous case of tetralogy of Fallot first reported by Nicolas Steno¹ was the first report of an extrathoracic heart.² Rashkind³ has argued that such malformations were almost certainly recognised long before 1671. In his opinion,³ they were recorded in the writings of the ancient Babylonians, although there is some dispute concerning the precise translation of the text on the tablet involved. Be that as it may, hearts positioned in part, or completely, out of the thorax fortunately remain very rare. Until recently, with relatively few exceptions, such occurrences proved uniformly fatal. The lesion is usually termed *ectopia*, but there are deficiencies in such usage.⁴ The Greek word *ektopos* simply means away from a place. As such, a heart found in the right chest of an otherwise normal person is *ectopic*. Despite this semantic failing, which represents yet another example of deficient use of a classical term, and supports the use

of the vernacular, *ectopia* is used universally to account for a heart located in part, or completely, outside the thoracic cavity.

Known cases of an extrathoracic heart have been reviewed extensively and well.⁴⁻⁶ In terms of categorisation, it was as long ago as 1845 that extrathoracic hearts were grouped according to their location, with description of cervical, thoracic and abdominal subsets.⁷ Subsequently, it was suggested that the combined thoracoabdominal position made up a further distinct pattern, with a combined thoracocervical group then added to this list.⁴ Cases encountered more recently continue to fall within these groupings.

When the heart is found in the neck, the sternum is usually intact. According to some,⁴ this arrangement reflects a retention of the normal initial site of cardiac development. This subset was dismissed by other experts,² who argued that it is found only in malformed fetuses. Examples have been recorded, nonetheless, when an infant survived for a few hours with a cervical heart, while one patient with this anomaly was reputed to have survived to adult life.⁸ This latter example, however, would probably be better placed in the thoracocervical group. Those dismissing the existence of the cervical subset have suggested the need to distinguish between a cleft to the sternum and an extrathoracic heart.² This seems to be unnecessarily divisive, since a heart within the neck is certainly not within the thorax, irrespective of whether or not the sternum is cleft. Irrespective of such niceties, hearts of the cervical type are by far the rarest. There is also a question mark over the group with the heart allegedly contained within the abdomen. Although 38 such hearts were catalogued in one series,⁵ re-examination of the original reports suggested that, in all but one, part of the heart was retained within the chest, thus making it better to group them within the combined abdominothoracic subset.² The majority of cases, therefore, either protrude from the chest, or else extend through a diaphragmatic defect. All occupy a midline deficiency of the body wall, lying partly in the chest and partly within the abdomen. In the cases exteriorised from the chest, the hearts are usually covered by neither skin nor pericardium (Fig. 48-1). In the past, various means had been employed to provide the lack of moisture ensuing from the absence of a pericardial cavity. Thus, quaint accounts survive from the 18th century, describing exteriorised hearts being covered with a contraption made of pliable osiers and linen, and anointed with wine and melted butter.⁹ Hearts were also covered with a pasteboard cone, with oil used for the anointing agent, or else saline sponges.⁶ Irrespective of the method employed, most patients survived for only a matter of hours or days.

Figure 48-1 A neonate with the heart exteriorised through the thoracic wall. (Courtesy of Dr Marshall Jacobs, Temple University, Philadelphia, Pennsylvania.)

The difference between exclusively thoracic exteriorisation, and those cases grouped together because the heart is located partly in the thorax and partly in the abdomen (Fig. 48-2), is that in the latter instances the heart is better covered by the body wall, having at least a covering of skin or membrane (Fig. 48-3). It is this group of patients that fall within the syndrome unified by five anomalies, known as the pentalogy of Cantrell. These are a midline deficiency of the abdominal wall, a defect of the lower part of the sternum, a deficiency of the pericardial sac, a deficiency of the diaphragm, and an intracardiac congenital lesion.¹⁰ Not all patients with extrathoracic hearts extending into the abdomen have all of these features. Indeed, the cases can themselves be grouped according to the number of the five features that are present.¹¹ Lesser forms of the pentalogy include the midline deficiencies shown in Figures 48-2 and 48-3, and protrusions of ventricular diverticula through midline deficiencies of the body wall (Fig. 48-4). Complete exteriorisation of the heart represents the extreme form of the syndrome. Treatment of the

Figure 48-2 This patient has the midline deficiencies of the pentalogy of Cantrell. The heart, occupying both the thorax and the abdomen, is covered by skin and a pericardial cavity. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

Figure 48-3 Opening the skin in the patient shown in Figure 48-2 revealed a midline heart with its apex also in the midline. There was isomerism of the right atrial appendages and the intracardiac anatomy of tetralogy of Fallot. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

Figure 48-4 This magnetic resonance image shows a left ventricular (LV) diverticulum protruding through a midline deficiency of the body wall (arrow). AO, aorta; L, left; R, right; RV, right ventricle. (Courtesy of Dr Walter Duncan, University of British Columbia, Vancouver, British Columbia, Canada.)

patients with the abdominothoracic type of exteriorisation has previously been more successful than for those having exclusively thoracic exteriorisation, although recent experience has shown that the exteriorised thoracic heart can successfully be placed back within the thorax (Fig. 48-5).

Until recently, very few patients survived reparative surgery, although several persons with abdominal hearts who did not undergo surgery survived into adult life. An example is an old soldier who reputedly fought through several campaigns, and died of suppurative nephritis of the right kidney.¹² The surgical problems encountered in restoring the heart to the body are considerable, including the small size of the deficient thoracic cavity, the excessive length of the venous and arterial connections to the extrathoracic heart, and the

Figure 48-5 The heart in the patient shown in Figure 48-1 was successfully replaced within the thorax. (Courtesy of Dr Marshall Jacobs, Temple University, Philadelphia, Pennsylvania.)

frequent co-existence of a large omphalocele. Recent experience, nonetheless, such as that shown in Figures 48-1 and 48-3, and that of Morales and associates,¹³ who reported four successful repairs encountered over a period of 6 years, suggests that the prognosis for those born with exteriorised hearts is now markedly improved, albeit conditioned by the severity of associated intracardiac defects.

CONGENITAL DEFICIENCY OF THE PERICARDIUM

An integral part of the various forms of extrathoracic heart is a gross deficiency of the fibrous pericardial sac. A deficiency of this firm bag can also be found when the heart is in its anticipated intrathoracic position. According to Van Praagh and his colleagues,² the anomaly was first observed by Columbus in 1559. Since then, about 150 cases have been described. Hence, the lesion is exceedingly rare. Only three examples were discovered amongst the 1716 hearts in the archive of Boston Children's Hospital.² We have knowingly observed only a single case at postmortem, this being a chance finding in a 68-year-old patient.¹⁴ Cases can, therefore, be entirely asymptomatic. Alternatively, such patients may have chest pain that can resemble angina. When associated with other anomalies, such as diaphragmatic hernia or lesions of the heart, it is the associated malformations that dominate the clinical picture. The biggest intrinsic problems occur with relatively localised left-sided deficiencies of the pericardium. Either the ventricles, or the left atrial appendage, can become herniated through a small opening, with strangulation and, in extreme cases, death. Limited deficiency of the fibrous sac on the right side can result in herniation of the lung into the pericardial cavity, with subsequent obstruction of the superior caval vein. The diagnosis is often made, or at least suggested, from the chest radiograph (Fig. 48-6). A large left-sided deficiency permits the entire heart to shift leftwards, with production of three rather than two knuckles on the left heart border as seen on the chest radiograph. When the defect is small, and there is herniation of the left appendage, the heart is

Figure 48-6 The chest radiograph shows an extensive bulge in the left border of the cardiac silhouette (arrows). This is very suggestive of herniation of the left atrial appendage through a pericardial deficiency.

normally positioned, but the malpositioned appendage produces an exaggerated bulge in the region of the pulmonary knob. Additional imaging (Fig. 48-7) can confirm herniation of the appendage if it is suspected. Only the small defects require surgical treatment, although large deficiencies may not be entirely benign. This is because the pericardial sac functions as the cardiac seat belt. The heart is more prone to traumatic injury when the pericardium is deficient. Surgical treatment of small defects is done either by enlargement of the defect, then incurring the small risk of losing the seat belt effect, or else by closure using a flap of mediastinal pleura.

Figure 48-7 Magnetic resonance imaging in the patient shown in Figure 48-6 confirms the herniation of the left atrial appendage (LAA), albeit through a thinned area of pericardium rather than a true pericardial defect (arrow). Ao, aorta; LA, left atrium; PA, pulmonary trunk; RA, right atrium; RAA, right atrial appendage.

CONJOINED TWINS

A malformation in the process of monozygotic twinning, which usually produces separate but identical individuals by cleavage of the single fertilised egg, can result in the twins becoming incompletely divided. This produces the rare examples of conjoined twins that, for centuries, have fascinated both medical and lay persons. The incidence is calculated at approximately 1 conjunction in every 50,000 births.¹⁵ The fanciful accounts of monsters and prodigies that appeared in centuries past are not that far removed from reality. The possibilities and sites for conjunction are legion. Accordingly, the categories provided for classification are formidable. The famous Siamese twins, Eng and Chang, who survived into old age, were joined only at the abdomen, sharing no more than a common cord of liver substance. Twins with cardiac involvement are all joined at the chest, although not necessarily with common cardiac chambers. Indeed, those with separate hearts in a common thoracic cavity have the best chance of survival. Even when the hearts themselves are quite separate, there can be extensive intermingling of the circulations between the twins. We have had the opportunity to study three sets of joined twins at autopsy.

In one case, the twins faced each other and were joined at the thorax and abdomen with a common rib cage, with a sternum at each side common to both twins. The right side of one twin faced the left side of the other, and each had its organs arranged in usual fashion. There were separate lungs, but a common liver. Each twin possessed a spleen in its own left side. The hearts were joined at ventricular and atrial level, even though each heart had two atriums and two ventricles. The latter were unconnected, even though set in a common ventricular mass. The interconnections of the great veins, however, were complex in the extreme and would have precluded any attempt at surgical separation.

One of the other sets of twins studied was joined at atrial level in a fascinating fashion. The hearts were joined in the fashion of leaves of a book, rather than faces to face. Within this arrangement, the twins shared a midline morphologically right atrium (Fig. 48-8). Consequently, while the one twin had usual atrial arrangement, the other exhibited isomerism of the right atrial appendages.¹⁶ In keeping with the right isomerism, the right-sided twin also had lungs and bronchuses bilaterally of right morphology, and there was no spleen in its abdominal cavity. Several other examples of conjoined twins have been recorded where the one twin had usual arrangement of its organs and the other had right isomerism. Always it is the right-sided twin that is afflicted by the isomerism. Recent investigations suggest the concept of cross-talk between the conjoined embryos as the basis for failure of lateralisation.¹⁷ The left-sided twin is hypothesised to synthesise an inhibitor of the gene *sonic hedgehog*, activin being proposed as the inhibitor. It is then suggested that diffusion of the inhibitor to the right-sided twin prevents the induction of *nodal*, this latter gene being considered necessary for the formation of morphologically left structures (see also Chapter 22).

Clinical diagnosis of conjunction is not now likely to be a problem. Intra-uterine cross sectional ultrasonography is now likely to reveal the diagnosis in the majority of cases. Although analysis will be difficult, an assessment can

Figure 48-8 The hearts from conjoined twins joined together at atrial and ventricular levels. In the right-sided heart, the right-sided appendage, although not well seen in the photograph, was of right morphology. There is a shared midline appendage, also of right morphology, whilst the left-sided appendage is of left morphology. Thus, the heart of the right-sided twin exhibits right isomerism, whilst the atrial appendages in the heart of the left-sided twin are usually arranged.

be made of the degree of cardiac involvement. If surgical separation is to be attempted, a full investigation will be needed after birth. Angiocardiology and echocardiography should always be performed, along with resonance imaging. Interpretation of the images, considered difficult in the past, should now be very much easier. Even in potentially suitable cases, survivors of attempted separation have thus far been rare. As with exteriorisation of the heart, the situation must be anticipated rapidly to improve, depending of course on the degree of fusion of the cardiac structures, and the severity of the intracardiac lesions in each twin.

ABNORMAL POSITIONING OF THE HEART

The heart is normally located in the mediastinum, with one-third of its bulk to the right, and two-thirds to the left of the midline. With this arrangement, the apex usually points inferiorly and to the left. This combined pattern is traditionally described as levocardia. There are several reasons why the heart can be deviated from this position, or its apex be pointed in an unexpected direction. Although the abnormal position of the heart can be due to the cardiac defect, it can also be secondary to a non-cardiac pathology. For example, the heart can be pushed to the right by a space-occupying lesion in the left lung or left pleural cavity, such as hyperinflation of the left lung, or pleural effusion and pneumothorax involving the left pleural cavity. The heart can also be pulled to the right when the right lung is underdeveloped or collapsed. The abnormally rightward position of the heart is typically seen in association with right pulmonary hypoplasia in scimitar syndrome and absence of the right pulmonary artery. The abnormal position is not in itself necessarily an abnormality of the heart. Normal individuals with mirror-imaged arrangement of the organs, for example, normally have a right-sided heart.

When assessing the significance of a right-sided heart, therefore, or a heart with its apex pointing to the right, it is necessary to take account of all these various features. Several questions should be asked. What is the overall arrangement of the organs? Is there an abnormality of the lungs or the thoracic contents? If present, is it of congenital or acquired aetiology? Is the heart itself abnormally structured, or are its chambers grotesquely enlarged? Only when these questions have been posed, and answered, can the significance of an abnormally positioned heart be fully appreciated. Attempts to compress all this information into short phrases or single words have led to complex and confusing usage of the terms dextrocardia, levocardia, dextroversion, eversion, and dextroposition, particularly when combined with adjectives such as isolated, pivotal, or mixed.¹⁸ For these reasons, it is better not to use these cryptic conventions.

When describing the abnormally positioned heart, it is necessary first to account for its overall location. This can be accomplished by describing it as left-sided, central, or right-sided. Thereafter, it is necessary to account for the orientation of its apex. This also can be left-sided, central, or right-sided. All locations can be categorised solely in terms of the position of the heart, and the orientation of its apex. This information, of course, must be placed in the context of the overall arrangement of the thoracic and abdominal organs, and the presence of acquired or congenital disease of either the heart or the lungs. If, for example, the heart is described as lying mostly in the right chest, and with its apex orientated to the left, there can be little room for misunderstanding this arrangement, irrespective of the precise reason for the abnormal position.

Abnormal positioning of the heart, therefore, should no longer be regarded as a diagnosis in its own right. Finding a right-sided heart, for example, gives no clue as to what is happening inside the organ. The heart itself may be entirely normal. Description of abnormal location is but one part of full sequential segmental analysis (see Chapter 1). Certain well-recognised lesions, or combinations of lesions, nonetheless, are associated with right-sided hearts, or left-sided hearts in those with mirror imagery. The heart is typically right-sided in association with hypoplasia of the right lung in the scimitar syndrome and its variants, known also as the broncho-pulmonary foregut malformation.¹⁹ The heart is also right-sided in well over a third of individuals who have an isomeric arrangement of their organs (see Chapter 22). The single lesion most associated with a right-sided heart, or left-sided heart with mirror-imaged arrangement, is congenitally corrected transposition (see Chapter 39). At best, these are clues to the final diagnosis. The variety of lesions that can exist when the heart is abnormally positioned is protean.

JUXTAPOSITION OF THE ATRIAL APPENDAGES

Although not necessarily representing an abnormal position of the heart itself, but often found when the heart is abnormally located, juxtaposition of the atrial appendages is a potentially confusing feature of a congenitally malformed heart. In the normally constructed heart, the appendages lie one to each side of the arterial pedicle. It is then the morphological nature of each

appendage that determines the arrangement of the atrial chambers (see Chapter 1). Juxtaposition of the appendages is seen when both the appendages are to the same side of the arterial pedicle. Such juxtaposition does not interfere with recognition of the structure of each appendage when this feature is assessed on the basis of the extent of the pectinate muscles. Juxtaposition, therefore, can occur in the person with usual atrial arrangement (Fig. 48-9), in the individual with mirror-imaged arrangement, or in the presence of isomeric appendages (Fig. 48-10).

Figure 48-9 In this heart, both the appendages are to the left of the arterial pedicle, albeit that they are still recognised as being morphologically right and morphologically left.

Figure 48-10 In this heart, both the appendages are to the right of the arterial pedicle, and both are recognisably of left morphology. This is right-sided juxtaposition in the setting of left isomerism.

Figure 48-11 This cross sectional echocardiogram, in the short axis of the heart, shows left juxtapposition of the right atrial appendage (RAA) in the setting of double outlet right ventricle (RV). Note that the morphologically right appendage has passed through the transverse sinus to lie alongside the morphologically left appendage (LAA). LA, left atrium; RA, right atrium.

Figure 48-12 The subcostal four-chamber echocardiogram from the patient shown in Figure 48-11 shows that the right atrial appendage (RAA) is displaced to the right. Note that the roof of the right atrium is indented by the arterial trunk (arrows), the pulmonary trunk (PT) in this case. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SCV, superior caval vein.

In the presence of usual atrial arrangement, juxtapposition occurs most frequently when the right appendage is deviated leftward through the transverse sinus so that it lies above the left appendage (see Figs. 48-9, 48-11, and 48-12). This is conventionally called left juxtapposition. It tends to be associated with relatively complex anatomical lesions. Noteworthy associated malformations are tricuspid atresia, hypoplasia of the right ventricle, and abnormal ventriculo-arterial connections,²⁰ such as double outlet right ventricle.

Sometimes the juxtapposition is only partial, with a small pouch of right appendage continuing to protrude forward on the right side of the arterial trunk. The effect of the juxtapposition is to distort the internal morphology of the atrial septum. On opening the relatively small atrial surface, the orifice of the juxtaposed appendage occupies the anticipated site of the oval fossa (Fig. 48-13). The oval fossa is more slit-like, and is deviated postero-inferiorly. The distortion of the right atrium can also produce potential problems in atrial redirection procedures, albeit that nowadays these are usually performed only as part of the double switch procedure, and this is rarely undertaken in patients with juxtapposition. Another consequence of the juxtapposition is to distort the landmarks to the sinus node. The terminal groove is orientated in horizontal rather than vertical fashion, and the sinus node itself is deviated towards the atrioventricular junction. Much more rarely, the appendages can be juxtaposed to the right of the arterial pedicle when there is usual atrial arrangement. It is then the left appendage that occupies the transverse sinus, coming to lie superiorly relative to the right appendage (see Fig. 48-10). In some cases, right juxtapposition is found in hearts when the only associated lesion is an atrial septal defect. In other instances, it may accompany

Figure 48-13 The distorted anatomy of the right atrium produced by left juxtapposition of the atrial appendages. The mouth of the appendage is occupying the usual position of the oval fossa. There is a persistent left superior caval vein (LSCV) that drains through the enlarged mouth of the coronary sinus

exceedingly complex lesions. In the person with mirror-imaged arrangement, of course, right-sided juxtapposition is the expected variant. It is associated with the same constellation of lesions as is left-sided juxtapposition in the individual with usual atrial arrangement. When there is left juxtapposition, a straight or concave right lower heart border, and a prominent bulging contour of the left mid-heart border, are seen on the chest radiograph because the right atrial appendage is not in its usual place but

Figure 48-14 The chest radiograph shows the characteristic appearances of left juxtaposition of the atrial appendages. Note the sigmoid configuration of the right border of the cardiac silhouette, and the bulge in the upper part of the left border (arrows). RA, right atrium; SCV, superior caval vein.

displaced to the left (Fig. 48-14; see also Fig. 48-13). The diagnosis is readily made with cross sectional echocardiography (see Figs. 48-10 and 48-11) or magnetic resonance imaging. During cardiac catheterisation, if the diagnosis has not already been made by echocardiography, the first pointer to the diagnosis may be the sampling of systemic venous blood from the left side of the heart in a low pressure zone. If necessary, selective injection of contrast medium into the appendage will establish the diagnosis.

CRISS-CROSS OR TWISTED HEARTS, SUPERO-INFERIOR VENTRICLES, AND RELATED CONDITIONS

The last group of hearts to be considered are those where the relationships of the cardiac chambers, or great arteries, are not as expected for the given segmental connections. The significance of these malformations has diminished markedly since it has been appreciated that segmental connections cannot, and should not, be inferred from abnormal relationships of cardiac structures. The abnormal relationships in themselves, however, can still be a confusing feature. The most commonly encountered is criss-crossing or, more precisely, twisting of the ventricular inlet components, combined with an unexpected relationship of the ventricles.^{21,22} There are other arrangements, however, that show an abnormal ventricular relationship without crossing or twisting of the ventricular inlets. There are three mutually exclusive mechanisms that can produce abnormal ventricular relationships for the given segmental connections, namely, twisting, tilting, and rotation. By

Figure 48-15 The cartoon shows the essence of the criss-cross heart in the setting of usual arrangement and congenitally corrected transposition. Usually the ventricles are positioned side-by-side, with the morphologically left ventricle (LV) to the right. If, however, the ventricular mass becomes twisted (right cartoon), then the morphologically right ventricle (RV) assumes an anterior location, the aortic valve is positioned anterior and to the right rather than the left, and part of the morphologically left ventricle can become left-sided. The twisting, in most instances, does not change the segmental connections. Although shown in the setting of congenitally corrected transposition, such twisting can occur in any setting.

twisting, we mean a spiral relationship of the atriums and ventricles in which the cardiac chambers and arterial trunks are aligned and arranged as if the heart were twisted clockwise, or anticlockwise, by a hand placed on the cardiac apex with the venous connections of the heart maintained in their normal positions (Fig. 48-15). Tilting, in contrast, produces a supero-inferior relationship of the ventricles, the parallel axes of the ventricular inlet and atrioventricular junctions being preserved as if the apex of the heart were simply lifted by a hand placed on the apex (Fig. 48-16). Rotation describes the much rarer condition, in which the cardiac chambers, arterial trunks and caval veins are all abnormally oriented within the thorax, as if the entire heart were rotated as a block around its long axis.

It is twisting that is the essential feature of the so-called criss-cross heart. The common characteristics of the twisted heart include loss of normal parallel axes of ventricular inlets, with an overt criss-crossed relationship in extreme cases, angulation of the atrial septum, a curved configuration of the ventricular septum, and unusual arterial relationships for the given pathology. The ventricular inlets also adopt a supero-inferior relationship, with the apical components showing the most unusual relationships. In extreme forms, the ventricular apices are displaced to the opposite side, and show a reversed side-by-side relationship. This can occur with any known combination of connections of the cardiac segments. It produces unexpected relationships of the ventricles and great arteries. Twisting is usually in such a direction to place the right ventricular inlet anterior and superior to the left ventricular inlet. In congenitally corrected transposition with usual atrial arrangement, for example, and as shown in Figure 48-15, the morphologically left ventricle is usually a right-sided structure, while the aortic valve most frequently is located anteriorly and to the left. The ventricular mass in the presence of the

Figure 48-16 The cartoon shows how supero-inferior ventricles are produced, in the setting shown here of congenitally corrected transposition, by tilting of the ventricular mass to either the right or the left. Oftentimes such tilting is combined with a twisting abnormality. The arrangement is also described as upstairs-downstairs heart.

criss-cross malformation is twisted counter-clockwise in such a way that the morphologically right ventricular inlet achieves a rightward and supero-anterior position relative to the left ventricular inlet, while the aortic valve becomes anterior and right-sided. In the presence of usual atrial arrangement, of course, a right-sided and anterior aorta arising from a right-sided morphologically right ventricle is more typically found with the segmental combinations of regular transposition (see Chapter 38). Twisting can also occur with the connections of the segments that normally produce regular transposition. The ventricular mass is twisted clockwise, giving the spurious impression of congenitally corrected transposition. Once the investigator is aware of the possibility, both the abnormal relationships and the true segmental connections are readily demonstrated by current techniques for imaging (Fig. 48-17). The key is first to analyse the connections between the cardiac segments, and only then to take note of the relations of the ventricles and arterial trunks. The secret is not to be surprised when the relationships observed are not as anticipated for the demonstrated segmental connections.

In the typical situation of the criss-cross heart, which can be encountered with any combination of

atrioventricular and ventriculo-arterial connections, the ventricular topology is as anticipated for the atrioventricular connections. Thus, in the illustrated situation with concordant atrioventricular connections (see Fig. 48-17), although the morphologically left ventricle is right-sided despite the usual atrial arrangement of the atrial chambers, the morphologically right ventricle will accept only the palmar surface of the right hand of the observer with the thumb, figuratively speaking, in the tricuspid valve. In other words, there is retention of right hand ventricular topology despite the rotation of the ventricular mass along its long axis. Rare cases exist, however, that emphasise the need to distinguish separately on some occasions between the connections of the segments and their topological arrangement.^{23,24} These hearts produce a different variant of the criss-cross heart, and one that cannot simply be explained on the basis of rotation of the ventricular mass.

In the examples we have seen, the atrial chambers were arranged in usual fashion. The right atrium connected to the morphologically right ventricle, which as in the heart shown in Figure 48-17, was left-sided relative to the morphologically left ventricle (Fig. 48-18). The left ventricle was connected to the left atrium. Despite

Figure 48-17 These magnetic resonance images in a patient with concordant atrioventricular connections, with the atriums (RA, LA) connected to their appropriate ventricles (RV, LV) show crossing of the atrioventricular inlets (arrows in A and B). This is the essence of the so-called criss-cross heart, the right-sided location of the morphologically left ventricle relative to the right ventricle giving the spurious impression of the discordant atrioventricular connections.

Figure 48-18 The heart illustrated has a very rare form of criss-cross malformation. A, The atria are connected to morphologically appropriate ventricles, in other words, the atrioventricular connections are concordant, with the pink probe passing from the usually arranged right atrium to the morphologically right ventricle. B, The morphologically right ventricle is left-sided, and gives rise to both arterial trunks in the setting of bilateral infundibula. There is left hand ventricular topology, despite the presence of usual atrial arrangement and concordant atrioventricular connections. Providing that the segmental connections are described separately from the ventricular topology, this arrangement should not cause confusion. LA, left atria; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle.

the concordant atrioventricular connections, however, there was left hand ventricular topology. In addition, there was double outlet from the morphologically right ventricle and left-sided juxtaposition of the atrial appendages. These rarer, and much more complex, cases emphasise the need, on occasions, to specify the topology of the cardiac segments when they differ from the anticipated arrangement. Provided that all these features are recognised, and accounted for separately, there should be little room for confusion or misunderstanding, irrespective of the specific words used for their description. The term criss-cross itself, however, describes a particular relationship of the ventricular inlets. Indeed, the atrioventricular valvar planes can cross each

other even when both valves open to the same ventricle²⁵ (Fig. 48-19). Simply describing the twisted atrioventricular connections does not account for the morphology of the entire heart. Full sequential segmental description is needed for that purpose.

In comparison with the potential problems encountered with criss-cross hearts, few should be posed by ventricles that are arranged in supero-inferior, or upstairs-downstairs, fashion which simply reflects a tilting of the ventricular mass along its long axis (see Fig. 48-16). Supero-inferior ventricles are usually described in the setting of congenitally corrected transposition, where in most instances the ventricles are arranged in side-by-side fashion. Tilting of the ventricular mass to either side then produces a stacking effect of the ventricles one on top of the other. Like the criss-cross pattern, supero-inferior ventricles are often seen in the presence of straddling and/or overriding atrioventricular valves. As was also the case with the criss-cross arrangement, noting an upstairs-downstairs, or supero-inferior, arrangement does not describe the complete heart, but only a particular ventricular relationship. Sequential segmental description is mandatory for full categorisation of the hearts showing this abnormality.

We now know that a further variation occurs in these unusual ventricular relationships. First described by Freedom and his colleagues in their textbook of angiography, the entirety has now been diagnosed during fetal life, and in a familial setting.²⁶ Called the topsy-turvy arrangement, the essential feature is rotation of the whole heart around its long axis, with supero-inferior relationships of the atriums and ventricles (Fig. 48-20), but without twisting of the axes of the atrioventricular connections. As the arterial roots, as well as the aortic arch and arterial duct, are displaced downward as a consequence of rotation of the whole heart, the branches of the aortic arch and the superior caval vein are elongated (Fig. 48-21). More importantly, the trachea is elongated and the left bronchus is severely compressed by the low-lying aortic arch and arterial duct (Fig. 48-22).

Figure 48-19 These magnetic resonance images from a patient with double inlet right ventricle show how the atrioventricular valves cross each other as they enter the dominant right ventricle (arrows), producing twisted double inlet atrioventricular connection. LA, left atrium; RA, right atrium; RV, dominant right ventricle.

Figure 48-20 These magnetic resonance images show the essence of the topsy-turvy arrangement. The ventricles (RV, LV) are located supero-inferiorly (*left panel*), but without any rotational twisted deformity. The arterial trunks (Ao, PA, RPA), are displaced downwards (*right panel*), with the brachiocephalic arteries and the caval veins elongated as they extend to the mediastinum (see Figure 48-21). LA, left atrium; RA, right atrium.

Figure 48-21 This magnetic resonance image shows the elongated brachiocephalic arteries produced in consequence of the topsy-turvy arrangement of the heart. Ao, aorta.

Figure 48-22 The reconstructed computerised tomographic image from the patient shown in Figure 48-20 illustrates the elongation of the trachea and narrowing of the left bronchus (asterisk) as a consequence of the low-lying aortic arch and arterial duct produced by the topsy-turvy arrangement.

These two articles review the morphology underscoring the so-called criss-cross arrangement, showing how in most instances the lesions simply reflect twisting of the heart around its long axis.

Cardiomyopathies

JUAN PABLO KASKI and PERRY ELLIOTT

It has become evident that primary myocardial disease represents one of the more neglected aspects of heart disease today. It is often overlooked or misdiagnosed; in addition, it is frequently considered rare, unimportant, or that treatment is of no avail . . . there are misconceptions concerning its rarity or unimportance, as well as treatment.

—W. Proctor Harvey, 1965¹

The cardiomyopathies are a heterogeneous group of disorders of cardiac muscle (Table 49-1). Previous classifications defined cardiomyopathies as myocardial diseases of unknown cause,² but increased understanding of their aetiology and pathogenesis has led to a revised definition of cardiomyopathy as 'a myocardial disorder in which the heart muscle is structurally and functionally abnormal, in the absence of coronary artery disease, hypertension, valvular disease and congenital heart disease sufficient to cause the observed myocardial abnormality'.³ Cardiomyopathies are classified according to the ventricular morphology and pathophysiology. Four major types are recognised, namely, the dilated, hypertrophic, and restrictive variants and arrhythmogenic right ventricular cardiomyopathy.⁴ Diseases that do not fit readily into these groups, such as endocardial fibroelastosis and ventricular non-compaction, are currently considered as unclassified cardiomyopathies. In some circumstances, mixed phenotypes can exist. For example, patients with hypertrophic and dilated cardiomyopathies frequently have restrictive left ventricular physiology; in other cases, hypertrophy and ventricular dilation may co-exist.

HYPERTROPHIC CARDIOMYOPATHY

Definition and Historical Aspects

Hypertrophic cardiomyopathy is defined as left ventricular hypertrophy in the absence of abnormal loading conditions, such as valvar disease, hypertension, or other congenital cardiac malformations, sufficient to explain the degree of hypertrophy.⁵ Asymmetrical hypertrophy of the interventricular septum was first described in 1869,^{6,7} but hypertrophic cardiomyopathy was only established as a clinical entity in the late 1950s.^{8,9} These latter landmark studies were followed by a period of intense clinical investigation, during which the characteristic morphological and haemodynamic features of the disease were defined. Angiographic and M-mode echocardiographic studies focused on dynamic subaortic obstruction, at the time thought to be the defining feature of the condition.^{10–13} Use of cross sectional echocardiography demonstrated that any pattern of hypertrophy can occur, and that only a minority have obstruction of the left ventricular outflow tract at

rest.¹⁴ The discovery that many patients with hypertrophic cardiomyopathy had familial disease led to a search for the genetic basis of the disease. In 1989, the first mutation in the gene encoding the cardiac β -myosin heavy chain was identified.¹⁵ Since then, more than 400 mutations have been identified in this and other cardiac sarcomeric protein genes.¹⁶

Epidemiology

Unexplained left ventricular hypertrophy occurs in approximately 1 in every 500 adults.^{17–21} The frequency of left ventricular hypertrophy in children is unknown, but population-based studies from Australia²² and the United States²³ report an incidence between 0.3 and 0.5 cases per 100,000, including cardiomyopathies associated with inborn errors of metabolism, neuromuscular disease, and malformation syndromes. The frequency is greater in males, and highest in the first year of life, with one study showing a second peak in adolescence.²³

Natural History

Hypertrophic cardiomyopathy can present from infancy to old age.^{5,16,24} Many patients follow a stable and benign course, with a low risk of adverse events, but a large number experience progressive symptoms, caused by gradual deterioration in left ventricular systolic and diastolic function and atrial arrhythmias. A proportion of individuals die suddenly, whereas others may die from thromboembolism, progressive cardiac failure, or infective endocarditis.

Sudden Death

Sudden death occurs most commonly in adolescents and young adults.²⁵ Whilst initial descriptions of the natural history reported annual rates of sudden death from 3% to 6%, recent studies in adults revealed rates of 1% or less per year.^{5,26} Similarly, early studies of highly selected populations of children reported rates of sudden death ranging from 2% to 8% per year,^{27–29} but recent population-based reports from Australia³⁰ and the United States³¹ report an overall annual rate of sudden death of 1% to 1.5% per year beyond infancy.

Cardiac Failure

Whilst many children and teenagers with hypertrophic cardiomyopathy have few if any symptoms, presentation in infancy can be associated with severe and intractable cardiac failure.^{32–35} Some studies have suggested that presentation in infancy itself constitutes an unfavourable prognosis,^{33,35} but this finding is not consistent.³⁴ Progression to an end-stage, or burnt-out, phase is a well-recognised

TABLE 49-1

CLASSIFICATION AND AETIOLOGY OF THE CARDIOMYOPATHIES

Hypertrophic Cardiomyopathy (HCM)	Dilated Cardiomyopathy (DCM)	Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)	Restrictive Cardiomyopathy (RCM)	Unclassified
FAMILIAL

Data from Elliott P, Andersson B, Arbustini E, et al: Classification of the cardiomyopathies: A position statement from the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases. Eur Heart J 2008;29:270–276.

complication,^{36–49} with a reported prevalence in up to one-sixth of adults.^{41,45,47} This end-stage is characterised by progressive left ventricular dilation, mural thinning, and systolic impairment.⁵⁰ It is associated with a poor prognosis,⁴⁷ with an overall rate of death of up to 11% per year.⁴¹ In children, progression to the burnt-out phase is extremely rare, with only isolated reports.^{36,51} Progression to left ventricular systolic dysfunction and dilation may occur in a minority of patients with mitochondrial cardiomyopathies.⁵²

Aetiology

Most adolescents and adults with hypertrophic cardiomyopathy have familial disease, caused by autosomal dominantly inherited mutations in sarcomeric protein genes. In less than one-tenth of infants and children, hypertrophic cardiomyopathy can be associated with inborn errors of metabolism, neuromuscular disorders, and malformation syndromes,³¹ including Pompe's disease, Friedreich's ataxia, and malformation syndromes such as Noonan's syndrome. Cardiomyopathy associated with metabolic disorders or malformation syndromes is diagnosed earlier in life, usually during infancy or early childhood, whereas neuromuscular diseases tend to be diagnosed in the teenage years. In children with idiopathic hypertrophy, approximately one-third are diagnosed in infancy, one-third during adolescence, and the other third between the ages of 1 year and 11 years.³¹

Sarcomeric Protein Disease

Most individuals with non-syndromic hypertrophic cardiomyopathy have familial disease, inherited in an autosomal dominant manner. Genetic studies have shown that up to three-fifths of adults with the disease have mutations in one of at least 11 genes that encode the proteins of the cardiac sarcomere. These are the MYH7 gene, encoding for β -myosin heavy chain, and carried on chromosome 14; MTBPC3 encoding for myosin-binding protein C and carried on chromosome 11, TNNT2 encoding for cardiac troponin T and carried on chromosome 1; TNNI3 encoding for cardiac troponin I and carried on chromosome 19; TMP1 encoding α -tropomyosin and carried on chromosome 15; ACTC encoding α -cardiac actin and carried on chromosome 15; MYL3 encoding for essential myosin light chain and carried on chromosome 3; MYL2 encoding for regulatory myosin light chain and present on chromosome 12; TNNC1 encoding for cardiac troponin C and carried on chromosome 3; MYH6 encoding for α -myosin heavy chain and carried on chromosome 14^{53–56}; and TTN encoding for titin and carried on chromosome 2.⁵⁷ There is considerable genetic heterogeneity, with over 400 different mutations identified to date, as well as marked variation in penetrance of the disease, and hence clinical expression.⁵⁸ The mechanisms through which mutations in the genes result in the characteristic pathophysiological features are incompletely understood. It has been speculated that the phenotype results from reduced contractile function, but studies of myocytic function in patients who harbour mutations in the genes are inconsistent, with some mutations appearing to depress contractility whereas others enhance sensitivity to calcium and contractility.⁵⁹

The majority of mutations have a dominant negative effect on sarcomeric function; in other words, the mutant protein is incorporated into the sarcomere, but its

interaction with the normal wild-type protein disrupts normal sarcomeric assembly and function. Allelic heterogeneity may be explained by the effect of different mutations on the structure and function of the complete peptide. β -Myosin heavy chain, for example, consists of a globular head, an α -helical rod, and a hinge region. The globular head contains binding sites for ATPase and actin, as well as sites for interaction with regulatory and essential light chains in the region of the head-rod. Most mutations in the β -myosin gene are missense DNA nucleotide substitutions that change a single amino acid in the polypeptide sequence. The majority of disease-causing β -myosin heavy chain mutations are found in one of four locations. These are the actin-binding site, the nucleotide-binding pocket, a region in the hinge region adjacent to the binding site for two reactive thiols, and the α -helix close to the essential light chain interaction site. Depending on the position of the mutation, therefore, changes might be expected in ATPase activity, actin-myosin interaction, and protein conformation during contraction.

There is substantial variation in the expression of identical mutations, indicating that other genetic and possibly environmental factors influence expression of the disease. The effect of age is perhaps the best characterised factor, most patients developing electrocardiographic and echocardiographic manifestations of the disease after puberty and before the age of 30. Other modifying factors include gender, polymorphism of the genes regulating the renin-angiotensin-aldosterone system, and the occurrence of homozygosity and compound heterozygotes.

The importance of genetic mutations in children with hypertrophic cardiomyopathy is unknown. The observation that the development of left ventricular hypertrophy in individuals with familial disease often occurs during the period of somatic growth in adolescence⁶⁰ has led to the suggestion that sarcomeric protein disease in very young children is rare.²⁴ There have been no systematic studies, however, evaluating the prevalence of genetic mutations in children with the disease.

Noonan's and LEOPARD Syndromes

Noonan's syndrome is characterised by short stature, dysmorphic facies, skeletal malformations, and a webbed neck.^{61–63} Cardiac involvement is present in up to nine-tenths of patients with Noonan's syndrome, most commonly as pulmonary stenosis, frequently secondary to a dysplastic valve, and hypertrophic cardiomyopathy.⁶⁴ Some children present with congestive cardiac failure in infancy, which may be associated with biventricular hypertrophy and bilateral obstruction of the ventricular outflow tracts.⁶⁴ The histological findings are indistinguishable from idiopathic hypertrophic cardiomyopathy.⁶⁵ The syndrome is usually inherited as an autosomal dominant trait with variable penetrance and expression. Recently, mutations in the *PTPN11* gene, encoding the protein tyrosine phosphatase SHP-2, a protein with a critical role in RAS-ERK-mediated intracellular signal transduction pathways controlling diverse developmental processes,⁶⁶ have been shown to cause the syndrome.⁶⁷ To date, at least 39 different mutations have been identified, accounting for approximately half of the cases.⁶¹

LEOPARD syndrome (an acronym representing lentiginos, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of the genitalia, retardation of growth, and deafness) shares many phenotypic

features with Noonan's syndrome. Recent studies have shown that most patients with LEOPARD syndrome also have mutations in the *PTPN11* gene.⁶⁸ Importantly, only up to one-tenth of individuals with mutations in the *PTPN11* gene have hypertrophic cardiomyopathy.^{69,70}

Other genes implicated in Noonan's syndrome include *SOS1*⁷¹, encoding a RAS-specific guanine nucleotide exchange factor, which accounts for up to three-tenths of cases^{72,73}; *KRAS*, which encodes a GTP-binding protein in the RAS-ERK pathway, in less than one-twentieth of cases⁷⁴; and *RAF1*, a downstream effector of RAS.^{75,76}

Danon Disease

This is a lysosomal storage disorder characterised clinically by cardiomyopathy, skeletal myopathy, and developmental delay. It is an X-linked disorder caused by mutations in the gene encoding the lysosome-associated membrane protein-2⁷⁷ that result in intracytoplasmic accumulation of autophagic material and glycogen within vacuoles in cardiac and skeletal myocytes.⁷⁸ Female carriers usually develop hypertrophic and dilated cardiomyopathy during adulthood, whereas males develop symptoms during childhood and adolescence.⁷⁹ The prognosis is generally poor, with most patients dying of cardiac failure. Sudden cardiac death is reported, even in female carriers.⁷⁹ Other features, which may aid in differentiating the condition clinically from idiopathic hypertrophic cardiomyopathy, include Wolff-Parkinson-White syndrome, elevated levels of creatine kinase in the serum, and retinitis pigmentosa.⁸⁰

Adenosine Monophosphate-activated Protein Kinase Mutations
Mutations in the gene encoding the γ_2 subunit of the adenosine monophosphate-activated protein kinase⁸¹ can cause a syndrome of hypertrophic cardiomyopathy, abnormalities in conduction, and Wolff-Parkinson-White syndrome. Histologically, there is accumulation of glycogen within cardiac myocytes and conduction tissue. Many affected individuals have a skeletal myopathy, and biopsy of the skeletal muscles shows excess mitochondria and ragged red fibres.⁸² Patients develop progressive conduction disease and left ventricular hypertrophy, with complete electrocardiographic expression by the age of 18 years.⁸² Atrial arrhythmias are common. Survival in one study was 91% at a mean follow-up of 12 years, with disease-related deaths occurring secondary to thromboembolic stroke related to atrial fibrillation and sudden death.⁸² Recent studies suggest that mutations of this gene account for no more than 1% of cases of hypertrophic cardiomyopathy.⁸²

Mitochondrial Cardiomyopathies

Primary mitochondrial disorders are caused by sporadic or inherited mutations in nuclear or mitochondrial DNA that may be transmitted as autosomal dominant, autosomal recessive, X-linked, or maternal traits. The most frequent abnormalities occur in genes that encode the respiratory chain protein complexes, leading to impaired utilisation of oxygen and reduced production of energy. The clinical presentation of mitochondrial disease is variable in age at onset, symptoms, and range and severity of involvement of the different organs. Numerous case reports and small series have described cardiovascular abnormalities in patients with primary mitochondrial dysfunction, but data on the prevalence of cardiac disease is sparse, and mostly derived from experience in children. Cardiac involvement is a feature in up to two-fifths of mitochondrial encephalomyopathies,⁸³ and usually takes the form of a hypertrophic

cardiomyopathy,⁸⁴ although other cardiomyopathies, including dilated and left ventricular non-compaction, are reported.⁸³ Children with mitochondrial disease and cardiac involvement present earlier than those with non-cardiac disease^{83,84} and have a much worse prognosis, with one study reporting survival of no more than one-fifth at 16 years, compared with 95% for those without cardiac involvement.⁸³ The cardiac phenotype is usually concentric left ventricular hypertrophy without obstruction of the outflow tract, and rapid progression to left ventricular dilation, systolic impairment, and cardiac failure.^{83,84} Sudden arrhythmic death has also been reported.^{83,84} Kearns-Sayre syndrome is a mitochondrial disorder comprising the triad of chronic progressive external ophthalmoplegia, retinitis pigmentosa, and atrioventricular block.⁸⁵ Cardiac manifestations occur in over half the patients, and include syncope, congestive cardiac failure, and cardiac arrest.⁸⁶ The conduction system is frequently affected, with rapid progression to complete heart block associated with death in up to one-fifth.⁸⁷

Friedreich's Ataxia

Friedreich's ataxia is an autosomal recessive condition caused by mutations in the frataxin gene. Cardiac involvement is very common, and is most commonly, but not exclusively, characterised by concentric left ventricular hypertrophy without obstruction to the left ventricular outflow tract.⁸⁸ Patients are usually asymptomatic, although progression to left ventricular dilation and cardiac failure is described.⁸⁹ Rarely, children with Friedreich's ataxia can present with left ventricular hypertrophy several years before the development of neurological signs.⁸⁸ Treatment with the antioxidant idebenone appears to reduce the degree of left ventricular hypertrophy,⁹⁰ but further studies are needed to assess the long-term effects.

Anderson-Fabry Disease

Anderson-Fabry disease is an X-linked lysosomal storage disorder caused by mutations in the α -galactosidase A gene. The resultant enzymic deficiency causes progressive accumulation of glycosphingolipid in the skin, nervous system, kidneys, and heart.⁹¹ Cardiac manifestations include progressive left ventricular hypertrophy, valvar disease, and abnormalities of conduction, with supraventricular and ventricular arrhythmias appearing after adolescence in males and females.⁹¹⁻⁹⁴ Treatment with recombinant α -galactosidase A improves renal and neurological manifestations, as well as quality of life, but its effect on the cardiac manifestations is still under investigation.⁹¹

Pompe's Disease

Pompe's disease, or acid maltase deficiency or glycogen storage disease IIa, is an autosomal recessive disorder with infantile, juvenile, and adult variants that differ with respect to age of onset, rate of progression, and extent of involvement of the tissues. The infantile and childhood forms are characterised by deposition of myocardial glycogen, massive cardiac hypertrophy, and cardiac failure. The infantile form presents in the first few months of life with severe skeletal muscular hypotonia, progressive weakness, cardiomegaly, hepatomegaly, and macroglossia, and is usually fatal before 2 years of age owing to cardiorespiratory failure. Obstruction of the left ventricular outflow tract occurs in one-twentieth of patients.⁹⁵ The electrocardiogram typically shows broad high-voltage QRS complexes and ventricular pre-excitation. In the variants presenting

in juveniles and adults, disease is usually limited to skeletal muscle, with a slowly progressive proximal myopathy and weakness of the respiratory muscles. Replacement with recombinant enzymes appears to cause regression of left ventricular hypertrophy in those with presentation during childhood, and is associated with improved survival.⁹⁶

Infants of Diabetic Mothers

Infants of diabetic mothers can develop transient asymptomatic left ventricular hypertrophy⁹⁷ that affects both ventricles, and generally resolves within 3 to 6 months. Rare reports of fatal hypertrophic cardiomyopathy in infants of diabetic mothers are described.⁹⁸ The aetiology is unknown, but may relate to increased levels of maternal insulin-like growth factor.⁹⁹

Pathology

Macroscopic Features

In the common form of autosomal dominant hypertrophic cardiomyopathy, myocardial hypertrophy is usually asymmetric, affecting the ventricular septum more than the posterior or lateral walls of the left ventricle.^{100,101} Other patterns also occur, including concentric (Fig. 49-1), mid-ventricular, sometimes associated with a left ventricular apical diverticulum,¹⁰² and apical hypertrophy.^{103–105} Co-existent right ventricular hypertrophy is present in up to one-fifth of cases.¹⁰⁰ The papillary muscles are often displaced anteriorly, contributing in one-quarter to systolic anterior motion in the resting state of the aortic, and in one-tenth, the mural, leaflets of the mitral valve. There is often an area of endocardial fibrosis on the septum beneath the aortic valve, caused by repeated contact with the aortic leaflet.^{100,101} The mitral valve itself is often structurally abnormal, with elongation of the aortic leaflet, an increased number of scallops in the mural leaflet, and occasional direct insertion of the papillary muscle into the ventricular surface of the aortic leaflet.¹⁰⁶ Myocardial bridging of the anterior interventricular coronary artery has been observed in adults and children with hypertrophic cardiomyopathy, and may cause myocardial ischaemia.^{107,108}

Figure 49-1 The gross pathological specimen shows concentric left ventricular hypertrophy in an 8-week-old infant with mitochondrial disease. (Courtesy of Dr Michael Ashworth, Great Ormond Street Hospital, London, United Kingdom.)

Figure 49-2 Histopathological slide of hypertrophic cardiomyopathy showing myocyte disarray and interstitial fibrosis. (Courtesy of Dr Michael Ashworth, Great Ormond Street Hospital, London, United Kingdom.)

Microscopic Features

The histological hallmarks of the familial variant are the triad of myocytic hypertrophy, myocytic disarray, and interstitial fibrosis (Fig. 49-2).^{100,101} Myocytic disarray is characterised by architectural disorganisation of the myocardium, with adjacent myocytes aligned obliquely or perpendicular to each other in association with increased interstitial collagen.^{100,101} The myofibrillary architecture within the myocyte itself is also disorganised, with loss of the normal parallel arrangement of the myofibrils. Although disarray occurs in many pathologies, the presence of extensive disarray, more than one-tenth of the ventricular myocardium, is thought to be a highly specific marker for hypertrophic cardiomyopathy.^{100,101} Small intramural coronary arteries are often dysplastic and narrowed due to mural thickening by hyperplasia of the smooth muscle cells.¹⁰⁹

Pathophysiology

Diastolic Function

The major pathophysiological consequence of left ventricular hypertrophy is impairment of left ventricular diastolic properties. Diastolic dysfunction results from abnormalities in both the active component of actin and myosin dissociation in the early filling phase, and the passive properties of the ventricle that affect compliance.^{16,110–113} Prolonged or incomplete left ventricular relaxation results in a reduced rate and magnitude of rapid filling. This in turn leads to reduced left ventricular diastolic volume, reduced stroke volume, and altered diastolic relationships of pressure and volume. The net result is elevation of left ventricular end-diastolic pressures and symptoms of reduced exercise tolerance, dyspnoea, and pulmonary oedema.

Systolic Dysfunction

Global measures of left ventricular systolic function are often normal, but progression to left ventricular dilation and systolic impairment is a recognised complication in a subgroup of patients. Predicting which patients are at risk of developing end-stage disease remains a challenge, and the subject of ongoing research. Several studies have identified a number of markers associated with

progression to systolic impairment. These include syncope, non-sustained ventricular tachycardia, an abnormal response of the blood pressure to exercise,⁴⁷ young age at diagnosis,^{37,41} and severe microvascular dysfunction, as assessed by positron emission tomography.¹¹⁴ A family history of end-stage disease may also be a useful predictor of left ventricular remodelling.⁴¹ Several studies have identified increased left ventricular mural thickness^{37,47,48} and cavity dimensions, particularly an increased end-systolic dimension,^{41,47} as predictors of progression to left ventricular dilation and systolic impairment, although the predictive value of these and other markers remains to be evaluated in large prospective studies. Although case reports of end-stage disease in children are documented,^{36,115} progression to this phase in childhood is extremely rare. Whether onset of hypertrophic cardiomyopathy in infancy or early childhood predisposes individuals to developing end-stage disease is unknown.

Obstruction of the Left Ventricular Outflow Tract

Approximately one-quarter of children and adults with hypertrophic cardiomyopathy have obstructed left ventricular outflow tracts at rest.^{16,29,116} The problem is caused by contact between the aortic leaflet, and occasionally the mural leaflet, of the mitral valve and the ventricular septum. The most widely accepted explanation for this phenomenon is that septal hypertrophy and narrowing of the left ventricular outflow tract produce a zone of high velocity anterior to the mitral valve that causes its aortic leaflet to be sucked against the septum by the Venturi effect. This hypothesis does not explain a number of features associated with systolic anterior motion, in particular, the fact that it begins prior to opening of the aortic valve, and that it can occur in patients with little or no septal hypertrophy. Experimental and observational data suggests that anterior displacement of the papillary muscles and submitral apparatus are necessary to create sufficient slack in the leaflets to permit them to move forward in systole. The effect of enhancing contractility in this model is to increase the drag forces on the leaflet, thereby driving rather than sucking it into the septum.

Many patients without obstruction at rest have gradients that can be provoked by physiological and pharmacological interventions that diminish left ventricular end-diastolic volume or increase left ventricular contractility. Labile obstruction refers to the spontaneous appearance and disappearance of obstruction, while latent obstruction describes those gradients that are present only with provocation. The most commonly used techniques used to provoke obstruction are inhalation of amyl nitrate, the Valsalva manoeuvre, and administration of intravenous inotropes. Increasingly, upright exercise is used to provoke gradients in patients with exertional symptoms.¹¹⁷ Obstruction causes acute reductions in cardiac output, elevated left ventricular filling pressures, and myocardial ischaemia. Corresponding symptoms include chest pain, exertional dyspnoea, presyncope, and syncope.

Arrhythmia

All arrhythmias increase in frequency with advancing age. In adults, atrial fibrillation is the commonest sustained arrhythmia, with an incidence of approximately 2% per year.¹¹⁸ During follow-up, as many as one-quarter of patients develop paroxysmal or chronic atrial fibrillation, which is associated with increased risk of thromboembolic stroke and death from cardiac failure, but not with

sudden death.^{5,118} Atrial fibrillation is rare in children and young adults, although paroxysms of haemodynamically compromising atrial fibrillation have been documented in individuals as young as 15 years.¹¹⁹ Factors that increase the likelihood of atrial fibrillation include older age, worsening functional class, and left atrial enlargement as a result of an obstructed left ventricular outflow tract or severe diastolic left ventricular dysfunction.¹¹⁸

The characteristic features of myocytic disarray and interstitial fibrosis seen in hypertrophic cardiomyopathy represent a potent substrate for ventricular arrhythmia. Furthermore, the presence of microvascular and coronary arterial abnormalities identified in some patients, and the haemodynamic alterations caused by the obstructed outflow tract, predispose patients to myocardial ischaemia,^{120–122} which is in itself a potential trigger for ventricular arrhythmias. In keeping with this, sudden arrhythmic death is the commonest mode of death, including in children and adolescents.²⁵ Despite this, ventricular arrhythmia is rarely identified in life in children.¹¹⁹ Isolated uniform ventricular extrasystoles are documented in up to three-tenths of children and adolescents, multi-form ectopics in one-tenth, and ventricular couplets in another tenth. Frequent ventricular extrasystoles, greater than 100 in 24 hours, however, are exceedingly rare. Furthermore, non-sustained ventricular tachycardia occurs in less than one-tenth of children and adolescents.¹¹⁹ If present, it is a particularly poor prognostic indicator.^{27,29,123} Greater maximal left ventricular mural thickness and left atrial size may be associated with the development of non-sustained ventricular tachycardia.¹²³

Patients that have been successfully resuscitated from sustained ventricular arrhythmias such as ventricular tachycardia or ventricular fibrillation are at a high risk of further events.¹²⁴ Interrogation of tracings from implantable cardioverter-defibrillators preceding appropriate discharges for sustained ventricular arrhythmias demonstrates that ventricular fibrillation is often preceded by sinus tachycardia, atrial arrhythmia, and ventricular tachycardia.^{124,125} The mechanisms by which other tachyarrhythmias trigger ventricular fibrillation have not been fully elucidated, but myocardial ischaemia and abnormal vascular responses may play a role.¹²⁴

Clinical Features

Symptoms

Most individuals with hypertrophic cardiomyopathy have few, if any, symptoms. The initial diagnosis is often made as a result of family screening, following the incidental detection of a heart murmur or an abnormal electrocardiogram. Presentation in infancy can be associated with symptoms of cardiac failure, such as breathlessness, poor feeding, excessive sweating, and failure to thrive.^{33–35,126,127} These symptoms usually occur in the presence of apparently normal left ventricular systolic function and are attributable to an obstructed outflow tract or to diastolic dysfunction.

In older children, the most common symptoms are dyspnoea and chest pain. Chest pain is commonly exertional, but may be atypical, and can also occur at rest or following large meals. Typically, there is considerable day-to-day variation in the amount of activity required to produce symptoms.^{27,28} Syncope is a relatively common

symptom, for which there are multiple mechanisms, including obstruction of the left ventricular outflow tract, abnormal vascular responses, and atrial and ventricular arrhythmias.^{16,128,129} Unexplained or exertional syncope is associated with increased risk of sudden death in children and adolescents.

Physical Examination

General physical examination may provide important diagnostic clues in patients with associated syndromes or metabolic disorders. Clinical examination of the cardiovascular system is often normal, but in patients with obstruction of the left ventricular outflow tract, a number of typical features may be identified. The arterial pulse has a rapid upstroke and downstroke, resulting from rapid ejection during the initial phase of systole, followed by a sudden decrease in cardiac output during mid-systole. This is, occasionally, followed by a palpable reflected wave, resulting in a bisferiens pulse. Examination of the jugular venous pulsation may reveal a prominent a wave, caused by reduced right ventricular compliance. Palpation of the precordium may reveal a sustained, or double, apex beat, reflecting a palpable atrial impulse followed by left ventricular contraction. An additional late systolic impulse may rarely result in a triple apical impulse.

On auscultation, patients with the obstructive variant of hypertrophic cardiomyopathy have an ejection systolic murmur that is heard loudest at the left sternal edge, and which radiates to the right upper sternal edge and apex, but usually not to the carotid arteries or axilla. This murmur may be associated with a palpable precordial thrill. As the obstruction in hypertrophic cardiomyopathy is a dynamic phenomenon, the intensity of the murmur is increased by manoeuvres that reduce the preload or afterload, such as standing from a squatting position and the Valsalva manoeuvre. Most patients with obstruction of the left ventricular outflow tract also have mitral regurgitation, resulting from failure of coaptation of the leaflets during systolic anterior motion of the valve. This causes a pansystolic, high-frequency murmur at the apex, radiating to the axilla.

Investigations

The routine investigation comprises a number of non-invasive assessments that aim to establish or confirm the diagnosis, to evaluate the mechanism of symptoms, and to identify predictors of sudden cardiac death and other disease-related complications.

Electrocardiography

The resting 12-lead electrocardiogram is abnormal in up to 95% of individuals. A variety of patterns are recognised (Fig. 49-3). The most common abnormalities include repolarisation abnormalities, pathological Q waves, most frequently in the inferolateral leads, and left atrial enlargement. Common patterns of abnormal repolarisation include inverted T waves and changes in the ST segments in leads I, aVL, V5, and V6, in leads II, III, and aVF, or in leads V1 to V4. Left-axis deviation, with a mean frontal QRS axis between -15 degrees and -90 degrees is common.¹⁰ Intraventricular conduction delay is not uncommon, but bundle branch block, usually involving the left bundle, is infrequent. Voltage criteria for left ventricular hypertrophy alone are not specific for hypertrophic cardiomyopathy, and are often seen in normal, healthy teenagers

and young adults. In infants, right ventricular hypertrophy is commonly found. Other recognised patterns include the presence of giant negative T waves in the mid-precordial leads, which are characteristic of hypertrophic cardiomyopathy localised to the distal portion of the left ventricle.¹³⁰ It is not uncommon for the corrected QT interval to be slightly prolonged. Some patients have a short PR interval not associated with the Wolff-Parkinson-White syndrome. Atrio-ventricular conduction delay, including first-degree block, is rare except in particular subtypes, such as in association with PRKAG2 mutations and mitochondrial disease.^{131,132}

Echocardiography

The presence on echocardiography of a left ventricular mural thickness greater than two standard deviations above the corrected mean relative to body surface area in any myocardial segment, in the absence of any other cardiac or systemic disease capable of producing a similar degree of hypertrophy, is sufficient for the diagnosis.⁵ The focus of early studies using M-mode interrogation was on the detection of asymmetrical septal hypertrophy, using a ratio between the diastolic thickness of the anterior septum and the left ventricular posterior wall of 1.3 to 1 as a diagnostic criterion.¹³³ Such an increased ratio, however, is commonly found in normal neonates, and in children with congenital cardiac disease.¹³⁴ The advent of cross sectional interrogation showed that any pattern of left ventricular hypertrophy is consistent with the diagnosis, including concentric equal hypertrophy across all segments of the left ventricle, eccentric hypertrophy with the lateral and posterior walls more affected than the septum, distal hypertrophy with the distal segments more affected than basal segments, and apical hypertrophy confined to the left ventricular apex (Fig. 49-4).^{14,104,135,136}

Dynamic obstruction in the left ventricular outflow tract is associated with mid-systolic closure of the aortic valve, often associated with coarse fluttering of the aortic valve (Fig. 49-5A) on M-mode echocardiography. Obstruction of the left ventricular outflow tract can be detected using colour flow Doppler, and quantified using continuous-wave Doppler (see Fig. 49-5B and C). Due to the dynamic nature of the obstruction of the left ventricular outflow tract, serial measurements of maximal gradients may not provide an accurate reflection of progression or stability. Surrogate measures of severity, such as left atrial dilation, should be documented. In some patients, systolic obliteration of the ventricular cavity may produce a high-velocity gradient in the mid-ventricle. Obstruction of the right ventricular outflow tract may be seen in infants, and in older children and adults with cardiomyopathy associated with Noonan's syndrome and some metabolic disorders.

Most patients with systolic anterior motion of the mitral valve and obstruction of the left ventricular outflow tract have mitral regurgitation with a posteriorly directed jet, which can be detected using colour Doppler imaging. The severity of regurgitation correlates with the degree of obstruction in individual patients, but varies considerably between patients with obstruction of similar severity. The presence of complex mitral regurgitant jets, such as those directed anteriorly or centrally, should trigger a search for other valvar abnormalities, such as prolapse of leaflets.

Left ventricular global systolic function, as assessed from change in ventricular volume during the cardiac cycle, is typically increased. Regional and long-axis function is often

Figure 49-3 Electrocardiographic patterns in hypertrophic cardiomyopathy. A shows a 12-lead ECG from a 12-year-old child with asymmetric septal hypertrophy. Note the pathological Q waves in leads II, III, aVF, V5, and V6, and voltage criteria for biventricular hypertrophy. B is a 12-lead tracing from an 8-year-old with severe hypertrophic obstructive cardiomyopathy, showing left ventricular hypertrophy and T wave inversion and ST segment abnormalities in leads I, aVL, and V4–V6.

reduced, and responses of cardiac output during exercise may be impaired.^{137–139} A small proportion of adults develop progressive thinning of the myocardium, associated with left ventricular systolic impairment and cavity dilation, but progression to this end-stage disease is rare in children.

Diastolic function is commonly assessed using pulsed wave Doppler to interrogate the mitral inflow and pulmonary veins, along with tissue Doppler imaging (Fig. 49-6). Patients may have evidence of impaired relaxation as shown by E/A wave reversal and increased E-wave deceleration time on the Doppler interrogation of the mitral inflow, with a ratio of the systolic to the diastolic waves of greater than 1 on pulmonary vein Doppler, and the duration of the atrial reversal wave seen in the pulmonary veins less than the duration of the mitral inflow A wave (see Fig. 49-6). With worsening diastolic function, a pseudo-normal pattern is seen, with normalisation of the mitral inflow E/A ratio and prolongation of the E wave deceleration time, decreased pulmonary venous systolic velocity, increased pulmonary venous diastolic and atrial reversal velocities, pulmonary venous atrial reversal wave duration

greater than mitral inflow A wave duration, and decreased velocity of the propagation slope on colour M-mode (see Fig. 49-6). In some patients, a restrictive phenotype is present, characterised by an increased mitral inflow E/A ratio, reduced E wave deceleration time, and increased pulmonary vein A reversal wave velocity.¹⁴⁰ The velocity of the pulmonary venous atrial reversal wave has been shown to correlate with left ventricular filling pressures.¹⁴¹ Tissue Doppler imaging, and strain and strain rate imaging, can also be used to assess diastolic and systolic function. These techniques have the advantage of being less dependent on loading conditions.^{141–145} Characteristically, patients with diastolic left ventricular impairment demonstrate reduced early diastolic velocities in the mitral annulus and septum, and reversal of the ratio of early to late diastolic velocities. In addition, the ratio of mitral inflow E wave to annular early diastolic velocity can be used as a measure of left ventricular end-diastolic pressure, and predicts exercise capacity.^{142,143} Tissue Doppler imaging may be useful in detecting mild disease in otherwise phenotypically normal gene carriers.^{144,146}

C

D

Figure 49-3—cont'd C is another 12-lead tracing, but from a 14-year-old with concentric left ventricular hypertrophy. It shows T wave inversion extending from V1 to V5, and deep Q waves in leads III and aVF. D is a 12-lead tracing from a young adult with apical hypertrophic cardiomyopathy. It shows widespread T wave inversion, with deep inverted T waves, particularly in the septal leads.

Ambulatory Electrocardiography

The frequency of arrhythmias detected during ambulatory electrocardiographic monitoring is age related.^{119,147–149} In adults, 48-hour monitoring reveals supraventricular arrhythmias in up to half the patients, and non-sustained ventricular tachycardia in one-quarter. Most episodes of the latter arrhythmia are relatively slow, asymptomatic, and occur during periods of increased vagal tone. Sustained ventricular tachycardia is uncommon, but may occur in association with apical aneurysms.¹⁵⁰ As discussed above, the frequency of arrhythmia in childhood is much lower, but the presence of ventricular arrhythmia in particular is a marker of poor prognosis.^{27,29,119}

Cardiopulmonary Exercise Testing

Individuals usually have a reduced peak consumption of oxygen compared with healthy age-matched controls, even when asymptomatic.^{151,152} In children, exercise capacity and peak consumption of oxygen correlate with diastolic impairment.^{143,153} Up to one-quarter of adults have an abnormal response of blood pressure to exercise,^{154,155} related to abnormal vasodilation of the non-exercising vascular beds, possibly triggered by inappropriate firing of left ventricular baroreceptors¹²⁸ and an impaired response

of cardiac output.¹⁵⁶ An abnormal response to exercise is associated with an increased risk of sudden death in young adults.¹⁵⁷ In children, the use of cardiopulmonary exercise testing as a tool for stratification of risk has not been evaluated, but there are several problems associated with the technique. Very young children, usually under the age of 7 or 8 years, cannot reliably perform exercise testing, and flat responses are normal in pre-adolescents. The technique, nevertheless, remains a useful tool for the evaluation of severity and response to treatment in older teenagers.

Cardiac Magnetic Resonance Imaging

Like echocardiography, cardiac magnetic resonance imaging can assess the distribution and severity of left ventricular hypertrophy and provide functional measurements of systolic and diastolic function. The technique is particularly useful in the evaluation of patients with hypertrophy of the lateral wall, an area that can be difficult to visualise adequately using cross sectional echocardiography. In addition, magnetic resonance imaging can be used to assess myocardial tissue characteristics during life using gadolinium contrast agents (Fig. 49-7). As many as four-fifths of adults have areas of patchy hyper-enhancement, the extent of which appears to correlate with risk factors

Figure 49-4 Echocardiographic patterns of hypertrophic cardiomyopathy. A shows a parasternal long-axis view of a 13-year-old with severe asymmetrical septal hypertrophy. The parasternal short-axis view of the same patient is shown in B. C shows the parasternal short-axis view from a 12-year-old with concentric left ventricular hypertrophy. D is a parasternal short-axis view from a 14-year-old with an eccentric distribution of left ventricular hypertrophy.

Figure 49-5 Echocardiographic features of left ventricular outflow tract obstruction. A shows an M-mode tracing of the aortic valve from a 5-year-old with severe obstructive hypertrophic cardiomyopathy, showing coarse fluttering and mid-systolic closure of the leaflets. B is another M-mode recording, but of the mitral valve from a 12-year-old with hypertrophic obstructive cardiomyopathy showing complete systolic anterior motion of the aortic mitral valvar leaflet. C is a continuous wave Doppler from the same patient, showing the characteristic waveform of the obstructed left ventricular outflow tract, in this case with a maximal velocity of nearly 5 m/s.

Figure 49-6 The panels show the echocardiographic features of left ventricular diastolic impairment. A is a pulsed wave Doppler tracing of the mitral inflow from a 7-year-old with hypertrophic cardiomyopathy. It shows E/A wave reversal and a prolonged E wave deceleration time, characteristic of impaired relaxation of the left ventricle. B is another pulsed wave Doppler recording of a 15-year-old, showing pseudo-normalisation of the pattern of mitral inflow, with a normal E/A ratio but prolonged E wave deceleration time. C is a pulsed wave Doppler recording in the right upper pulmonary vein in a 14-year-old with severe hypertrophic cardiomyopathy, showing impaired relaxation of the left ventricle, characterised by a reduced diastolic wave and increased atrial reversal wave. D is a pulsed wave tissue Doppler recording of the lateral mitral annulus in a 13-year-old with hypertrophic cardiomyopathy showing reduced systolic (Sa), early diastolic (Ea), and late diastolic (Aa) velocities.

for sudden death and with progressive left ventricular remodelling.^{158,159}

Other Imaging Modalities

Cardiac catheterisation and angiography are no longer used routinely in the assessment of children, as structural and haemodynamic data is easily obtained using non-invasive techniques. Coronary arteriography may demonstrate myocardial bridging and systolic compression of the epicardial and intramural coronary arteries, but the clinical significance of this observation remains controversial.^{108,121,122}

Myocardial perfusion scanning using radioisotopes such as thallium-201 has been used to study the pathophysiology of myocardial ischaemia. Although an association between impaired myocardial perfusion and a history of syncope or resuscitated cardiac arrest has been reported in children,¹⁶⁰ larger studies in young adults showed no association between reversible perfusion defects and

exertional chest pain or electrocardiographic ST segment changes.^{161,162}

Management

Management focuses on three main areas, namely, the counselling of other family members, management of symptoms, and the prevention of disease-related complications.

Family Evaluation

All patients should be counselled on the implications of the diagnosis for their families. Careful analysis of the pedigree can reassure relatives who are not at risk of inheriting the disease.⁵ For those who may be at risk, clinical screening with electrocardiograms and echocardiography may be appropriate after counselling. Current guidelines recommend screening with a 12-lead electrocardiogram and echocardiogram at intervals of 12 to 18 months, usually

Figure 49-7 Cardiac magnetic resonance imaging in hypertrophic cardiomyopathy. **A** shows black-blood HASTE imaging of a child with apical hypertrophic cardiomyopathy. **B** shows late gadolinium enhancement of the apical region in the same patient. (Courtesy of Dr Marina Hughes, Great Ormond Street Hospital, London, United Kingdom.)

starting at the age of 12 years, unless there is a malignant family history of premature sudden death, the child is symptomatic or a competitive athlete in intensive training, or there is a clinical suspicion of left ventricular hypertrophy. Screening continues until full growth and maturation are achieved, usually by the age of 18 to 21 years. Following this, if there are no signs of phenotypic expression, screening approximately every 5 years is advised, as the onset of left ventricular hypertrophy may be delayed until well into adulthood in some families.^{55,163–168}

It is now possible to offer relatively rapid genetic testing to individuals with unequivocal disease. If a mutation causing disease is identified, relatives can be offered predictive testing. Again, this should be performed only after appropriate genetic counselling and consideration of issues relating to autonomy, confidentiality and psychosocial harm, including loss of self-esteem, stigmatisation or discrimination, and guilt.

Treatment of Symptoms Caused by Obstruction of the Left Ventricular Outflow Tract

By convention, obstruction of the left ventricular outflow tract is defined as a pressure gradient greater than or equal to 30 mm Hg,^{12,104} but theoretical models examining the relationship between the gradient and stroke volume predict that only gradients in excess of 50 mm Hg are likely to represent significant obstruction to ventricular ejection.¹⁰⁴ The first-line strategy for control of symptoms in patients with obstructive disease is medical therapy with β -adrenergic receptor blockers, such as propranolol, given at 1 to 2 mg/kg per dose, or more cardioselective drugs such as atenolol, metoprolol, nadolol, and bisoprolol. At standard doses, β -blockers can reduce symptoms of chest pain, dyspnoea, and presyncope on exertion, although they probably do not reduce obstruction under resting conditions. Studies using very large doses of propranolol, up to 23 mg/kg per day, in children and adolescents have reported improved long-term survival,¹⁶⁹ but this is not generally accepted practice, as side effects of β -blockers are common, and even moderate doses can affect growth and school

performance in young children, or trigger depression in children and adolescents.⁵ If β -blockade is unsuccessful, the addition of the class I antiarrhythmic disopyramide can reduce obstruction and improve symptoms.^{170–172} This effect is exerted via its negative inotropic action. Disopyramide is usually well tolerated in children, but initiation at a low dose is recommended, as some patients may experience marked anticholinergic effects. As disopyramide causes accelerated atrioventricular nodal conduction, and may increase the ventricular rate during atrial fibrillation, it is usually administered in combination with a β -blocker. Disopyramide causes prolongation of the QT interval, and so the electrocardiogram must be monitored regularly. Other drugs that prolong the QT interval, such as sotalol or amiodarone, should be avoided.

The calcium antagonist verapamil improves symptoms caused by obstruction, probably by relieving myocardial ischaemia and reducing myocardial contractility.^{110,173} Chronic oral therapy has been shown to be effective in children with both obstructive and non-obstructive forms of the disease.¹⁷⁴ Side effects include constipation and hair loss. In patients with severe symptoms caused by large gradients and pulmonary hypertension, verapamil can cause severe haemodynamic deterioration,^{175,176} and so should be used with caution.

Several options are available to patients with obstructive hypertrophic cardiomyopathy who do not tolerate drugs, or whose symptoms are refractory to medical therapy. The gold standard^{177–181} is septal myotomy or myectomy, in which a trough of muscle is removed from the ventricular septum via an aortic incision. Recently, extended myectomies to the level of the papillary muscle have been performed.¹⁸² In the hands of experienced surgeons, the mortality is less than 1%, and the rate of success is high, with complete and permanent abolition of the gradient, and a marked improvement in symptoms and exercise capacity in over nine-tenths of patients. Non-fatal complications include complete heart block requiring insertion of a permanent pacemaker in less than one-twentieth of patients,

and inadvertent creation of small ventricular septal defects. In most cases, a single procedure is required to achieve a permanent reduction in gradient, but repeated operations may be needed in very young children, possibly resulting from a limited initial myectomy due to a small aortic diameter, or from continued remodeling of the left ventricular outflow tract.

Atrioventricular, or dual-chamber, pacing has been shown to reduce gradients in uncontrolled, observational studies including one performed in children,^{183–185} and in two randomised controlled clinical trials. The randomised trials showed no objective improvement in exercise capacity and a symptomatic effect no better than placebo,^{186,187} except possibly in elderly patients with relatively mild hypertrophy.

An alternative to surgery for adults with obstructive disease is ablation of the ventricular septum by injection of 95% alcohol into a septal perforating coronary artery. This produces an area of localised myocardial necrosis within the basal septum.^{188,189} Myocardial damage is kept to a minimum by first visualising the area supplied by the perforator branch using echocardiographic contrast injection.¹⁹⁰ Although short-term results are promising, the long-term effects are unknown, and there is potential for the resulting myocardial scar to act as a substrate for ventricular arrhythmia and sudden death. This, and the fact that the results in children and adolescents are often suboptimal, means that alcohol septal ablation is not recommended for use in this age group.

Management of Symptoms in Non-obstructive Disease

In patients without obstruction of the left ventricular outflow tract, chest pain and dyspnoea are usually caused by diastolic dysfunction and myocardial ischaemia. Treatment in this group of patients is empirical, and often suboptimal. Both β -blockers and calcium antagonists such as verapamil and diltiazem can improve symptoms by improving left ventricular relaxation and filling, reducing left ventricular contractility, and relieving myocardial ischaemia. Other drugs, such as nitrates and inhibitors of angiotensin-converting enzyme, may be beneficial in some patients, but should be used with caution in those in whom obstruction can be provoked, as they can exacerbate the gradient by virtue of their vasodilating effects. Adults who develop end-stage disease should receive conventional treatment for cardiac failure, including inhibition of angiotensin-converting enzymes, and use of angiotensin II receptor antagonists, spironolactone, β -blockers such as carvedilol or metoprolol, digoxin, and if necessary, cardiac transplantation.

Prevention of Sudden Cardiac Death

Although the overall risk of sudden death in children and adults is only approximately 1% per year, a significant minority of individuals have a much greater risk of ventricular arrhythmia and sudden death.¹⁹¹ The mechanism of sudden death is thought to be ventricular arrhythmia in the majority, and several triggers are recognised, including atrial arrhythmia, myocardial ischaemia, and exercise.¹⁹² The most reliable predictor is a history of previous cardiac arrest.^{124,193} In patients without such a history, the most clinically useful markers of risk are a family history of sudden cardiac death,^{27,194} unexplained syncope unrelated to neurocardiogenic mechanisms, a flat or hypotensive response of blood pressure to upright exercise,^{155,157,195} non-sustained ventricular tachycardia on ambulatory electrocardiographic monitoring or during exercise,^{123,147,157} and severe left ventricular hypertrophy on echocardiography,

defined as a maximal left ventricular wall thickness of 30 mm or more.^{196,197} Importantly, these markers of increased risk can all be identified non-invasively. Studies have shown that patients with none of these features have a low risk of sudden death, less than 1% per year, whereas those with two or more risk factors are at substantially higher risk of dying suddenly, with an estimated annual mortality rate of 3% for those with two risk factors, rising to 6% in those with three or more risk factors.¹⁵⁷ Patients with a single risk factor represent a more difficult group, as the annual death rate in this group is low, but the confidence intervals are wide, suggesting that some individuals with a single risk factor may be twice as likely to die suddenly than patients without risk factors. The evaluation of risk in these patients, therefore, has to be tailored to the individual, taking into account the significance of the risk factor—for example, a particularly malignant family history may be sufficient to trigger primary preventative measures in the absence of a second risk factor—as well as patient specific variables such as age (Fig. 49-8).^{157,198} Several studies have shown that obstruction of the left ventricular outflow tract is associated with increased cardiovascular mortality, including sudden death.^{199,200} The absolute risk of sudden death associated with obstruction in isolation is low, but it may represent an incremental risk factor in combination with other conventional markers.¹⁹⁹

Although the algorithm for stratification of risk described above has been applied with some success to children and adolescents,¹²⁵ extrapolation of data derived from adults may not always be appropriate for children. Of the conventional markers of an increased risk for sudden death, unexplained syncope, severe left ventricular hypertrophy, and a family history of sudden death have been reported as being particularly relevant to young individuals.^{27,157,194,196,197,201} The response of blood pressure to exercise, however, may not be a sensitive marker of the risk in children, and whilst non-sustained ventricular tachycardia is a poor prognostic marker in this population, most children and teenagers who die of hypertrophic cardiomyopathy do not have this arrhythmia.¹¹⁹

In patients who are considered to be at high risk, insertion of an implantable cardioverter-defibrillator should be regarded as the treatment of choice.⁵ Retrospective registry data demonstrates that implantable cardioverter-defibrillators prevent sudden death in predominantly adult populations, with annual appropriate discharge rates of one-tenth in those undergoing secondary prevention, in other words, those with a history of cardiac arrest or sustained ventricular arrhythmia, and in one-twentieth of groups selected for primary prevention because of risk factors.²⁰² In children, appropriate discharge rates are higher at 71% per year in those chosen for secondary prevention,^{125,203} and 4% per year in those having primary prevention. Despite the life-saving benefits of implantable cardioverter-defibrillators, an increased incidence of complications has been reported in children compared with adults, including a higher rate of inappropriate discharges for supraventricular or sinus tachycardia, an increased risk of infection, complications with leads related to growth,^{204–206} and the psychological sequels of appropriate and inappropriate discharges.^{207,208} Prior to the advent of implantable cardioverter-defibrillators, amiodarone was used to prevent sudden death in patients considered at

Figure 49-8 The key features in the management of patients with hypertrophic cardiomyopathy. ACEI, angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; BP, blood pressure; ICD, implantable cardioverter-defibrillator; LVOTO, left ventricular outflow tract obstruction; VF/VT, ventricular fibrillation/ventricular tachycardia. high-risk.²⁰⁹ The drug, however, does not prevent sudden cardiac death in this group at high-risk.¹²⁵ Amiodarone does, nonetheless, remain useful for the treatment of atrial fibrillation.

MYOCARDITIS

Definition and Historical Aspects

The term myocarditis was first used in the early 19th century to describe myocardial diseases not associated with valvar abnormalities, but it now refers to disorders characterised by myocardial inflammation.^{210,211} Although a large number of infectious and non-infectious aetiologies of myocarditis have been identified, viruses are thought to be the most important cause in Europe and the United States.²¹¹ Viral myocarditis remains the prototype for the study of the disease,²¹² and is the focus of this chapter. Recent advances in molecular biology have revealed new insights into the complex interactions between viral injury and myocardial immune responses, which has led to a better understanding of the pathogenesis of myocarditis, and to the development of novel diagnostic and therapeutic approaches.²¹³

Epidemiology

The exact incidence of myocarditis is unknown, since the clinical presentation varies from asymptomatic electrocardiographic abnormalities to haemodynamic collapse and sudden death. Furthermore, the diagnosis can be difficult,

as histopathological features²¹⁴ have been shown to underestimate its true prevalence.²¹⁵ Population estimates of the prevalence range from 1 in 100,000 to 1 in 10,000, with retrospective and prospective postmortem studies reporting myocarditis in up to one-eighth of young victims dying suddenly.^{216–220} In children, definite or borderline evidence of myocarditis was found in almost two-fifths of individuals.²²¹ It has been suggested that infants and young children may be more prone to developing myocarditis, due to a higher rate of enteroviral and adenoviral infections in this age group.²²²

Natural History

The natural history of myocarditis is varied, reflecting its heterogeneous clinical presentation. Most patients probably recover fully, even when they present with a syndrome mimicking acute myocardial infarction.^{223,224} Patients presenting with clinical cardiac failure and mild left ventricular systolic impairment typically improve within weeks or months.²¹² In patients with more severe left ventricular dysfunction, with an ejection fraction less than 35%, and left ventricular end-diastolic diameters greater than 60 mm, approximately one-quarter progress to transplantation, half develop chronic dilated cardiomyopathy, and the others recover spontaneously.^{212,225}

Survival in children ranges from 70% to 100%,^{221,226–228} with two-thirds recovering completely.²²⁶ Whilst the prognosis in infants and children with myocarditis is generally good, a high rate of death is reported for neonates with

enteroviral myocarditis,²²⁹ suggesting that neonatal myocarditis may represent a higher risk.

Aetiology

Many infectious, inflammatory, and toxic causes of myocarditis have been identified (Table 49-2). Worldwide, the commonest infective myocarditis is Chagas' disease.^{230–232} In the Western world, viral myocarditis is the most common cause of inflammatory cardiac disease. Several viruses have been implicated, the most relevant of which are discussed below. Rarer myocarditides in children include giant cell myocarditis, characterised by a giant cell inflammatory infiltrate within the myocardium associated with prominent myocyte necrosis and a high mortality rate, and myocarditis complicating autoimmune disorders such as systemic lupus erythematosus, rheumatoid arthritis, and ulcerative colitis. An important cause in young adults, and increasingly in teenagers, is abuse of cocaine, which can result in acute coronary arterial vasospasm, but may also lead to acute and severe left ventricular systolic dysfunction.²²²

Enterovirus

Historically, the most commonly implicated virus in myocarditis has been the coxsackie B enterovirus.²³³ Strains with marked cardiotropic virulence have been identified.²³⁴ A causal association between enteroviruses and myocarditis was initially suggested by studies showing a relationship between rising titres of coxsackievirus B antibodies in the serum and acute symptomatic presentation.^{235,236} More recently, the enteroviral genome has been detected in myocardial biopsies of patients with myocarditis and dilated cardiomyopathy.²³⁷ The pathogenic mechanism relates cleavage of dystrophin by the coxsackievirus protease, which disrupts the cytoskeletal structural integrity of the cardiac myocyte.²³⁸

Adenovirus

An early study using viral cultures and serological markers showed the presence of adenovirus in one-sixth of children with acute myocarditis.²³⁹ More recently, adenovirus DNA has been identified using polymerase chain

reaction in up to two-fifths of samples from explanted hearts or endomyocardial biopsies in children with acute myocarditis.^{240–243} In one study, adenovirus was identified more frequently than enterovirus in both children and adults with myocarditis.²⁴⁴ Coxsackievirus and adenovirus are known to share a common cellular receptor.^{245,246}

Parvovirus

Parvovirus B19 infection is common in humans, usually causing erythema infectiosum. There are several reports of myocarditis associated with parvovirus infection, with one recent study finding viral DNA in one-tenth of endomyocardial biopsy samples taken from adults with histological evidence of myocardial inflammation or left ventricular dysfunction.²⁴⁷ Childhood parvovirus myocarditis has also been reported with sudden cardiac death.^{248–252}

Other Viruses

Many other viruses have been implicated in myocarditis in children, including cytomegalovirus, hepatitis C virus, and herpes simplex virus. In addition, the human immunodeficiency virus has been associated with myocarditis and left ventricular dysfunction.^{253–255}

Pathology

Proposed in 1986, the Dallas criteria²¹⁴ provide standardised histopathological criteria for classification, defining myocarditis according to the presence of histological evidence of myocytic injury with degeneration or necrosis, and an inflammatory infiltrate not due to ischaemia.²¹⁴ Four forms of myocarditis are recognised: active in the presence of both myocytic degeneration or necrosis and definite cellular infiltrate, borderline when there is a definite cellular infiltrate but no evidence of myocardial cellular injury, persistent when active myocarditis is found on a repeat biopsy, and resolving or resolved when there is diminished or absent infiltrates with evidence of connective tissue healing on a repeated biopsy. Despite their widespread use, the criteria have many limitations, including low specificity and sensitivity, with a diagnostic yield as low

TABLE 49-2

COMMON CAUSES OF MYOCARDITIS

Infectious		Immune-mediated		Toxic
Viral	Adenovirus	Autoantigens	Churg-Strauss syndrome	Anthracyclines
	Coxsackievirus		Inflammatory bowel disease	Cocaine
	Hepatitis C virus		Giant cell myocarditis	Interleukin-2
	Human immunodeficiency virus		Diabetes mellitus	Ethanol
Bacterial	Mycobacteria	Hypersensitivity	Sarcoidosis	Heavy metals
	<i>Streptococcus</i> sp.		Systemic lupus erythematosus	
	<i>Mycoplasma pneumoniae</i>		Thyrotoxicosis	
	<i>Treponema pallidum</i>		Takayasu's arteritis	
Fungal	<i>Aspergillus</i>		Wegener's granulomatosis	
	<i>Candida</i>		Sulphonamides	
	<i>Coccidioides</i>		Cephalosporins	
	<i>Cryptococcus</i>		Diuretics	
	<i>Histoplasma</i>		Tricyclic antidepressants	
Protozoal	<i>Trypanosoma cruzi</i>		Dobutamine	
Parasitic	Schistosomiasis			
	Larva migrans

as 10% to 20% in some series.²¹² Sampling error and variation in interpretation contribute further to the low diagnostic accuracy.²⁵⁶ Furthermore, some studies have shown a poor association between histological evidence of myocarditis and the presence of autoantibodies in patients with clinically suspected myocarditis.²⁵⁷ In addition, studies in large cohorts of patients with clinically suspected myocarditis have failed to demonstrate associated positive biopsy findings,^{258,259} and a study in children has shown that virus may be present in the myocardium despite a lack of histological evidence of myocarditis.²⁴² These data suggest that using the Dallas criteria alone to establish a diagnosis of myocarditis may result in significant under-diagnosis of the condition. Newer immunohistochemical and virologic techniques should be used in conjunction with the traditional histological tools to provide a more accurate diagnosis of myocarditis.

Pathophysiology

Studies in animals, mostly mice, have yielded important insights into the pathogenesis of viral myocarditis.²⁶⁰ Initially, there is direct invasion of the myocardium by cardiotropic viruses, which enter the myocyte via receptor-mediated endocytosis. The viral genome is then translated intracellularly to produce viral protein, or is incorporated into the host cell genome, contributing to myocytic dysfunction by cleaving dystrophin. This is followed by a second phase, in which rapid activation of the host immune system, including recruitment of natural killer cells and macrophages, results in the expression of pro-inflammatory cytokines such as interleukin-1, tumour necrosis factor, and nitric oxide. Activation of CD4+ T lymphocytes, which promotes clonal expansion of B lymphocytes, results in further myocardial damage, local inflammation, and the production of circulating anti-heart antibodies directed against contractile, structural, and mitochondrial proteins.^{212,261} This autoimmune response may result in long-term ventricular remodeling through direct effects on myocardial structural components, or through alterations in extracellular matrix turnover, which disrupt the structural integrity of the heart.²⁶²

Clinical Features

The diagnosis of myocarditis requires a high index of suspicion, particularly in children, as it may mimic other common diagnoses (see Table 49-2). Many individuals with myocarditis may be asymptomatic and manifest only transient electrocardiographic abnormalities. Others may present with symptoms and signs of fulminant cardiogenic shock with acute cardiovascular collapse. In some cases, sudden cardiac death may be the first presentation of myocarditis,²¹² and cases of sudden infant death syndrome associated with enterovirus and parvovirus have been reported.^{263,264} In other cases, there may be prodromal symptoms of viraemia, including fever, myalgia, coryzal symptoms or gastroenteritis, but the prevalence of these in different series is highly variable, ranging from one-tenth to four-fifths in adults.^{211,212,265} A viral prodrome may be more common in children, in whom studies have reported frequencies of up to nine-tenths^{226,242} of those with histologically confirmed myocarditis.

Presentation with signs and symptoms of congestive cardiac failure, resulting from an acute impairment of systolic function with or without left dilation, may differ in adults and children.²⁶⁶ The prevalence of biopsy-proven myocarditis among adults with acute-onset dilated cardiomyopathy is between one-tenth and one-sixth.^{225,267} Prevalence in children ranges from half to four-fifths.^{242,244,268}

Investigations

Electrocardiography

Transient electrocardiographic abnormalities occur commonly during community viral epidemics, with most patients remaining asymptomatic.²¹² In childhood studies, the electrocardiographic changes described include non-specific ST segment and T wave abnormalities, pathological Q waves, T wave inversion, and low QRS voltages.^{226,228} Electrocardiographic changes that mimic acute myocardial infarction have also been described.^{223,224} Myocarditis also causes atrioventricular block and ventricular arrhythmia, ranging from the presence of frequent ventricular extrasystole to sustained ventricular tachycardia.^{212,223,224} These electrocardiographic abnormalities are frequently asymptomatic, but occasionally may be associated with symptoms such as palpitation, presyncope, or syncope. In some cases, the only electrocardiographic manifestation of myocarditis may be a sinus tachycardia.

Chest Radiography

The chest radiograph may show an increased cardiothoracic ratio, increased pulmonary venous markings, and pulmonary oedema in some patients with acute myocarditis. The heart size may be normal in patients with acute, haemodynamically compromising left ventricular dysfunction, and in those with transient electrocardiographic abnormalities.

Echocardiography

Echocardiographic findings are varied and often non-specific, although the echocardiogram is rarely entirely normal in myocarditis, other than in some patients presenting only with ventricular ectopy. Evidence of impaired left ventricular systolic performance, with reduced fractional shortening and ejection fraction, is common.²⁶⁹ Regional abnormalities of wall motion occur commonly, and functional mitral regurgitation, in the setting of left ventricular dilation, may also be found. Left or right ventricular thrombus may be present. Evidence of left ventricular diastolic impairment may also be detected. Less frequently, right ventricular systolic and diastolic function may also be compromised. Pericardial effusions are common. In the neonatal period and early infancy particularly, echocardiography has an important role in excluding anomalous coronary arterial anatomy, in particular, anomalous origin of the left coronary artery from the pulmonary trunk, as well as left-sided obstructive lesions, which can have a similar clinical presentation to myocarditis.

Cardiac Biomarkers

Routine blood tests such as full blood count and erythrocytic sedimentation rate are not usually helpful in confirming the diagnosis of myocarditis. Markers of myocardial injury may be of use.^{270,271} Troponin I has a high specificity for diagnosing myocarditis but a sensitivity of only 34%.²⁷¹ Creatine kinase and its cardiac isoform CK-MB are less sensitive and specific than troponin, and are therefore not clinically useful for screening. Increased levels of autoantibodies against myocardial proteins have also been

reported, and correlate with progressive worsening of ventricular function.^{272,273}

Endomyocardial Biopsy

Cardiac catheterisation with right ventricular endomyocardial biopsy remains the gold standard diagnostic test for myocarditis, albeit the analysis using the Dallas criteria suffers from several important limitations. Immunohistochemical staining of samples can be used to obtain precise characterisation of lymphocyte subtypes.²⁷⁴ The quantification of major histocompatibility complex and intercellular cell adhesion molecule induction using molecular immunohistochemical techniques has been demonstrated to have a higher sensitivity than the Dallas criteria for diagnosing myocarditis, although this may represent a subgroup of patients with a more chronic form of myocardial injury.^{275,276}

Viral Polymerase Chain Reaction

The confirmation of a viral cause for myocarditis has been the subject of much recent interest. The diagnosis of viral myocarditis previously was based on the presence of positive viral cultures or serological confirmation of an antiviral immune response. These methods, however, are time consuming and have a low diagnostic yield. Polymerase chain reaction techniques have been shown successfully and rapidly to detect the presence of viral genome in samples from patients with myocarditis and dilated cardiomyopathy, including children.^{242,244,277}

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging can demonstrate myocardial inflammation and myocyte injury, including the presence of pericellular and cellular oedema. In addition, the technique can provide useful anatomical and functional information. Although there have been no studies in children with myocarditis, data from adults²⁷⁸ may be applicable to children.

Management

General Principles

The first-line treatment is supportive. General principles of stabilisation include afterload reduction, anticoagulation, diuresis, and inotropic support. Patients with fulminant acute myocarditis may require intensive intravenous haemodynamic support. Diuretics and vasodilators, such as nitroglycerin or glyceryl trinitrate, are the mainstay of afterload reduction. In some cases, mechanical assist devices or extracorporeal membrane oxygenation may be required.^{279–282}

Following initial stabilisation, treatment for patients with symptoms and signs of cardiac failure should follow current guidelines set out by the International Society for Heart and Lung Transplantation.²⁸³ This includes the use of inhibitors of angiotensin-converting enzyme and diuretics. The addition of β -blocking agents such as carvedilol should also be considered in patients with compensated cardiac failure. In addition, patients with left ventricular enlargement should receive anticoagulation with aspirin or warfarin. Patients with intractable and deteriorating cardiac failure may require cardiac transplantation.

Immunotherapy

Intravenous immunoglobulin has been considered the standard therapy for children with suspected myocarditis. The reason is that immunoglobulin may help clear

the virus directly, or may stimulate the immune response to the viral infection.²⁸⁴ In support of this, clinically beneficial effects of intravenous immunoglobulin have been reported in both children and adults with acute myocarditis.^{285–288} The only double-blind randomised controlled trial, however, failed to show any treatment-related differences in all-cause mortality or any improvement in left ventricular ejection fraction.²⁸⁹ There are no randomised controlled trials of intravenous immunoglobulin therapy in children with myocarditis. As a result, a recent Cochrane Database review concluded that current evidence does not support the use of intravenous immunoglobulin for the management of presumed viral myocarditis, and that 'intravenous immunoglobulin for presumed viral myocarditis should not be part of routine practice'.²⁹⁰

The suggestion that immune responses to viral infection of the myocardium may cause the long-term sequelae of viral myocarditis has led to the use of immunosuppression to suppress the acute inflammatory response.^{211,212} The contrary argument is that immunosuppression could impair the ability of the host immune system to eradicate virus.²⁹¹ Prednisolone increases mortality in mice with acute viral myocarditis.²⁹² In the Myocarditis Treatment Trial, there was no difference in mortality or improvement in left ventricular function between the control group and those being immunosuppressed,²⁶⁵ and patients with more robust immune responses had less severe disease and a better outcome. In another study, there was improvement in left ventricular ejection fraction in the immunosuppressed patients, but no difference in mortality, transplantation, or rehospitalisation.²⁷⁶

The data in children are scant. Observational case series appear to show a beneficial effect of immunosuppression,^{221,228,268,293} but these studies are limited by a lack of randomisation and placebo control.²⁹¹

Novel Therapeutic Strategies

Studies in mice have shown encouraging results with monoclonal antibodies directed against coxsackievirus B²⁹⁴ and with enterovirus life-cycle inhibitors.²⁹⁵ In children, preliminary studies using pleconaril, a drug that binds directly to coxsackievirus B and prevents it from infecting target cells, have also shown promise.²⁹⁶ Ribavirin, started early in the disease process, may also be beneficial in enterovirus myocarditis.²⁹⁷ More recently, interferon- α ²⁹⁸ and interferon- β ²⁹⁹ have shown encouraging initial results, although their efficacy and long-term side effect profile need to be evaluated in larger randomised controlled trials. Modulation of the renin-angiotensin-aldosterone system using inhibitors of angiotensin-converting enzyme or antagonists of angiotensin receptors has been shown to downregulate autoimmune responses without causing immunosuppression in murine models of myocarditis, suggesting that these agents may be useful in preventing the development of progressive left ventricular remodeling and chronic dilated cardiomyopathy in patients with myocarditis.³⁰⁰ From a public health perspective, it is possible that vaccines targeting the common viruses associated with myocarditis, such as coxsackievirus B, adenovirus, and parvovirus, might be a more effective strategy.²⁸⁴

DILATED CARDIOMYOPATHY

Definition

Dilated cardiomyopathy is a myocardial disorder defined by dilation and impaired systolic function of the left ventricle, or both ventricles, in the absence of coronary arterial disease, valvar abnormalities, or pericardial disease.⁴ As will be discussed, a number of different cardiac and systemic diseases are associated with left ventricular dilation and impaired contractility, but in most patients, no identifiable cause is found.³⁰¹

Epidemiology

Dilated cardiomyopathy is the commonest cardiomyopathy in children, accounting for up to three-fifths of cases.^{22,23} The annual incidence is between 0.58 and 0.73 cases per 100,000 of the population.^{22,23} Overall, males and females are approximately equally affected, but in dilated cardiomyopathy associated with neuromuscular disorders or inborn errors of metabolism, there is a striking male predominance,³⁰² associated with X-linked inheritance in many cases. The majority of children with dilated cardiomyopathy present before 1 year of age,^{302,303} with the exception of the group with an underlying neuromuscular disease, in whom presentation occurs more commonly in adolescence.³⁰²

Natural History

Early studies of outcome in children reported an actuarial survival from presentation of 79% at 1 year and 61% at 5 years.³⁰⁴ In a more recent study, freedom from death or transplantation was 69% at 1 year and 54% at 5 years³⁰² (Fig. 49-9). Actuarial rates of freedom for death or

transplantation in a smaller Australian study were 72% at 1 year, and 63% at 5 years.³⁰³ Risk factors for subsequent death or transplantation include older age at diagnosis,^{302,303} fractional shortening, congestive cardiac failure at presentation, and familial disease. Patients with idiopathic disease and neuromuscular disorders also do less well.³⁰²

Aetiology

A number of conditions associated with dilated cardiomyopathy have been described, including neuromuscular disorders, inborn errors of metabolism, and malformation syndromes (see Table 49-1).³⁰² In the majority of patients, no identifiable cause is found, and the disease is considered idiopathic.³⁰¹ Up to one-third of individuals with dilated cardiomyopathy have familial disease, in which at least one other first-degree relative is affected.³⁰⁵

Familial Dilated Cardiomyopathy

Familial disease occurs in over a third of adult patients.³⁰⁵ The reported prevalence of familial dilated cardiomyopathy in children is much lower, from one-twentieth to one-sixth,^{302,303} but this is likely to represent an underestimate, resulting from reduced awareness of the inherited nature of the condition among paediatricians, and possibly a higher prevalence of metabolic or syndromic causes in children. A number of genetic mutations can cause dilated cardiomyopathy.⁵³ In most cases, these are transmitted as an autosomal dominant trait, but other forms of inheritance, including autosomal recessive, X-linked and mitochondrial also occur.

Autosomal Dominant Dilated Cardiomyopathy

Autosomal dominant inheritance accounts for approximately one-quarter of all cases,³⁰⁶ and was the commonest mode of inheritance in the study from North America,

Figure 49-9 Freedom from death or transplantation in children with dilated cardiomyopathy. DCM, dilated cardiomyopathy. (Reproduced with permission from Towbin JA, Lowe AM, Colan SD, et al: Incidence, causes, and outcomes of dilated cardiomyopathy in children. *JAMA* 2006;296:1867–1876.)

accounting for two-thirds of familial cases.³⁰² Two major forms of autosomal dominant dilated cardiomyopathy are recognised, namely, isolated (or pure), and dilated cardiomyopathy associated with disease of the cardiac conduction system. In many cases, there may also be a skeletal myopathy.

Genes implicated in the isolated form include cytoskeletal (δ -sarcoglycan,³⁰⁷ β -sarcoglycan,³⁰⁸ desmin,^{309,310} and sarcomeric protein genes including α -cardiac actin,³¹¹ troponin T,³¹² β -myosin heavy chain,³¹² troponin C,³¹³ and α -tropomyosin.³¹⁴ Although a number of genes have been mapped when dilated cardiomyopathy is associated with disease of the conduction system,^{53,315} only one has been identified to date. Mutations in the lamin A/C gene, which encodes a nuclear envelope intermediate filament protein, usually results in atrial arrhythmia and progressive atrioventricular conduction disease, which precede the development of dilated cardiomyopathy by several years.^{316–318} The pathophysiological mechanisms remain poorly understood. Some mutations result in dilated cardiomyopathy and conduction disease alone,³¹⁷ whereas others lead to juvenile-onset muscular dystrophies, including Emery-Dreifuss muscular dystrophy^{319,320} and familial partial lipodystrophy with insulin-resistant diabetes.³²¹

X-linked Dilated Cardiomyopathy

X-linked inheritance accounts for up to one-twentieth of familial cases of dilated cardiomyopathy.^{302,322–324} In the study from North America,³⁰² neuromuscular disorders accounted for one-quarter of cases, and nine-tenths were caused by Duchenne, Becker, and Emery-Dreifuss muscular dystrophies. Patients were significantly older at presentation than children with other causes of dilated cardiomyopathy, and almost all were male, reflecting the X-linked inheritance. Their outcome was poor, with only half surviving or free from transplantation after 5 years.³⁰² X-linked dilated cardiomyopathy, also caused by mutations in the dystrophin gene, was first described in 1987 in young males with severe disease and rapid progression of congestive cardiac failure to death or transplantation.³²⁵ The condition is characterised by raised isoforms of creatine kinase in the serum, but does not result in clinical signs or symptoms of muscular dystrophy as in Duchenne or Becker muscular dystrophies. Female carriers develop dilated cardiomyopathy in their fifties, and progression of the disease is slower.

Barth syndrome, made up of dilated cardiomyopathy, skeletal myopathy, and neutropaenia, is an X-linked disorder caused by mutations in the G4.5 gene, which encodes the protein tafazzin.^{326,327} The condition typically presents in male neonates or young infants, producing congestive cardiac failure, neutropaenia, and 3-methylglutaconic aciduria. Although some children die in infancy, usually due to progressive cardiac failure, sudden death, or sepsis, most survive infancy, but the dilated cardiomyopathy persists. Mutations in the G4.5 gene also cause isolated dilated cardiomyopathy, endocardial fibroelastosis, and left ventricular non-compaction, with or without the other features of Barth syndrome.^{328,329}

Other Causes of Dilated Cardiomyopathy in Childhood

Myocarditis is an important cause of dilated cardiomyopathy, accounting for one-sixth to one-third of cases in population-based studies.^{302,303} The features of myocarditis were discussed in the preceding section of this chapter.

Inborn errors of metabolism account for less than one-twentieth of cases. Of these, mitochondrial disorders are the commonest, accounting for almost half, followed by Barth syndrome, accounting for one-quarter, and primary or systemic deficiency of carnitine, accounting for another tenth.³⁰² Patients with metabolic disease causing cardiac disease typically present in infancy, and three-quarters are male. Malformation syndromes are rarely associated with dilated cardiomyopathy, accounting for only 1% of cases.³⁰² Hypocalcaemic rickets, however, can present as an isolated dilated cardiomyopathy in infancy.^{330–334}

Pathology

Macroscopically, dilated cardiomyopathy is characterised by the presence of a globular heart, with dilation of the ventricles and diffuse endocardial thickening.³³⁵ Atrial enlargement is also seen, often with thrombus present in the appendages. Overall, myocardial mass is increased, but in the presence of reduced ventricular mural thickness.³³⁵ The histological features are non-specific, but show a combination of myocytic degeneration, interstitial fibrosis, and myocytic nuclear hypertrophy and pleomorphism. Frequently there is an increase in interstitial T lymphocytes, and focal accumulations of macrophages associated with death of individual myocytes. There is often extensive myofibrillary loss, giving the myocytes a vacuolated appearance.³³⁵

Pathophysiology

The identification of disease-causing mutations in genes encoding various components of the cardiac myocytic cytoskeletal and sarcomeric contractile apparatus shows that the pathogenesis of dilated cardiomyopathy is heterogeneous. Two models have been proposed to explain ventricular remodelling.⁵³ Those using the concept of a final common pathway argue that the cardiomyopathy reflects a non-specific degenerative state, resulting from a variety of stimuli, including genetic mutations, viral infections, toxins, and volume overload.^{53,306} The mechanisms underlying this final pathway remain speculative, but may include altered myocytic energetics and handling of calcium. Those supporting the alternative hypothesis suggest that a number of distinct, independent pathways can remodel the heart and cause dilated cardiomyopathy, with the different causes of dilated cardiomyopathy sharing common histopathology but having distinct molecular biologic characteristics.⁵³

Clinical Features

The symptoms and signs associated with dilated cardiomyopathy are highly variable, and depend on the age of the patient and the degree of left ventricular dysfunction. Whilst the first presentation may be sudden death or a thromboembolic event, most patients present with symptoms of high pulmonary venous pressure and/or low cardiac output which can be acute, sometimes being precipitated by intercurrent illness or arrhythmia,³⁰¹ or more chronic, preceding the diagnosis by many months or years. Increasingly, dilated cardiomyopathy is diagnosed incidentally in asymptomatic individuals during family screening.

Symptoms

Infants with dilated cardiomyopathy typically present with poor feeding, tachypnoea, respiratory distress, diaphoresis during feeding, and failure to thrive. Older children and adults initially present with reduced exercise tolerance and dyspnoea on exertion. With worsening left ventricular function, dyspnoea at rest, orthopnoea, paroxysmal nocturnal dyspnoea, peripheral oedema, and ascites develop. In children in particular, symptoms may occur related to mesenteric ischaemia as a result of insufficient cardiac output to perfuse the gastrointestinal tract. This can produce abdominal pain after meals, nausea, vomiting, and anorexia. Symptoms related to arrhythmia, such as palpitation, presyncope, and syncope may occur at any age.

Physical Examination

Features of low cardiac output include persistent sinus tachycardia, weak peripheral pulses, and in advanced disease, hypotension. In older children, the jugular venous pressure may be elevated. Signs of respiratory distress resulting from pulmonary oedema may be present, particularly in infants and younger children, and include intercostal and subcostal recession, nasal flaring, and during acute decompensations, grunting. Palpation of the precordium usually reveals a displaced apical impulse. Hepatomegaly and ascites are common in patients with congestive cardiac failure, including infants. Peripheral oedema may also be seen, affecting the legs and sacrum in older children, and the face and scrotum in infants.

Auscultation of the heart may reveal the presence of a third, and sometimes a fourth, heart sound. In patients with functional mitral regurgitation, there may be a pansystolic murmur at the apex radiating to the axilla, but frequently no murmurs are heard, even in the presence of mitral incompetence, especially if cardiac output is very low. Auscultation of the chest may reveal basal crackles. Indeed, infants may present with wheezing that is difficult to distinguish from asthma or bronchiolitis. Examination of other systems is important, as it may reveal clues to the possible aetiology. In particular, examination of the neuromuscular system may reveal features of mild or subclinical skeletal myopathy. Ophthalmological examination is important if mitochondrial disorders are suspected.

Investigations

Electrocardiography

The electrocardiogram in dilated cardiomyopathy may be normal,³⁰¹ but more typically shows sinus tachycardia and non-specific changes in the ST segments and T waves, most commonly in the inferior and lateral leads (Fig. 49-10). In patients with extensive left ventricular fibrosis, abnormal Q waves in the septal leads may be present. Evidence of atrial enlargement and voltage criteria for ventricular hypertrophy, usually involving the left but occasionally both biventricles, are common. All degrees of atrioventricular block may be seen, and raise the possibility of mutations in the *lamin A/C* gene. Supraventricular and ventricular arrhythmias are also common. In children, arrhythmias occur in up to half, and half of these are atrial.³³⁶ Studies in predominantly adult populations have shown a prevalence of non-sustained ventricular tachycardia in just over two-fifths,³³⁷ albeit that ventricular tachycardia is less common in children, occurring in only one-tenth of cases.³³⁶

Chest Radiography

The chest X-ray is frequently abnormal. An increased cardiothoracic ratio is typical, reflecting left ventricular and left atrial dilation. In addition, patients with pulmonary oedema have signs of increased pulmonary vascular markings. Pleural effusions may also be present.

Echocardiography

In general, the presence of ventricular end-diastolic dimensions greater than two standard deviations above body surface area-corrected means, or greater than 112% of predicted dimension, and fractional shortening of less than 25% are sufficient to make the diagnosis.^{4,301,338} These criteria have some limitations, and therefore a number of other useful parameters of left ventricular function are usually measured. These include ejection fraction, myocardial performance index, and assessment of cardiac output, using velocities in the aorta and left ventricular outflow tract as assessed with pulsed and continuous wave Doppler. Cross sectional echocardiography is also used to determine whether intracavitary thrombus is present in the ventricles or atriums (Fig. 49-11). Colour flow Doppler interrogation is used to determine the presence, and quantify the severity, of functional mitral and tricuspid regurgitation.

Figure 49-10 The 12-lead electrocardiogram from a 2-year-old with familial idiopathic dilated cardiomyopathy, showing non-specific ST segment and T wave abnormalities.

Figure 49-11 Echocardiographic features of dilated cardiomyopathy. A shows an apical four-chamber view from a child with dilated cardiomyopathy. Note the dilated left ventricular cavity with thin walls. B is a parasternal long-axis view, again showing a dilated, thin-walled left ventricle, but with thrombus in the left ventricular cavity. (Courtesy of Dr Jan Marek, Great Ormond Street Hospital, London, United Kingdom.)

In addition, pulsed and continuous wave Doppler interrogation can be used to estimate pulmonary arterial pressures. Patients frequently have abnormalities of diastolic left ventricular function. These include impaired relaxation or pseudo-normal patterns of mitral inflow and pulmonary venous flow. Occasionally, patients with severe disease have restrictive left ventricular physiology. Tissue Doppler systolic and diastolic annular velocities are significantly lower compared to controls,³³⁹ but further studies are needed to assess whether these parameters have a prognostic role.

Cardiac Biomarkers

Levels of creatine kinase should be measured in the serum of all patients with dilated cardiomyopathy, as this may provide important clues to its aetiology. Other cardiac biomarkers, such as troponin I and troponin T, also may be elevated, suggesting the possibility of inflammatory or ischaemic causes. Levels of B-type natriuretic peptide are elevated in the plasma of children with chronic cardiac failure, and serve to predict rates of survival, hospitalisation, and listing for cardiac transplantation.³⁴⁰

Exercise Testing

Symptom limited exercise testing using a treadmill or bicycle, combined with analysis of respiratory gases, is a useful technique to assess functional limitation and progression of disease in those in a stable condition. The children have lower durations of exercise, consume less oxygen, and have lower systolic pressures at peak exercise than their normal peers.³⁴¹ The use of the technique as a prognostic tool, however, has not been assessed. Exercise testing remains useful, nonetheless, in the evaluation of children prior to transplantation. The detection of respiratory markers of severe lactic acidemia during metabolic exercise testing can be caused by mitochondrial or metabolic causes.

Cardiac Catheterisation

Cardiac catheterisation with endomyocardial biopsy may be a useful adjunct in the investigation of some children, but its use is declining with improved non-invasive techniques. Endomyocardial biopsy may be diagnostic for myocarditis, although as already discussed, the diagnostic yield is low. It can also prove valuable in identifying metabolic or mitochondrial disorders. Haemodynamic assessment of left ventricular end-diastolic and pulmonary arterial pressures can be carried out in the catheter laboratory, but this has been superseded by echocardiographic techniques, which are non-invasive and do not require exposure to irradiation or general anaesthesia.

Cardiac Magnetic Resonance Imaging

This is a useful alternative technique for imaging in patients with poor echocardiographic windows. In addition, the detection of fibrosis with gadolinium contrast enhancement may provide an imaging-guided method to improve the diagnostic yield of endomyocardial biopsies.³⁴²

Management

There are no specific therapies for most patients with dilated cardiomyopathy. The aim of management should be to improve symptoms and prevent progression and complications, such as progressive cardiac failure, sudden death, and thromboembolism. Guidelines for pharmacological therapy of cardiac failure in children are based largely on consensus, coupled with extrapolation of data from studies in adults. Data from children is very limited.²⁸³

Diuretics

There are no published studies evaluating the effects of diuretics in reducing mortality or improving symptoms in children.²⁸³ Loop and thiazide diuretics, nonetheless,

should be used in all patients with fluid retention due to cardiac failure to achieve a euvolaemic state. They should not be used as monotherapy, as they exacerbate neurohormonal activation, which may contribute to progression of the disease.³⁰¹ Spironolactone, a specific antagonist of aldosterone, reduces relative mortality by almost one-third in adults with severe cardiac failure and ejection fractions less than 35%.³⁴³ Side effects include hyperkalaemia, although this is infrequent in the presence of normal renal function, and gynaecomastia.

Inhibitors of Angiotensin-converting Enzyme and Blockers of Angiotensin Receptors

Activation of the renin-angiotensin-aldosterone system is central to the pathophysiology of cardiac failure, regardless of the underlying aetiology.^{283,301} Multiple large clinical trials have shown that inhibition of angiotensin-converting enzyme improves symptoms, reduces hospitalisations, and reduces cardiovascular mortality in adults with cardiac failure.^{344–347} Furthermore, such inhibition or blockade also reduces the rate of progression of disease in asymptomatic patients. A substantial proportion of patients taking inhibitors of angiotensin-converting enzyme in clinical practice are not titrated to the target doses reported in many trials, but evidence suggests that higher doses are associated with a greater reduction in the combined risk of death or transplantation.³⁴⁸ In most cases, the inhibitors are well tolerated, the most common side effects being a troublesome cough and symptomatic hypotension, which can be prevented with careful up-titration of doses. First-dose hypotension is more problematic when inhibition is obtained using captopril than with the newer agents. A number of small observational studies have reported a beneficial effect in children with cardiac failure.^{283,349–352} Only one retrospective report has described the effect of inhibition on mortality in children, showing improved survival during the first year of treatment but not subsequently.³⁵¹

Blockers of the angiotensin receptors have similar haemodynamic effects to inhibitors of angiotensin-converting enzyme, but with fewer side effects. Clinical trials in adults with cardiac failure have shown similar haemodynamic effects, efficacy, and safety,^{353,354} and the blockers are currently recommended for adults who do not tolerate inhibition of the angiotensin-converting enzyme. Recent studies have suggested that combined treatment with inhibitors and blockers may be more beneficial in preventing ventricular remodeling than either drug alone, but has no additional impact on survival.^{355,356} There is no data relating to efficacy or safety regarding the use of the blockers in children with cardiac failure.

Current recommendations for children with dilated cardiomyopathy are that inhibitors of angiotensin-converting enzyme should be routinely used in all individuals with moderate or severe left ventricular dysfunction regardless of the presence of symptoms. Patients who are intolerant of these agents should be considered for blockade of the angiotensin receptors.²⁸³ The use of inhibitors of angiotensin-converting enzyme is not recommended as initial therapy in patients with decompensated left ventricular dysfunction.²⁸³

Beta-Blockers

Excess sympathetic activity contributes to cardiac failure, and several multi-centric, placebo-controlled trials using carvedilol,^{357,358} metoprolol,³⁵⁹ and bisoprolol³⁶⁰ have shown substantial reductions in mortality in adults with symptoms of

cardiac failure but in relatively good condition. Beta-blockade is usually well tolerated, but side effects include bradycardia, hypotension, and retention of fluid. The drugs should be started at low doses and carefully uptitrated, and they should not be started in patients with decompensated cardiac failure. A recent trial has suggested that they can be started safely before use of inhibitors of angiotensin-converting enzyme for patients in stable cardiac failure.³⁶¹ Their reported use in children with cardiac failure is limited. Small observational studies using carvedilol^{362–364} and metoprolol³⁶⁵ have shown clinically important improvements in left ventricular systolic performance and functional class. In addition, carvedilol appears to delay the time to transplantation or death.³⁶⁶ The results of the first randomised controlled trial in paediatric cardiomyopathy, from the multi-centre Paediatric Carvedilol Study Group, were recently published.³⁶⁷ Although there was a trend towards benefit in those receiving carvedilol in terms of all-cause mortality, cardiovascular mortality, and hospitalisation for cardiac failure, this was not statistically significant. It is likely that carvedilol and other β -blockers do improve outcomes for some children with cardiac failure, but larger studies with longer follow-up are needed to confirm this. At present, there are no specific recommendations regarding β -blockade in children with compensated cardiac failure, but their routine use is increasing.

Digitalis

Digoxin improves symptoms in adults with cardiac failure,³⁶⁸ but no benefit in terms of survival has been demonstrated in studies of large cohorts.²⁸³ High levels of digoxin in the serum may be associated with increased mortality in some patients.³⁶⁹ The drug is still widely used to treat cardiac failure in infants and children, but there is little data to support its efficacy. Current guidelines recommend the use of low doses to improve symptoms in children with symptomatic cardiac failure, including those with dilated cardiomyopathy, but not for asymptomatic individuals.²⁸³

Novel Pharmacological Therapies

Nesiritide, a recombinant B-type natriuretic peptide with diuretic, natriuretic, and vasodilator effects, and used in adults with decompensated cardiac failure, has recently been shown to be safe in children, producing improvements in urinary output and functional state.^{370,371} Its value over more conventional therapies remains to be determined.

Anticoagulation

The annual risk of thromboembolism in children with dilated cardiomyopathy is unknown, but is likely to be low. The cumulative risk of systemic embolisation in a patient diagnosed at a young age, nonetheless, is substantial.³⁷² In adults with dilated cardiomyopathy, intramural thrombosis and systemic thromboembolisation are found in up to half, with an incidence between 1.5% and 3.5% per year.³⁷³ Anticoagulation with warfarin is advised in patients in whom an intracardiac thrombus is identified echocardiographically, and in those with a history of thromboembolism. There is no trial data to guide prophylactic anticoagulation in those with dilated cardiomyopathy, but patients with severe ventricular dilation and moderate to severe systolic impairment may benefit from anticoagulation using warfarin.

Treatment of Arrhythmias

Whilst arrhythmias are common in patients with dilated cardiomyopathy, negative chronotropic and proarrhythmic effects limit the use of many commonly used antiarrhythmic agents. Data on the effect of amiodarone on

survival in dilated cardiomyopathy is contradictory,^{374,375} but the use of implantable cardioverter-defibrillators was associated with a reduction in overall mortality of almost one-quarter.³⁷⁶ Amiodarone, therefore, appears to be safe in patients with dilated cardiomyopathy, and may be effective at preventing or treating atrial arrhythmias, but does not prevent sudden death. In adults, insertion of an implantable cardioverter-defibrillator is recommended for those having symptomatic ventricular arrhythmias, and in those with ventricular arrhythmias and an ejection fraction less than 35%.³⁷⁶ This will prevent sudden death, and can serve as a bridge to transplantation. The role of implantable cardioverter-defibrillators as primary prophylaxis in children has not been addressed.

Non-pharmacological Treatment of Advanced Dilated Cardiomyopathy

Cardiac transplantation remains the mainstay of management of children with intractable cardiac failure symptoms and end-stage disease (Fig. 49-12). A number of other approaches aimed at improving symptoms and stabilising the disease or delaying transplantation have now emerged.

Cardiac Resynchronisation Therapy

Many adults with dilated cardiomyopathy have abnormal left ventricular activation that in turn results in prolonged and incoordinate ventricular relaxation. Cardiac resynchronisation therapy using biventricular or multi-site pacing attempts to re-establish synchronous atrioventricular, interventricular, and intraventricular contraction to maximise ventricular efficiency. Studies in adults with severe cardiac failure and left bundle branch block have shown marked improvements in some patients.³⁷⁷ Similar studies are lacking in children.

Ventricular Assist Devices

In some cases, mechanical assist devices, such as left ventricular assist devices, the Berlin heart, or extracorporeal membrane oxygenation, may be required.^{279–281} Studies in

children have shown good results with aggressive management of end-stage dilated cardiomyopathy, including bridging to recovery.²⁸² Ventricular assist devices and transplantation are discussed in detail elsewhere.

RESTRICTIVE CARDIOMYOPATHY

Definition

Restrictive left ventricular physiology is characterised by a pattern of ventricular filling in which increased stiffness of the myocardium causes ventricular pressure to rise precipitously with only small increases in volume. As restrictive ventricular physiology occurs in a wide range of different pathologies, the definition of restrictive cardiomyopathy has been confusing and variable. For our current purposes, we define restrictive cardiomyopathy on the basis of restrictive ventricular physiology found in the presence of normal or reduced diastolic volumes of one or both ventricles, normal or reduced systolic volumes, and normal ventricular mural thickness.

Epidemiology

The restrictive variant is the rarest of the cardiomyopathies, accounting for less than 3% of cardiomyopathies found in children.^{22,23} The total number of children with restrictive cardiomyopathy reported in the literature is less than 150. Their age at presentation ranges from 0 to 19 years, but the majority present between the ages of 2 and 11 years, with a median of 4.7 years. Some reports have suggested a slight female predominance, but this has not been confirmed in other studies.³⁷⁸

Natural History

The prognosis when found in children is grave. Without transplantation, approximately half die within 2 years of diagnosis.^{379–384} Most children require transplantation within 4 years of diagnosis.³⁸⁵ Freedom from death or transplantation is 80.5% at 1 year, decreasing dramatically to 39% at 5 years.³⁸³ Pulmonary vascular pressures may rise within a very short period of time following diagnosis,^{381,384,385} but this is not easily predicted clinically. All patients with restrictive cardiomyopathy, therefore, should undergo serial assessment of pulmonary vascular resistance, and assessment for potential transplantation should be made early, prior to haemodynamic decompensation.³⁸⁵ After transplantation, survival is good.^{384,385}

Although the majority of deaths in children are caused by rapidly progressive cardiac failure with elevated pulmonary vascular resistance, sudden cardiac death occurs in just over one-quarter, at a rate of 7% per year.³⁸⁶ Children at risk of sudden death often have no evidence of cardiac failure, but frequently have symptoms and signs of myocardial ischaemia, including chest pain, syncope, and electrocardiographic changes.³⁸⁶ Individuals with restrictive cardiomyopathy are also at risk of thromboembolic events.^{381,385} Risk factors for death from cardiac failure include an increased cardiothoracic ratio on chest radiography,³⁸⁰ age younger than 5 years at presentation,³⁸⁰ clinical and radiographic evidence of pulmonary venous congestion,³⁷⁹ elevated pulmonary vascular resistance index,^{381,384,387} and left atrial dilation and elevated ventricular filling pressures.³⁸³

Aetiology

The disease is caused by many conditions (see Table 49-1), including infiltrative and storage disorders, and endomyocardial disease.³⁸⁸ In adults, amyloidosis is the commonest cause of restrictive cardiomyopathy in the Western world.^{389,390} Cardiac amyloidosis, however, is unheard of in children. In the tropics, endomyocardial fibrosis is the commonest cause in adults, and probably also in children.³⁸⁸ Outside the tropics, most cases of restrictive cardiomyopathy in children are idiopathic.³⁸⁸

Idiopathic Restrictive Cardiomyopathy

The disease is familial in about three-tenths of children.³⁷⁸ Mutations in the gene encoding desmin, an intermediate filament protein with key structural and functional roles within skeletal and cardiac myocyte myofibrils, are known to cause restrictive cardiomyopathy associated with skeletal myopathy and abnormalities of the cardiac conduction system.³⁹¹ The mutations are inherited in an autosomal dominant manner, but sporadic mutations are not infrequent.

Mutations in the gene encoding cardiac troponin I have been identified in over half of adults with the idiopathic variant.³⁹² Individual examples of these mutations have been reported in children.^{392,393}

Endomyocardial Fibrosis and Eosinophilic Cardiomyopathy (Löffler's Endocarditis)

Restrictive ventricular physiology can be caused by endocardial fibrosis, fibroelastosis, and thrombosis. These disorders are subclassified according to the presence of eosinophilia as endomyocardial diseases with or without hypereosinophilia. Parasitic infection, drugs such as methysergide, and inflammatory and nutritional factors are implicated in acquired forms of endomyocardial fibrosis. The disease is endemic in tropical and subtropical parts of Africa, India, Asia, and South and Central America, and may account for up to one-quarter of cardiac-related deaths in equatorial Africa.³⁹⁴ It is rare outside the tropics.³⁸⁸ Adolescents and young adults are most frequently affected. Onset is usually insidious, with progressive biventricular failure in most cases. The overall prognosis is poor, with almost half dead by 1 year, and almost nine-tenths at 3 years.³⁹⁵ Typically, fibrous endocardial lesions cause incompetence of the atrioventricular valves, leading to pulmonary congestion and right cardiac failure.

Other Infiltrative and Storage Disorders Associated with Restrictive Cardiomyopathy

Several infiltrative and storage disorders cause restrictive cardiomyopathy (see Table 49-1). These include lysosomal storage disorders such as mucopolysaccharidosis and Anderson-Fabry disease (see Chapter 57), albeit that the latter is more commonly associated with hypertrophic cardiomyopathy.³⁸⁸

Cardiac sarcoidosis can produce restrictive cardiomyopathy progressing to systolic impairment, and is also typically associated with conduction disease and a risk of sudden death. The diagnostic tests for sarcoidosis may be normal, and a high index of suspicion is required for diagnosis. Cardiac magnetic resonance imaging and positron emission tomography are the most sensitive imaging techniques, and changes appear to correlate with the activity of the disease. Treatment includes corticosteroids, implantable cardioverter-defibrillators for patients with a

history of non-sustained ventricular tachycardia, and cardiac transplantation. Sarcoid granulomatous lesions may recur in the transplanted cardiac allograft.³⁹⁶ Sarcoidosis is more common in adults than in children, being rare in children below the age of 15 years, and exceedingly rare in those younger than 4 years.³⁹⁷

Pathology

The macroscopic features include biatrial dilation in the presence of normal cardiac weight, a small ventricular cavity, and no left ventricular hypertrophy. The morphological spectrum of primary disease includes mild ventricular hypertrophy with increased cardiac weight, sometimes described as hypertrophic restrictive cardiomyopathy, and mild ventricular dilation without hypertrophy.³⁹⁸ These findings highlight the substantial overlap between restrictive cardiomyopathy and the other cardiomyopathies. In many hearts, there is thrombus in the atrial appendages and patchy endocardial fibrosis.³⁸⁸ The histological features are classically non-specific, with patchy interstitial fibrosis, which may range in extent from very mild to severe.³⁸⁸ There may also be fibrosis of the cardiac nodes.³⁹⁹ Myocytic disarray is not uncommon in patients with pure restrictive cardiomyopathy, even in the absence of macroscopic ventricular hypertrophy.³⁹⁸ In those with infiltrative and metabolic cardiomyopathies, there will be specific findings appropriate to the disorder.³³⁵

Pathophysiology

The characteristic feature is the precipitous rise in intraventricular pressures during ventricular filling, caused by a reduction in left ventricular compliance. The result is that ventricular filling is completed in early diastole, and there is little or no filling in late diastole, thereby elevating left ventricular filling pressures and compromising cardiac output. Impaired and delayed active relaxation of the left ventricle may also play a role in the pathophysiology of the idiopathic disease in children.⁴⁰⁰

The finding that mutations in the sarcomeric protein genes cause restrictive cardiomyopathy has provided new insights into the pathophysiology of restrictive left ventricular physiology. Experimental studies have suggested that mutations of troponin I that cause restrictive cardiomyopathy have a greater increase in the sensitivity of calcium ions than those causing hypertrophic cardiomyopathy, resulting in more severe diastolic dysfunction and potentially accounting for the restrictive phenotype in humans.^{401,402} In addition, the hearts of troponin I-mutated transgenic mice show increased contractility and impaired relaxation.⁴⁰³ Similar results have been observed in mice with disease-causing mutations of α -myosin heavy chain.⁴⁰⁴ The fact that the same sarcomeric mutation within the same family can result in both restrictive and hypertrophic phenotypes suggests that other genetic and environmental factors are likely to be involved.¹⁴⁰

Clinical Features

Symptoms

The presentation is usually with symptoms and signs of cardiac failure and arrhythmia. In children, the cardiomyopathy can mimic other, more common, diseases such as

asthma or recurrent chest infections, epilepsy, or hepatic conditions. Because of this, referral to the cardiologist is often delayed.³⁷⁸ Common symptoms include dyspnoea on exertion, recurrent infections of the respiratory tract, and general fatigue and weakness. This may progress rapidly to dyspnoea at rest, orthopnoea, and paroxysmal nocturnal dyspnoea in older children. Symptoms related to increased right-sided pressures may include peripheral oedema and abdominal distention due to ascites. Many patients complain of chest pain and symptoms suggestive of arrhythmia, such as palpitation. Syncope is a presenting symptom in one-tenth of affected children.^{386,400} Rarely, sudden death may be the initial manifestation of the disease.

Physical Examination

Clinical examination typically reveals signs of left- and right-sided cardiac failure. Tachypnoea, signs of respiratory distress, and failure to thrive are seen in infants and young children. In older children, the jugular venous pressure is elevated, with a prominent y descent, and fails to fall, or may even rise, during inspiration. The latter is called Kussmaul's sign. Peripheral oedema, ascites, and hepatomegaly are common. The apical impulse is usually normal. Cardiac auscultation reveals a normal first heart sound and normal splitting of the second heart sound. The pulmonary component of the second heart sound may be loud if pulmonary vascular resistance is high. There is usually a third heart sound, and occasionally a fourth heart sound giving rise to a gallop rhythm. The murmurs of atrioventricular valvar regurgitation may be heard.

Investigations

A number of investigations are useful. The purpose is to confirm the diagnosis, to exclude constrictive pericarditis, and to assess suitability for cardiac transplantation.

Electrocardiography

The resting 12-lead electrocardiogram is abnormal in the majority of children with restrictive cardiomyopathy. The most frequent abnormalities include enlargement of the left and right atriums, so-called p-mitrale and p-pulmonale, non-specific changes in the ST segments, and T wave abnormalities. There can be depression of the ST segment

and T wave inversion, usually in the inferolateral leads (Fig. 49-13). Voltage criteria for left and right ventricular hypertrophy may also be present. Abnormalities of conduction, including intraventricular conduction delay, and abnormal Q waves may also be seen.

Chest Radiography

The chest radiograph is usually abnormal, showing cardiomegaly caused by atrial enlargement, and pulmonary venous congestion. Interstitial oedema, manifested by the presence of Kerley B lines, may be seen in severe cases.

Echocardiography

Typically, there is marked dilation of both atriums, often dwarfing the size of the ventricles, in the presence of normal or mildly reduced systolic function, and a non-hypertrophied, non-dilated left ventricle (Fig. 49-14A). Severe impairment of left ventricular systolic function, with fractional shortening less than 25%, may develop in up to one-third of children.^{380,381,384,400} Many patients with a clinical label of restrictive cardiomyopathy also have mild left ventricular hypertrophy,^{380-382,384,400} but in many cases, this may represent part of the spectrum of sarcomeric protein disease.

The flow through the mitral valve as assessed by pulsed-wave Doppler velocities typically shows increased velocities of early diastolic filling, decreased velocities of atrial filling, an increased ratio of early diastolic to atrial filling, a decreased deceleration time, and a decreased isovolumic relaxation time (see Fig. 49-14B). Interrogation of the pulmonary and hepatic veins with pulsed wave Doppler reveals higher diastolic than systolic velocities, increased atrial reversal velocities, and a duration of atrial reversal greater than that of atrial filling (see Fig. 49-14C). Tissue Doppler imaging shows reduced diastolic annular velocities, and an increased ratio of early diastolic tissue Doppler annular velocity to mitral early diastolic filling velocity, reflecting elevated left ventricular end-diastolic pressures. Mitral inflow and pulmonary, hepatic, and tissue Doppler velocities should be evaluated in the context of published normal values for children.

Ambulatory Electrocardiographic Monitoring

Disturbances of atrioventricular conduction, and atrial arrhythmias, are common when restrictive cardiomyopathy is found in childhood, occurring in one-sixth

Figure 49-13 This 12-lead electrocardiogram from a 12-year-old with familial restrictive cardiomyopathy shows left and right atrial enlargement and T wave abnormalities extending from leads V1 to V5.

of patients.^{378–386} Analysis of the ST segments may reveal evidence of myocardial ischaemia, particularly at higher heart rates, which may precede the development of ventricular arrhythmia.³⁸⁶

Cardiopulmonary Exercise Testing

Symptom-limited exercise testing with analysis of respiratory gases provides a useful objective measure of limitation, which can help in management of symptoms and is an important component of assessment prior to transplantation. Peak consumption of oxygen is usually reduced. Exercise testing may also reveal ischaemic electrocardiographic changes at higher heart rates, which may correlate with symptoms such as chest pain.

Cardiac Catheterisation

Cardiac catheterisation is important, particularly prior to consideration for transplantation. The characteristic haemodynamic feature is a deep and rapid early decline in ventricular pressure at the onset of diastole, with a rapid rise to a plateau in early diastole, the so-called dip-and-plateau, or square root, sign.³⁸⁸ Left ventricular end-diastolic, left atrial, and pulmonary capillary wedge pressures are markedly elevated, and usually 5 mmHg or more greater than right atrial and right ventricular end-diastolic pressures. Volume loading and exercise accentuate the difference between left- and right-sided pressures.

Pulmonary hypertension is frequently present during initial cardiac catheterisation. Elevated indexes of pulmonary vascular resistance are commonly found, and tend to progress during follow-up.^{384,385,387} Elevated pulmonary

vascular resistance may initially be reversible with nitric oxide or prostacyclin,^{385,387} but it is usually not possible to predict the development of fixed pulmonary vascular resistance.³⁸⁴ Endomyocardial biopsy is usually non-diagnostic, but may be useful in some of the cases due to storage disease or infiltrations.

Management

The prognosis for children with restrictive cardiomyopathy in the absence of transplantation is poor. Medical treatment in severely symptomatic patients is usually supportive until transplantation is performed. Occasionally, patients may remain stable for several months or years before an acute decompensation necessitating transplantation occurs. By that stage, however, pulmonary hypertension may preclude orthotopic transplantation, and heart-lung transplantation or heterotopic cardiac transplantation may be the only options.⁴⁰⁵ Medical management should follow guidelines for the management of diastolic cardiac failure set out by the International Society for Heart and Lung Transplantation.²⁸³

Symptomatic Therapy

Diuretics are useful in patients with symptoms and signs of pulmonary or systemic venous congestion. Over-diuresis, however should be avoided, as it may result in excessive preload reduction and haemodynamic collapse. Careful management of fluids is an important aspect of treatment. In view of atrial enlargement and propensity

Figure 49-14 Echocardiographic features of restrictive cardiomyopathy. A shows an apical four-chamber view from a 6-year-old with restrictive cardiomyopathy. Note the massively dilated left and right atria without significant left ventricular hypertrophy or dilation. B is a continuous wave Doppler recording of mitral inflow and left ventricular outflow from the same patient, showing a short isovolumic relaxation time; the restrictive mitral inflow pattern can also be appreciated, with a peaked E wave, short E wave deceleration time and E/A ratio greater than 2.5. C is a pulsed wave Doppler of a hepatic vein in an 8-year-old with restrictive cardiomyopathy, showing an increased atrial reversal wave.

to atrial arrhythmia, prophylactic anticoagulation with warfarin or antiplatelet agents is recommended. Since the atrial contribution to ventricular filling is important, efforts to maintain sinus rhythm with β -blockers and amiodarone may be appropriate. Treatment with afterload-reducing agents, such as inhibitors of angiotensin-converting enzyme, blockers of calcium channels, and nitrates, rarely improves symptoms and can cause deterioration.³⁴⁹

Optimisation of Haemodynamics Prior to Transplantation

Transplantation is the only definitive treatment. Whilst fixed and irreversible elevations in pulmonary vascular resistance preclude orthotopic cardiac transplantation,³⁸⁴ short-term treatment with prostacyclin, for around 2 months, has been shown to reduce transpulmonary gradients sufficiently to allow orthotopic heart transplantation in most children with restrictive cardiomyopathy.³⁸⁵ While on the waiting list for transplantation, patients should undergo serial Holter monitoring. Cardioverter-defibrillators should be implanted in patients with evidence of ventricular arrhythmia as a bridge to transplantation.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Definition and Historical Aspects

Arrhythmogenic right ventricular cardiomyopathy is a myocardial disease characterised by progressive replacement of right ventricular myocardium by fibrous tissue and fat, initially with regional, and later with global, right and left ventricular involvement. It is associated with ventricular arrhythmias, cardiac failure, and sudden cardiac death. The term arrhythmogenic right ventricular cardiomyopathy now replaces arrhythmogenic right ventricular dysplasia, which was initially used to describe the condition.

Epidemiology

The reported prevalence is approximately 1 in 5000,⁴⁰⁶ but emerging data from family studies suggests that this is almost certainly an underestimate caused, in part, by the difficulty in making the diagnosis clinically. In children, arrhythmogenic cardiomyopathies account for less than 3% of all cardiomyopathies.^{22,23} The condition has been described, nonetheless, in children as young as 1 year of age,⁴⁰⁷ and presentation with sudden death is reported in adolescents as well as in younger children.^{408–418} There is a male predominance across all ages.⁴¹⁹

Natural History

The disease is currently thought to progress through several phases, starting with an early concealed phase, during which patients are asymptomatic, and clinical features are absent. This progresses to an overt electrical disorder, characterised by symptomatic ventricular arrhythmia and morphological abnormalities usually detectable by imaging, followed by a right ventricular phase, characterised by extension of fibro-fatty infiltration throughout the right ventricular myocardium, causing right cardiac failure. The final stage in many patients is a biventricular phase, characterised by left ventricular involvement and biventricular failure,

which is often indistinguishable from dilated cardiomyopathy.⁴²⁰ Studies of families have shown that some patients present for the first time with biventricular dilation, or with predominant, or even exclusive, left ventricular involvement. Sudden cardiac death can occur at any stage, including the concealed phase.⁴¹⁸ Given the progressive nature of the condition, children might be expected to present during the early concealed or arrhythmic phases, rather than with overt cardiomyopathy. Left and right ventricular dilation in children with familial disease, nonetheless, is increasingly recognised.^{410,421,422}

Aetiology

Systematic familial studies have shown that this cardiomyopathy is inherited in up to half the cases.⁴¹⁹ The mode of transmission is usually autosomal dominant with variable penetrance, but autosomal recessive forms are also recognised. The first insights into the genetic basis came from the description of an autosomal recessive syndrome characterised by cardiomyopathy, woolly hair, and palmoplantar keratoderma. The afflicted families came from the Greek island of Naxos.⁴²³ The cardiac phenotype demonstrated the typical clinical and histopathological characteristics.⁴²⁴ Following this initial description, families with a similar phenotype were reported from other Mediterranean areas,^{425–428} India,⁴²⁹ and South America.⁴³⁰ Subsequent molecular genetic investigations in families with these cardiocutaneous syndromes revealed mutations in the genes encoding plakoglobin and desmoplakin.^{425,431,432} These proteins are major components of cell adhesive junctions, with key roles in cell-to-cell communication and transduction of mechanical stress. Mutations in these, and other cell adhesive molecules, including plakophilin-2,^{417,433} desmoglein,⁴³⁴ and desmocollin⁴¹³ have been identified in autosomal dominant cases without cutaneous manifestations.^{411,435} Rare examples of implicated non-desmosomal genes include the ryanodine receptor-2,⁴³⁶ more commonly associated with catecholaminergic polymorphic ventricular tachycardia, and transforming growth factor- β .⁴³⁷ Other aetiopathogenic factors have been suggested to play a role in development. In particular, enteroviral and adenoviral genomes have been identified in a few patients with the condition⁴³⁸ although other studies have not replicated these findings.⁴³⁹

Pathology

In the early stages, abnormal pathological findings are localised to the apical, inflow, and infundibular areas of the right ventricle, initially referred to as the triangle of dysplasia.⁴⁴⁰ With progression, the left ventricle may also become involved, with particular involvement of the posterolateral wall and relative sparing of the septum. In some cases, the pathological abnormalities may be confined to the left ventricle.^{335,441} Macroscopic examination (Fig. 49-15) may show diffuse or focal thinning of the right ventricular wall, with aneurysms present in up to half the cases.^{335,442} Histologically, there is myocardial atrophy and fibro-fatty replacement. Islands or strands of surviving myocytes exhibit a combination of degenerative change with myocytic vacuolation, and are frequently associated with focal infiltrates of mononuclear inflammatory cells.^{443–445} In some cases,

Figure 49-15 Histopathological features of arrhythmogenic right ventricular cardiomyopathy, characterised by fibro-fatty infiltration of the myocardium. (Courtesy of Dr Michael Ashworth, Great Ormond Street Hospital, London, United Kingdom.)

typical histological findings may be present in the absence of any macroscopic features.⁴⁴⁶ A second histological pattern, characterised by transmural infiltration of adipose tissue without fibrous replacement or mural thinning, has been suggested to represent an earlier stage of the condition,^{443,447} but this is probably a normal finding, particularly in older females.⁴⁴²

Clinical Features

The first presentation of the disease is often sudden cardiac death in previously asymptomatic individuals, including young children and teenagers.^{408,409,418,448} Occasionally, patients will have experienced syncope in the months preceding their death.^{408,449,450} An imbalance of adrenergic activity has been suggested as a possible factor in the genesis of lethal ventricular arrhythmias; thus, exposure to catecholamines, particularly during exercise, may increase the risk of sudden death.⁴⁵¹ Overall, syncope and other symptoms of arrhythmia, including presyncope, palpitation, and chest pain, are common clinical manifestations, but family studies have shown that most affected individuals are asymptomatic, particularly in the early stages.⁴⁵² With progression, features of right, and later biventricular, failure may be present, including dyspnoea on exertion.

In children, reports of the condition are biased towards those who have presented with symptoms, and in these patients, arrhythmic symptoms predominate.^{410,414,421,450}

Investigations

There is no single diagnostic test, and the diagnosis is based on the presence of major and minor criteria that describe structural, histological, electrocardiographic, arrhythmic, and familial features (Table 49-3).⁴⁵³ In this scheme, the diagnosis is fulfilled in the presence of two major criteria, or one major plus two minor criteria, or four minor criteria from different categories.⁴¹⁹ Family studies have shown that first-degree relatives of affected individuals may have minor cardiac abnormalities, which, although not fulfilling the above diagnostic criteria, are likely to

represent expression in the context of an autosomal dominant disease. Because of this, modified diagnostic criteria have been proposed for diagnosis in family members of affected individuals.⁴⁵² Whether these modified criteria are also applicable to pre-adolescent children remains to be evaluated.

Electrocardiography

The most common electrocardiographic abnormality is inversion of the T waves in leads V1 to V3 in the absence of right bundle branch block (Fig. 49-16). This is a normal finding in children, and cannot therefore be used as a diagnostic criterion. Presence of such inversion of T waves beyond lead V3 outside the neonatal period, nonetheless, should raise suspicion of an underlying myocardial pathology. Other electrocardiographic features include abnormalities of depolarisation and conduction such as QRS dispersion, a delay in right intraventricular conduction delay, progressing to right bundle branch block in some patients, and the presence of an epsilon wave. These features are also recognised in children.⁴⁵⁰

Signal-averaged Electrocardiography

The signal-averaged electrocardiogram is used to evaluate the presence of late potentials.⁴⁵⁴ Up to four-fifths of patients with arrhythmogenic right ventricular cardiomyopathy have evidence of late potentials on the signal-averaged electrocardiogram,^{455,456} and this finding correlates with the risk of ventricular arrhythmia⁴⁵⁷ and progression of disease.⁴⁵⁸ Normal values for signal-averaged electrocardiography in children have been reported, but to date, there have been no systematic studies evaluating its role in the diagnosis of arrhythmogenic right ventricular cardiomyopathy. Extrapolation from adult data may not be applicable, as late potentials have been shown to be present in less than one-third of individuals with arrhythmogenic right ventricular cardiomyopathy associated with only localised right ventricular abnormalities and normal right ventricular end-diastolic volumes,⁴⁵⁸ likely to be the morphology most commonly encountered in children.

Ambulatory Electrocardiographic Monitoring

Perhaps the most useful investigation in children is ambulatory electrocardiographic monitoring. The spectrum of ventricular arrhythmia ranges from frequent ventricular extrasystoles to sustained ventricular tachycardia. The distinctive QRS morphology of ventricular arrhythmia in arrhythmogenic right ventricular cardiomyopathy is a left bundle branch pattern, indicating a right ventricular origin. The morphology of the QRS complex may provide clues as to the site of origin. An inferior axis suggests an origin in the right ventricular outflow tract, whereas a superior axis implies origin in the right ventricular apex or inferior wall. With more advanced disease, several different right ventricular morphologies may be seen, reflecting multiple arrhythmogenic foci.

Ventricular arrhythmias, ranging from isolated premature ventricular beats to non-sustained or sustained ventricular tachycardia, are common. Suggested arrhythmic mechanisms include re-entry circuits arising from fibro-fatty myocardial replacement, and heterogeneous conduction resulting from destabilisation of cell adhesion complexes and gap junctions.⁴²⁰ Hot phases are recognised, during which previously stable patients may suffer repeated episodes of ventricular arrhythmia in a short period of

TABLE 49-3

DIAGNOSTIC CRITERIONS FOR ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

	Major	Minor
1. Global and/or regional dysfunction and structural alterations	Severe dilatation and reduction of right ventricular ejection fraction with no (or only mild) left ventricular impairment Localised right ventricular aneurysms (akinetic or dyskinetic areas with diastolic bulging) Severe segmental dilatation of the right ventricle	Mild global right ventricular dilatation and/or ejection fraction reduction with normal left ventricle Mild segmental dilatation of the right ventricle Regional right ventricular hypokinesia
2. Tissue characterisation of walls	Fibro-fatty replacement of myocardium on endomyocardial biopsy	
3. Depolarisation abnormalities	Epsilon waves or localised prolongation (>110 ms) of the QRS complex in right precordial leads (V1–V3)	Late potentials (signal averaged ECG)
4. Repolarisation abnormalities		Inverted T waves in right precordial leads (V2 and V3) (>12 years of age; in absence of right bundle branch block)
5. Arrhythmias		Left bundle branch block type ventricular tachycardia (sustained and nonsustained) on ECG, Holter monitor, or exercise testing Frequent ventricular extrasystoles (>1000 in 24 hours)
6. Family history	Familial disease confirmed at postmortem or surgery	Familial history of premature sudden death (<35 years of age) due to suspected right ventricular dysplasia Family history, with clinical diagnosis based on present criterions

Task Force of the Working Group Myocardial and Pericardial Disease of the European Society of Cardiology and of the Scientific Council on Cardiomyopathies of the International Society and Federation of Cardiology. *Br Heart J* 1994;71:215–218.

time, and sudden death may occur. In children, isolated ventricular extrasystoles, ventricular couplets and triplets, non-sustained and sustained ventricular tachycardia, and ventricular fibrillation have all been reported.⁴⁵⁰

Exercise Testing

The role of exercise testing in children is primarily to detect ventricular arrhythmias induced by physical activity. Ventricular ectopy and non-sustained ventricular tachycardia of right ventricular origin have been described in young individuals.⁴⁵⁰ Cardiopulmonary exercise testing may also

be useful as an objective measure of functional capacity in patients with advanced disease.

Echocardiography

A major role of echocardiography in the evaluation of the disease, particularly in children, is the exclusion of congenital cardiac disease in the differential diagnosis, such as partially anomalous venous drainage and Ebstein's malformation.^{459–461} The echocardiographic findings include right ventricular dilation and hypokinesia, aneurysms (Fig. 49-17), abnormalities of regional wall motion,

Figure 49-16 The 12-lead electrocardiogram from an undiagnosed 15-year-old who died suddenly, and was found to have arrhythmogenic right ventricular cardiomyopathy on postmortem. There is T wave inversion extending from V1 to V4 with flat T waves elsewhere, reduced right ventricular voltages, and mild QRS dispersion. (Courtesy of Dr Antonis Pantazis, The Heart Hospital, London, United Kingdom.)

Figure 49-17 This end-systolic parasternal long-axis echocardiographic frame of the right ventricular outflow tract from a young male with arrhythmogenic right ventricular cardiomyopathy shows a small aneurysm of the anterior wall (arrow). (Courtesy of Dr Antonis Pantazis, The Heart Hospital, London.)

including dyskinesia of the inferobasal right ventricular segment, increased echogenicity of the moderator band, and right ventricular apical hypertrabeculation.^{410,450,461–463} Given the segmental nature of the disease, structure and function should be assessed using multiple views.⁴⁶⁴ Left ventricular involvement should also be evaluated. Tricuspid annular early diastolic velocities are reduced.⁴⁶⁴

Cardiac Magnetic Resonance Imaging

Cardiovascular magnetic resonance imaging is an attractive tool, as it is not limited by acoustic windows, and the acquisition of three-dimensional data sets permits accurate determination of right ventricular volumes and function.⁴⁶⁵ Late enhancement with gadolinium has been shown to correlate with fibro-fatty changes.⁴⁶⁶ There is, nonetheless, an inherent subjectivity in the interpretation of mural thinning, localised abnormalities of wall motion, and intramyocardial fat in the right ventricle.^{465,467–469} Reproducibility and accuracy, therefore, are strongly operator dependent.⁴⁶⁵

Endomyocardial Biopsy

Although a histological diagnosis may be definitive, the sensitivity of endomyocardial biopsies is low, since samples are usually taken from the septum, a region that is usually not involved in this disease.⁴¹⁹ Furthermore, there is a high rate of complications, including cardiac perforation and tamponade, resulting from thinning of the right ventricular wall.⁴⁵³ Endomyocardial biopsies are no longer considered part of the routine diagnostic workup.

Management

Patients with symptomatic, non-life-threatening arrhythmias are usually treated empirically with antiarrhythmic agents, including β -adrenoreceptor blockers and amiodarone.⁴⁷⁰ Beta-blockers in particular are effective at treating symptoms related to exercise-induced arrhythmia, and sotalol can suppress ventricular arrhythmia in a high proportion of patients.⁴⁷⁰ Patients with severe right ventricular or biventricular involvement should be treated according to current guidelines for cardiac failure, using diuretics, inhibitors of angiotensin-converting enzyme, and anticoagulation. Some patients may become candidates for cardiac transplantation. Patients are discouraged from participating

in strenuous physical activities.^{418,448,449} Recent studies, however, have shown that most patients who die suddenly do so at rest.⁴⁰⁸ Patients considered to be at high risk of sudden cardiac death should be offered an implantable cardioverter-defibrillator. Studies evaluating their role, albeit predominantly in adults, have shown a high rate of appropriate discharges.^{471,472} Whilst it is clear that implantation of the cardioverter-defibrillators saves lives in this disease, the problem lies in identifying those individuals at risk who would benefit most from primary prophylaxis. This is particularly important, as implantation of internal defibrillators is not without its side effects, especially in children. A number of markers of increased risk have been proposed, including unexplained syncope, symptomatic ventricular tachycardia, family history of sudden death, young age, left ventricular involvement, and diffuse right ventricular dilation.^{473–475} Population-based survival studies are needed to evaluate the significance of these and other factors, such as asymptomatic non-sustained ventricular tachycardia, and to develop an algorithm for stratification of risk for patients with arrhythmogenic right ventricular cardiomyopathy.

UNCLASSIFIED CARDIOMYOPATHIES

The unclassified cardiomyopathies include diseases that do not fit readily into any morphological subgroup. These include left ventricular non-compaction and endocardial fibroelastosis.

Left Ventricular Non-compaction

Left ventricular non-compaction is a disorder of myocardial morphogenesis that results in multiple prominent trabeculations and deep intertrabecular recesses in the left ventricular myocardium.^{476–478} The condition, previously termed spongy myocardium or spongiform cardiomyopathy, is thought to result from an arrest in the process of involution of endomyocardial trabeculations, which normally occurs by the end of the 10th week of embryonic development. In infants, as already discussed, left ventricular non-compaction can occur in the X-linked Barth syndrome.^{328,479} Mutations in the genes encoding α -dystrobrevin and Cypher/ZASP, two important structural proteins with a role linking the cytoskeleton of the cardiac myocyte to the extracellular matrix, have also been reported in adults with left ventricular non-compaction.^{479,480} A family history of non-compaction or dilated cardiomyopathy is present in approximately one-quarter of cases.⁴⁸¹ The abnormality can also occur in congenitally malformed hearts^{479,482,483}; indeed, it is probably commoner than thought in these settings. In some cases it is caused by mutations in the NKX2.5 transcription factor.^{484,485} It is increasingly becoming recognised as an important cause of cardiomyopathy in children, accounting for nearly one-tenth of cases registered in the Australian study.²²

Diagnosis can be made using cross sectional echocardiography (Fig. 49-18). Several diagnostic criteria have been proposed. One suggests a ratio of 0.5 or less for the distance from the epicardial surface to the trough of a trabecular recess compared to the distance from the epicardial surface to the peak of the trabeculation measured in end-diastole.⁴⁷⁶ Another requires the presence of numerous, excessively prominent trabeculations and deep

intertrabecular recesses supplied by blood on colour Doppler, and a bilayered arrangement with a thin compacted layer and a thick non-compacted layer, the ratio of non-compacted to compacted endocardial layers being greater than 2 when measured in end-systole, in the absence of co-existing structural cardiac abnormalities.⁴⁸⁶ A third requires the presence of more than three trabeculations protruding from the left ventricular wall distal to the papillary muscles visible in one imaging plane and associated with intertrabecular spaces visualised using colour Doppler.⁴⁸⁷ Each proposed criterion has limitations, and the three are probably complementary in making the diagnosis.⁴⁸¹ Although awareness of the condition is increasing, some patients may be misdiagnosed as having distal or apical hypertrophic cardiomyopathy,⁴⁸⁸ and an overlap with dilated cardiomyopathy is also recognised.⁴⁸¹ Alternative imaging modalities, particularly cardiac magnetic resonance imaging, may prove useful for distinguishing between left ventricular non-compaction and hypertrophic cardiomyopathy.^{488–491} In some children, an undulating phenotype characterised by alternating features of dilated cardiomyopathy and hypertrophic cardiomyopathy has been reported.⁴⁸³

The natural history remains to be fully characterised. Initial studies reported a poor prognosis,⁴⁹² but subsequent reports in children and adults have suggested a better prognosis.^{481,483} Family studies suggest that there may be a prolonged preclinical phase before the onset of symptomatic clinical disease, evidenced by the finding of left ventricular enlargement with preserved systolic function and asymptomatic hypertrabeculation in relatives.⁴⁸¹ In some cases, systolic impairment may have been present early in life, recovering during childhood only to present again in adulthood.⁴⁸³ The clinical features in adults and children include left ventricular systolic and diastolic dysfunction, thromboembolism, and ventricular arrhythmia.^{476,481,483,492–501}

The medical treatment aims to improve symptoms and prevent complications. Aspirin has been recommended in all patients by some groups,⁴⁸³ with warfarin for patients with documented thromboembolic events. Patients with ventricular dilation and systolic impairment should be managed with vasodilators and β -blockers, according to current guidelines.²⁸³ Patients with evidence of ventricular arrhythmia may benefit from insertion of an implantable cardioverter-defibrillator. In some children refractory to medical therapy, cardiac transplantation may be considered.

Endocardial Fibro-elastosis

Endocardial fibro-elastosis is a rare and poorly understood disease of the endomyocardium. The diagnosis is made histologically, and the pathological hallmarks consist of deposition of collagen and elastin, ventricular hypertrophy, and diffuse endocardial thickening.⁵⁰² Sporadic and familial disease has been described.⁵⁰³ The aetiology is not fully understood. Isolated, or primary, endocardial fibroelastosis often mimics dilated cardiomyopathy.⁵⁰⁴ More commonly, it occurs in association with other structural cardiac abnormalities, including left-sided obstructive lesions such as aortic stenosis, and anomalous coronary artery arising from the pulmonary trunk. It is likely that the fibroelastosis represents the end-stage pathological phenotype of a heterogeneous group of conditions, rather than a single disease entity.⁵⁰⁵ Possible aetiopathogenic factors include viral infections with agents such as coxsackievirus,^{506,507} adenovirus,⁵⁰⁸ parvovirus,⁵⁰⁹ and mumps virus.^{508,510} In addition, it may be associated with metabolic and storage disorders, including primary deficiency of carnitine and respiratory chain abnormalities.^{511–515} More recently, it has been recognised in fetal and postnatal life, in association with maternal

(Courtesy of Dr Jan Marek, Great Ormond Street Hospital, London, United Kingdom.)

anti-Ro and anti-La antibodies, in children with and without congenital complete heart block.^{516,517}

Endocardial fibroelastosis usually presents in infancy, and the clinical features are typically indistinguishable from those seen in dilated cardiomyopathy.⁵¹⁸ In many cases, patients progress to end-stage cardiac failure and death.^{519–521} Survival of three-quarters at 4 years has been reported.⁵¹⁸ The management is symptomatic, and follows that of dilated cardiomyopathy, including diuretics, vasodilators and digoxin.

Tako-tsubo Cardiomyopathy

Stress cardiomyopathy is a recently described cardiomyopathy characterised by transient and rapidly reversible left ventricular apical ballooning and systolic dysfunction in the absence of coronary arterial disease, triggered usually by profound psychological stress.^{522–524} It is associated with characteristic elevation of the ST segments on the electrocardiogram that mimics acute myocardial infarction. The condition was first described in Japan as takotsubo cardiomyopathy, after the Japanese name for an octopus trap, *tako-tsubo*, that has a similar configuration to the affected left ventricle. Most affected patients are over 60 years old. Recently, a case of suspected takotsubo cardiomyopathy was reported in a 2-year-old girl, following withdrawal of buprenorphine treatment.⁵²⁵ The pathogenesis of the condition remains to be elucidated.

Arterio-venous Fistulas and Related Conditions

SHAKEEL A. QURESHI and JOHN F. REIDY

An arterio-venous fistula is an abnormal connection between an artery and a vein in the absence of any intervening capillary bed. As a result of the low resistance in the veins, a large shunt can occur through such fistulas. The shunting occurs throughout the cardiac cycle, thus producing a continuous flow murmur. Arterio-venous fistulas can involve either the pulmonary or systemic circulations. These are separate entities, and will be considered separately.

EXTRACARDIAC SYSTEMIC ARTERIO-VEINUS MALFORMATIONS

Arterio-venous malformations and fistulas can affect any part of the body. They have a wide range of pathologies, ranging from malformations consisting of abnormal capillaries and dilated venous spaces to direct fistulous communications between major arteries and veins.

Systemic arterio-venous malformations and fistulas can be subdivided into those within and those outside the heart. Extracardiac systemic arterio-venous malformations are of importance to the paediatric cardiologist only when they are haemodynamically significant, and are associated with a large left-to-right shunt. This is a rare situation. Abnormalities with such features are usually congenital in origin. Any large systemic malformation may present with high-output cardiac failure in later life, but rarely in childhood. When a neonate or infant presents with high-output cardiac failure, the most likely extracardiac cause is an aneurysm of the vein of Galen.

Aneurysm of the Vein of Galen

The aneurysmal vein of Galen is an intracerebral arterio-venous malformation. It is the most frequent haemodynamically significant extracardiac arterio-venous shunt encountered in neonates and infants, and affects males three times more frequently than females. It is an uncommon cause of severe cardiac failure in infancy. Affected neonates and infants may present with congestive cardiac failure that suggests a cardiac cause, and this can give rise to diagnostic difficulties. The abnormality consists of multiple feeding arteries, principally the anterior and posterior choroidal arteries and the anterior cerebral artery, which drain directly into an enlarged venous sump. The abnormal vein is considered to be the precursor of the vein of Galen, hence the name of the malformation. The aneurysmal vein drains directly into the straight sinus, and then into the superior sagittal sinus.

Clinical Presentation

The malformations are uncommon. Over a period of almost 20 years, 16 patients with the lesion were encountered at Great Ormond Street Hospital in London,¹ while 29 patients were seen at the Hospital for Sick Children in Toronto over a period of 30 years.² Review of the English literature from 1937 to 1981 found only 128 cases. It has been estimated that, in a population of 3 million, it might be expected that one new patient would be seen each year.³ The cause of these aneurysms is unknown, but they probably result from an early embryonic somatic mutation.

Antenatal scans using ultrasound may occasionally detect the aneurysms in late pregnancy. Colour flow Doppler studies will show the vascular abnormality. Antenatal magnetic resonance imaging will confirm the diagnosis and assess any cerebral damage. Prenatal diagnosis will enable referral to a specialist centre, with all the requisite skills needed to deal with these complex patients.

The majority of cases are diagnosed after birth. Amongst the patients collected from the literature review, about one-third presented in the neonatal period, one-quarter were seen between 3 weeks and 11 months, and the remainder were encountered as older children and adults. Of the neonates, all but two presented with cardiac failure, these patients presenting with subarachnoid haemorrhage and hydrocephalus, respectively. In addition to cardiac failure, which is often refractory to treatment, the neonates showed features of pulmonary hypertension and myocardial ischaemia, as well as cerebral ischaemia resulting from the cerebral steal effect. Compared with the neonates, only two of those presenting as infants had cardiac failure. The majority had hydrocephalus, although one patient presented with a subarachnoid haemorrhage. In the older children and adults, only one had cardiac failure. At these ages, the most common presentation was with subarachnoid haemorrhage, seen in almost half. About one-third developed hydrocephalus, with venous hypertension resulting in epistaxis and distended veins, seen in one-sixth, and generalised neurological deterioration in another sixth thought to be caused by the steal effect of the fistula. In those with the aneurysms, the initial days of life are often unremarkable. If the pulmonary vascular resistance remains high, right-to-left shunting and cyanosis can occur as a result of the grossly increased systemic return. As the run-off from the arterial to venous circulations is of low resistance, there may be bounding pulses, particularly in the carotid arteries, as well as tachycardia. The veins in the neck may be engorged, and a continuous murmur is typically heard over the vault of the skull.

Figure 50-1 This chest radiograph from a neonate shows the non-specific features of marked cardiac enlargement and pulmonary plethora. The absence of any intracardiac abnormality on echocardiography should suggest the diagnosis of an aneurysmal vein of Galen.

Diagnosis

When the fistula is large, the chest radiograph usually shows cardiac enlargement with marked pulmonary plethora (Fig. 50-1). If there is significant right-to-left shunting as a result of an elevated pulmonary vascular resistance, then pulmonary oligoemia may also be present. The electrocardiogram usually shows biventricular hypertrophy. Echocardiography demonstrates enlargement of all four chambers, and excludes a cardiac cause for heart failure. Prior to the availability of ultrasound, the diagnosis was often difficult, and angiography was usually necessary. Angiography should now be performed only with a view to proceeding with embolising the abnormal connection. Ultrasonic scanning of the head across the anterior fontanelle will demonstrate the centrally situated aneurysmal vein. It also often shows the presence of the feeding arteries (Fig. 50-2). Doppler interrogation, and in particular colour Doppler, more readily demonstrates the direction of flow of blood. Where the ultrasound findings are not clear, or when more information is required in older patients, magnetic resonance imaging is indicated. This is now preferred to using computed tomographic (CT) scanning with contrast.

Management

The therapeutic options are embolisation or endovascular treatment. This involves very specialised neuro-interventional techniques, and very few specialised centres achieve the level of expertise and experience required to provide consistent treatment.

The outlook for neonates treated medically is grim.⁴ In the series reported from Toronto,² all but one of the children treated medically died. Surgery has little or no role nowadays, as the surgical approach also carried a very high mortality, and resulted in significant morbidity. If possible, treatment is initially conservative, as arteriography and embolisation in the neonate is technically very difficult.⁵ If the cardiac failure can be managed medically, the therapeutic options are much more encouraging at the age of about 6 months.

Figure 50-2 Ultrasonic interrogation across the anterior fontanelle shows a large central circular echo-free abnormality typical of an aneurysmal vein of Galen. A large vein is seen draining from the right side. Colour Doppler should demonstrate arterial flow.

Arteriography is performed at the same time as embolisation. Different patterns have been described. In neonates, multiple arteries arise from the internal carotid arterial branches and feed the aneurysm at its antero-superior border (Fig. 50-3). The aneurysm then drains by very large straight and lateral sinuses (Fig. 50-4). Most

Figure 50-3 Selective carotid arteriography, in the antero-posterior view, shows the aneurysmal vein of Galen filling via multiple small arterial branches. It gained a further supply from the other carotid artery.

Figure 50-4 The aneurysmal vein of Galen has been catheterised via the trans-torcular approach (lateral view). The tip of the catheter is in the aneurysm and multiple large steel coils have been positioned within it. Injection of contrast material demonstrates the large straight sinus draining to the lateral sinuses.

commonly in infants, the feeding artery is situated inferiorly and laterally and consists of a single posterior choroidal artery. In infants and older children, the feeding arteries are usually located anteriorly and superiorly, and consist of one or two posterior choroidal arteries, as well as anterior cerebral arteries. In older children, most commonly the feeding vessels consist of a network of branches arising from the posterior choroidal and thalamic perforating arteries.

The transtorcular venous approach was used at one time directly to access the venous aneurysm,⁶⁻⁸ but has now largely been superseded by the transarterial route. This involves transfemoral approach and selectively catheterising the small feeding branches to the aneurysm. Embolisation is best performed with liquid embolic agents, such as cyanoacrylate glue. The outlook, if treatment is performed before the onset of cerebral damage, is good.⁹ In this the largest series of endovascular treatment, neonates presenting early with severe cardiac failure had the worst prognosis. When there is associated cerebral damage, known as the melting brain syndrome, death or survival with severe cerebral damage is likely. There is often a restriction on the amount of embolisation that can be performed at any one session, particularly in neonates and infants, so multiple embolisations may be necessary. Sometimes these cases may be complicated by stenoses in the jugular bulbs, and stenting has been described in this situation.¹⁰

CORONARY ARTERIO-VEIN FISTULAS

These lesions, also known as coronary arterial fistulas or malformations, are connections between one or more of the coronary arteries and a cardiac chamber or great vessel, having bypassed the myocardial capillary bed. They are rare, and usually occur in isolation. The exact incidence is unknown, although they are the most common haemodynamically significant coronary arterial anomaly.¹¹⁻¹³ A majority of the fistulas have a congenital origin, but some may occasionally be detected after cardiac surgery, such as valvar replacement, coronary arterial bypass grafting, and after repeated myocardial biopsies in cardiac transplantation.¹⁴⁻¹⁷ The lesions

were discovered in 0.1% of more than 33,000 patients undergoing coronary angiography.¹⁸

Morphology

It is difficult to provide accurate data on the distribution of the origins and sites of drainage of the fistulas, because reports vary depending on the analysed populations. Patients undergoing interventional or surgical treatment are likely to represent the severe end of the spectrum, whilst information will be unavailable in those with asymptomatic fistulas.

The artery feeding the fistula may be a main coronary artery or one of its branches. The vessel may be dilated and tortuous, and terminates in one of the cardiac chambers or another vessel. The more proximal its origin from the feeding artery, the more dilated the fistula is likely to be. If the fistula drains to the right atrium, and arises proximally from a main artery, it tends to be considerably dilated and less tortuous (Fig. 50-5). When the origin is more distal, and in particular when it arises from the left coronary artery and the drainage is to the right ventricle, the feeding artery may be very tortuous and present a challenge for interventional catheter closure (Fig. 50-6). Multiple arteries can feed into a single coronary arterio-venous fistula, or alternatively the fistula can have multiple sites of drainage.^{16,19} The fistulas originate from the right coronary artery in about half the cases, the left anterior interventricular artery being the next most frequently involved, in approximately one-third, and the circumflex artery in about one-fifth.²⁰ Over nine-tenths of the fistulas, irrespective of their origin, drain to the right side of the heart.²¹ In those draining to the right heart, the fistulas open most frequently to the right ventricle, in about two-fifths, followed by the right atrium, coronary sinus, and pulmonary trunk. Multiple fistulas between the three major coronary arteries and the left ventricle have also been reported.²²⁻²⁴ In adults, fistulas may occasionally be encountered which originate from both the coronary

Figure 50-5 Left coronary angiogram in right anterior oblique projection shows a coronary arterio-venous fistula from a dilated branch arising from the circumflex coronary artery draining to the right atrium. The feeding vessel is dilated and less tortuous.

Figure 50-6 Selective left coronary angiogram in antero-posterior projection shows a coronary arterio-venous fistula arising from the left coronary artery. The feeding artery is considerably dilated and tortuous and drains into the right ventricle.

arteries and drain into the pulmonary trunk. These fistulas may cause angina even in the absence of coronary arterial disease (Fig. 50-7). They require closure.

Pathophysiology

When the fistula drains to the right side of the heart, the volume load is increased to the right heart, as well as to the pulmonary vascular bed, the left atrium, and the left ventricle. This results in a left-to-right shunt similar to that produced by an atrial or ventricular septal defect, or patency of the arterial duct. When the fistula drains into the left atrium or the left ventricle, there is volume overloading of these chambers but no increase in the pulmonary blood flow. The situation then mimics mitral regurgitation. When the fistula drains into the left ventricle, the haemodynamic effect is similar to that produced by aortic regurgitation. Thus, there may be different echocardiographic appearances, with dilation of different cardiac chambers depending on the sites of the shunts. The size of the shunt is determined by the size of the fistula, and the difference in pressure between the coronary artery and the chamber into which the fistula drains. Occasionally, there may be congestive cardiac failure, while in adults, myocardial ischaemia may rarely occur due to a coronary arterial steal.

Clinical Features

The fistulas are usually asymptomatic in the first two decades, especially when they are haemodynamically small. Indeed a small number may close spontaneously.²⁵

Figure 50-7 Selective right coronary angiogram in the right anterior oblique projection shows a fistula arising from the proximal part of the right coronary artery, which takes a tortuous course and drains into the pulmonary trunk.

After the second decade, there is an increase in the frequency of symptoms and complications.²⁶ Complications include steal from the adjacent myocardium causing myocardial ischaemia, thrombosis and embolism, cardiac failure, atrial fibrillation, rupture, endocarditis or endarteritis, and arrhythmias.^{13,20,27-31} Thrombosis within the fistula, although rare, may cause acute myocardial infarction and atrial and ventricular arrhythmias.³²⁻³⁴ Spontaneous rupture of an aneurysmal fistula has been reported to produce haemopericardium.³⁵ Recurrent septic pulmonary embolism may occur as a complication of endocarditis of the tricuspid valve if associated with a coronary arterial fistula.³⁶ Jet lesions may be found on the wall of the coronary sinus opposite the site of entry of the fistula, on the tricuspid valve, or at the orifice of the coronary artery.³⁶⁻³⁸

The fistulas may increase in size over time, although some may be large in the newborn period, and may even be detected prenatally.³⁹ They may form a short and direct connection with a chamber or a large vessel or form complex long tortuous and aneurysmal cavities. The aneurysmal section of the fistula may dilate progressively, and the feeding artery may become more tortuous.⁴⁰ The largest shunts occur when the coronary artery connects to the right rather than the left heart chambers. Even then, the left-to-right shunt is rarely more than 3 to 1.

The presentation varies between finding an asymptomatic continuous murmur, to presentation with congestive cardiac failure or exercise-induced angina.¹⁸ The majority of the patients are asymptomatic, with normal exercise tolerance. Patients with large left-to-right shunts may have symptoms of congestive cardiac failure, especially in infancy, and occasionally in the neonatal period.^{41,42} Congestive cardiac failure may also occur in the elderly.⁴³ Some adult patients may have angina and electrocardiographic evidence of myocardial ischaemia.¹⁶ The mechanism of the angina is presumed to be a steal phenomenon.^{28,44,45} Exercise-stress thallium scintigraphy has shown the presence of reversible ischaemia supporting such a phenomenon.⁴⁶

Some patients may be referred because of an asymptomatic murmur, which will be continuous, and heard over the praecordium. Whilst the murmur may sound similar to that of a patent arterial duct, it must be differentiated from the latter. The murmur of a coronary arterial fistula is heard over the mid-chest, rather than below the left clavicle. It may even be audible to the right of the sternal border, and typically peaks in mid-diastole rather than systole, as is the case when the murmur originates from the persistently patent arterial duct. Such findings should alert the physician to the possibility of a coronary arterio-venous fistula. If the fistula connects to the left ventricle, only an early diastolic murmur may be heard. The patient is then referred for echocardiographic assessment.

The differential diagnoses include persistent patency of the arterial duct, ruptured aneurysm of a sinus of Valsalva, ventricular septal defect with aortic regurgitation, venous hums, and other systemic and pulmonary arterio-venous fistulas. Indeed, when it became possible to close patent arterial ducts surgically, the similarities in physical findings led, on occasion, to unintentional surgical exploration of patients with coronary arterial fistulas.

Investigations

The electrocardiogram and chest X-ray are usually unhelpful in the diagnosis and assessment. The electrocardiogram may show the effects of left ventricular volume overload and ischaemic changes. If it is normal, and the patient is old enough to exercise either on the treadmill or a bicycle, changes in the ST segments indicative of ischaemia may become apparent. The chest X-ray is usually normal, but occasionally moderate cardiomegaly may be present when there is a large left-to-right shunt.

When the fistula and the resulting shunt are small, colour Doppler echocardiography may be helpful, demonstrating the chamber or the vessel into which the fistula drains. Conventional pulsed and continuous wave Doppler can then confirm the high velocity of the flow through the fistula. Cross sectional and colour Doppler echocardiography are helpful in demonstrating dilation of the affected coronary artery. As indicated, colour flow mapping may show the site of drainage, but it is difficult to define the detailed anatomy of the fistula with this technique.^{47,48}

Additional clues may be present when the coronary artery feeding the fistula is enlarged, ectatic or tortuous, or when there is a large shunt. If a dilated coronary artery can be traced from its aortic origin into the fistula, the diagnosis can be confirmed with certainty by conventional Doppler, and in particular by colour flow mapping. Transoesophageal echocardiography has also been used for better definition of the fistulas.⁴⁸⁻⁵¹ On colour Doppler interrogation, significant flow may be seen at the origin, or even along the length, of the vessel. It may also be possible to see flow into the chambers of the right heart. Magnetic resonance imaging can confirm, permitting recognition of the proximal coronary arteries, or even the whole length of the fistula.

In patients who are able to exercise, and especially those who complain of angina or dyspnoea, myocardial perfusion or stress thallium scanning may demonstrate reversible ischaemia. It may also determine the size of the territory under threat of ischaemia.⁴⁶ In older patients,

other areas of acquired coronary arterial disease may be discovered that influence the subsequent management. In these older patients, if a coronary arterial fistula is discovered, even if the coronary arteries are free of atheromatous disease, closure of such a fistula may relieve the symptoms.⁵²

The main diagnostic technique remains cardiac catheterisation and angiography, the investigation also helping in planning the appropriate treatment. Initial diagnostic catheterisation is used to assess the haemodynamic significance of the fistula, and to provide details of its anatomy, in particular its size, origin, course, presence of any stenoses, and its site of drainage. Selective angiography of the coronary arteries allows confirmation of the diagnosis, and demonstrates the detailed anatomy of the fistula (Fig. 50-8). Selective injections, however, should be performed only when definitive treatment is planned, such as an interventional procedure or surgery. They should rarely be required nowadays to make the diagnosis. A preliminary aortogram taken in the root helps to determine which coronary artery should be catheterised selectively, but it is usually good practice to perform selective angiography of both the coronary arteries. Visualisation of the fistula may be improved by using the so-called laid-back aortogram.⁵³ This is obtained by adding caudal angulation at 45 degrees to the frontal view, with slight left or right anterior oblique orientation. A more important reason for detailed selective coronary angiographic assessment is to investigate the possibility of multiple arteries feeding the fistula (Fig. 50-9). Coronary angiography in several planes then assumes great importance. It should be performed as in adults. These views include right anterior oblique, straight antero-posterior, left anterior oblique, left anterior oblique with caudocranial angulation, and left lateral projections.

Figure 50-8 Selective angiography of the left coronary artery in the left lateral projection shows a dilated feeding vessel with a tortuous course draining into the right ventricle.

Figure 50-9 Left coronary angiogram with follow-through of the contrast in the left lateral projection in the same patient shown in Figure 50-8. Two vessels drain into the aneurysm, which in turn drains into the right ventricle. In this patient, it is important to close the fistula by deploying coils into the aneurysm.

Management

The options include closure at surgery, or by use of devices inserted through a catheter. The goal of treatment is to occlude the fistula whilst preserving normal coronary arterial flow. The options can be optimised by careful identification of the number of fistulous connections, the nature of the feeding vessel or vessels, the sites of drainage, and quantification of myocardium at risk for injury or loss. The indications for treatment include the presence of a large or increasing left-to-right shunt, left ventricular volume overload, myocardial ischaemia, left ventricular dysfunction, congestive cardiac failure, and prevention of endocarditis or endarteritis.

As techniques for accurately diagnosing coronary arterio-venous fistulas have improved, open heart surgery has become safer, making it even more unlikely that the natural history will ever be clearly defined. In the past, most authors have advocated surgical closure of the fistulas in view of the low operative mortality.^{54–57}

Even as long ago as 1979, it had been noted that symptomatic patients over the age of 20 years suffered more problems, as well as more post-operative complications, than did younger patients.²⁶ This prompted the suggestion that all haemodynamically significant fistulas should be closed, even in the absence of symptoms, to prevent potential complications, such as endarteritis, progressive enlargement of the fistula, secondary atherosclerotic involvement with rupture, and thrombo-embolism. Early surgery also avoids the post-operative problems that can complicate operations performed in later life. The policy of closure, however, has to be balanced against the reports of spontaneous regression or closure, in some younger children with relatively small fistulas draining in particular into the right ventricle.^{25, 26, 58–62}

The aim of surgery is to close the fistula while preserving the flow of blood through the normal coronary arterial branches. Different surgical techniques have been used, and all of them appear to be adequate. The fistula is closed at the point of entry into the heart, without interrupting the continuity of the more proximal artery. When the lesion is clearly visible, closure can be achieved, without extracorporeal circulation, by clamping and suturing the fistulous channels on the outside of the heart. This approach does not require opening the fistula, the cardiac chambers, or the coronary arteries, and may be performed with the heart beating. More frequently, however, cardiopulmonary bypass is needed. This may be essential if it becomes necessary to enter a chamber to close the fistula from within, or if insertion of a bypass graft is necessary to maintain viability of the myocardium distal to the ligated artery. A small proportion of patients may develop complications post-operatively. These include ischaemia or infarction downstream from the point of ligation. This may be especially significant when a fistula from the right coronary artery drains to the right atrium or the superior caval vein. Ligation of such a vessel may interrupt the supply to the artery of the sinus node.

Surgical treatment is associated with morbidity, but low mortality rate, which ranges in reported series from zero to 6%.^{13,56,57,63–68} Mortality rate, as expected, was higher in the historically older series. Myocardial infarction has been reported in less than one-twentieth of patients,⁶⁴ albeit that there is a low, but significant, risk of persistence or recurrence of the fistula.^{63–66,69} The true incidence of recurrence, however, is unknown. The reason for the recurrence may be the presence of multiple fistulas, which are difficult to deal with by surgery. Median sternotomy and cardiopulmonary bypass also have their own associated morbidity.⁶⁸ Little has been said about the possibility of developing arteriosclerosis in the region of the fistula either subsequent to or prior to surgical treatment.

Until recently, surgery was the only available definitive treatment. In the last two decades, percutaneous transcatheter embolisation has emerged as an effective and safe alternative. When available, it should now be considered the treatment of choice.^{16,70–77} The aim of closure by catheterisation is to occlude the artery feeding the fistula as distally, and close to its point of termination, as is possible to avoid occlusion of branches feeding normal myocardium. If the feeding artery is occluded too distally, and if there is no significant stenosis within the artery, then the possibility exists for inadvertent embolisation into the pulmonary circulation. Occlusion should be performed at a precise point, using various materials which include detachable balloons, stainless steel coils, or platinum microcoils.^{16,74–79} It is rare nowadays to use detachable balloons, although they proved useful in the past. A large variety of equipment should be available in the catheterisation laboratory to achieve successful closure, because different techniques may be required should the fistula have unusual morphology. It is also necessary to have access to devices of different shapes and sizes, such as the conventional Gianturco coils, controlled-release coils, and a variety of devices normally used to close atrial or ventricular septal defects, persistently patent arterial ducts, or other abnormal vessels.

The choice of the equipment, and the technique to be used, is determined by the morphology of the fistulas.

Other important determinants include the age and size of the patient, the size of the catheter that can be used in the patient, the size of the vessel to be occluded, and the tortuosity of the course required to reach the intended point of occlusion. For example, if the route to the target vessel is tortuous, then superfloppy guide wires combined with Tracker or Micro-ferret infusion catheters are recommended. In the presence of high flow, a stop-flow technique with a balloon is recommended during deployment of a coil or a device. Because of the need for precise occlusion, it is always preferable to use a potentially reversible technique.

For many years, stainless steel coils of 0.038-inch calibre have been widely used for embolisation elsewhere in the vascular system. They can be delivered through standard non-tapered catheters of 5 or 6 French size to occlude coronary arterial fistulas. Positioning such catheters satisfactorily in a distal location in a tortuous fistula, however, may be both difficult and hazardous. In such circumstances, it is safer to insert platinum microcoils, with calibre of 0.018 inch, which are delivered through a co-axial 3 French catheter. Such catheters, used with steerable guidewires, can be manipulated safely through tortuous arteries into very distal locations (Fig. 50-10). Moreover, the high flow that is often encountered in large fistulas makes them difficult to occlude. A mass of platinum coils is frequently necessary. In the last 10 years or so, new interlocking detachable coils have been used, the delivery of which can be controlled.^{78,80} Use of such coils makes closure much safer, with the added advantage that they can be retrieved into the catheter if the final position is deemed unsatisfactory. Such coils offer very little resistance to passage through the microcatheters. Even if they embolise inadvertently, they are easy to retrieve with snares. Fistulous arteries permitting

very high flow present a particular problem, but temporary occlusion of the proximal portion with a balloon permits safe insertion of an occluding mass of coils (Figs. 50-11 and 50-12).^{80,81}

Preliminary arteriography will usually have demonstrated the anatomy of the fistula prior to embolisation. Further detailed, and more selective, coronary angiography is essential to obtain details of the normal coronary arterial branches, which may be small but are at risk during occlusion. The steal from a fistula permitting high flow usually results in poor opacification of the normal branches and possible underestimation of their size. With all the current techniques, occlusion or near occlusion should be

Figure 50-10 A cine frame in the left anterior oblique projection shows a guiding catheter at the origin of the main stem of the left coronary artery. A 3 French Tracker catheter has been passed through the guiding catheter into the tortuous coronary arterio-venous fistula and placed in a distal location. A controlled release coil is seen just protruding through the tip of the Tracker catheter.

Figure 50-11 A cine frame in the left anterior oblique projection shows a balloon catheter inflated in the proximal part of the left coronary artery in order to allow safe deployment of coils distally in the fistula.

Figure 50-12 A cine frame in the left anterior oblique projection in the same patient shown in Figure 50-11 showing an occluding mass of coils, the balloon having been deflated and removed.

achieved soon after the embolisation. Sometimes, a small second feeding branch to the fistula may only become opacified when the main artery has been occluded (Figs. 50-13 and 50-14). The key to success is to select a technique for embolisation that is suitable for the size and the location of the fistula.

Some fistulas may be more easily closed from the right side of the heart. These fistulas tend to be large, less tortuous, and have a short course to their point of drainage

to the right heart (Fig. 50-15). Depending on their size, they may be suitable for occlusion with a vascular plug, a ductal occluder (Fig. 50-16), or an occluder usually used to close atrial or ventricular septal defects.^{42,82-86} Fistulas closed in this fashion should be large, and should permit relatively easy and straight access from the right heart. If needed, occlusion can be achieved with the help of an arterio-venous guide wire circuit, using either femoral venous or internal jugular venous access.

Figure 50-13 A selective left coronary angiogram in the right anterior oblique projection showing a coronary arterio-venous fistula arising from the left anterior descending coronary artery and draining into the right ventricle. There are possibly two feeding vessels supplying the aneurysmal portion, which drains into the right ventricle.

Figure 50-15 A selective left coronary angiogram showing a fistula arising from the left coronary artery. The dilated feeding artery takes a less tortuous course and drains into the right atrium.

Figure 50-14 A cine frame of the same patient shown in Figure 50-13. After deployment of coils in the aneurysmal part, two further vessels draining into the aneurysm are apparent.

Figure 50-16 A cine frame of the same patient shown in Figure 50-15 demonstrates an Amplatzer duct occluder still attached at the correct location to close the fistula.

After occluding the main fistulous vessel, repeat selective coronary angiography in both the coronary arteries should be performed in order to see if there is a second branch feeding the fistula, which may also need occlusion at the same procedure. When closing fistulas through a catheter, complete occlusion is expected in well over nine-tenths of procedures. The main complications include inadvertent embolisation of coils, transient electrocardiographic T-wave changes, transient bundle branch block, and myocardial infarction. All these complications are rare, apart from inadvertent embolisation, which may result from high flow in the large fistulas, or use of undersized coils.⁸⁰ As already discussed, should the coils migrate, they can easily be retrieved with snares.

AORTO-LEFT VENTRICULAR TUNNEL

The aorto-left ventricular tunnel is a rare defect, consisting of an endothelialised communication between the aorta and the left ventricle which bypasses the line of attachment of one of the aortic valvar leaflets. The abnormal channel originates in the ascending aorta, and terminates in the left ventricle (Fig. 50-17).⁸⁶ The lesion is found more frequently in males than females, with a ratio of 2:1 to 3:1.^{87,88} Although it was originally believed that the lesion was acquired after birth, it is now generally agreed that the entity is congenital,^{87,89} having been detected prenatally by echocardiography.^{90,91} Detected as early as 19 weeks of gestation, the most important clue to presence of the lesion was colour Doppler evidence of marked aortic regurgitation.

The tunnel usually originates above the right aortic sinus of Valsalva, and can involve the orifice of the right coronary artery. The tunnel courses in the tissue plane between the free-standing muscular right ventricular infundibulum and the aortic sinus, and usually enters the left ventricle through the fibrous triangle between the right and left coronary leaflets of the aortic valve.⁹² Occasionally, the tunnel may originate above the origin of the left coronary artery (Fig. 50-18).⁹³ The tunnel itself may be dilated aneurysmally through part or the entirety of its course. Associated cardiac defects include aortic valves with two leaflets, with

Figure 50-18 This left ventricular angiogram profiled in antero-posterior projection shows an aorto-left ventricular tunnel originating above the left coronary artery. The ascending aorta and the aortic root are very dilated. (Courtesy of Dr Wolfgang Kohler, Erfurt, Germany.)

aortic stenosis or regurgitation present in the majority of patients. Other defects include patency of the arterial duct, ventricular septal defect, pulmonary stenosis, infundibular right ventricular obstruction, aneurysm of the membranous septum, and critical aortic stenosis.^{94,95} Distortion of the aortic valve occurs because of the lack of support of the afflicted leaflet, producing severe regurgitation.

Clinical Features

The symptoms and signs depend on the size of the tunnel and the severity of aortic regurgitation. Patients with severe regurgitation usually present with symptoms of congestive cardiac failure, with presentation at any point from birth to adult life.^{88,96} The signs may include a wide pulse pressure, and loud systolic and diastolic to-and-fro murmurs at the base of the heart, usually with a short interval separating them. The anomaly should be considered in the differential diagnosis of any neonate or infant with systolic and diastolic murmurs along with the signs of aortic regurgitation. The abnormal haemodynamics may produce congestive cardiac failure in the neonate or infant, often with associated left ventricular enlargement and overactivity, with a dilated ascending aorta on a chest radiograph. As emphasised already, the key to diagnosis in fetal life is aortic regurgitation, sometimes with left ventricular dysfunction and hydrops.^{90,91}

Investigations

The electrocardiogram shows left ventricular hypertrophy in the majority of patients. Cross sectional and colour Doppler echocardiography usually confirms the diagnosis. In

Figure 50-17 As shown in the specimen, the aorto-left ventricular tunnel is a defect bypassing the detached hinge of the aortic valve, which has come apart from the valvar sinus. The tunnel extends through the tissue plane between the aortic sinus and the free-standing muscular subpulmonary infundibulum.

the occasional patient in whom the diagnosis is difficult, magnetic resonance imaging or cardiac catheterisation may be helpful.⁹⁷ Angiography in the aortic root usually confirms the diagnosis, although this should be rarely required nowadays. There may be gross dilation and distortion of the aortic sinus, ascending aorta, and the left ventricle. Angiography may also show normal origin of the coronary arteries, thus differentiating the tunnel from a fistula from the coronary artery to the left ventricle. The anterior location of the abnormal tunnel, and the demonstration of a normal aortic sinus of Valsalva, distinguishes the tunnel from ruptured aneurysm of a sinus of Valsalva into the left ventricle.

Management

Surgical closure in early life was first reported over 45 years ago.⁸⁷ Presentation with severe regurgitation is at or soon after birth, with early congestive cardiac failure.^{88,98} Symptoms of congestive cardiac failure may also appear later, in the second or third decade of life.^{87,96} Some patients may die despite medical treatment,⁸⁷ but others survive to undergo successful surgical repair. In presence of congestive cardiac failure, surgery is clearly indicated. In asymptomatic neonates, or in those patients in whom cardiac failure is well controlled, surgery can be delayed for a few weeks or months. Early intervention can prevent progressive damage to the aortic valvar leaflets or deformity of the aortic root,^{99,100} and early surgery is also required should there be severe aortic stenosis rather than regurgitation.¹⁰¹

The technique of repair depends on the type of tunnel. For those with a small aortic opening, closure of the orifice in two layers is advocated.⁸⁷ In the setting of larger openings, the aortic end is closed with a patch, while both the aortic and left ventricular ends of the tunnel can be closed.¹⁰² In all the techniques, it is imperative to avoid distortion of the aortic valve and damage to the right coronary artery or the conduction system. The reported operative mortality ranges between zero and 20%.^{91,100,102,103} Late complications after repair include aortic regurgitation in up to three-quarters of patients.^{100,103} This may necessitate reoperation on the aortic valve. Occasionally, should it be severely stenotic, it may not be possible to preserve the native aortic valve. Replacement with an aortic homograft may then be required to repair both the tunnel and the stenotic valve.¹⁰¹

ANEURYSMS OF THE SINUSES OF VALSALVA

Aneurysm of one of the aortic sinuses of Valsalva is a rare defect, which may be congenital or acquired. The incidence varies from 0.14% to 0.35%.¹⁰⁴ Its prevalence appears to be increased in the Asian countries when compared to Western populations.¹⁰⁵ Congenital aneurysms are the result of sinusal mural weakness, which produces downward prolapse of the leaflet. The dilated sinus may bulge into an atrium or ventricle, and may rupture. It is rare in infancy and childhood, being more commonly seen in adults. Aneurysms may be acquired through bacterial endocarditis, albeit that the endocarditis may have occurred on a congenital aneurysm. It can be difficult, therefore, to distinguish between congenital and acquired aneurysms, although frequently the congenital ones are associated with a ventricular septal defect and aortic coarctation. Most aneurysms are single, and most commonly affect the right coronary aortic sinus.

Figure 50-19 The sites of potential rupture of aneurysms of the aortic sinuses of Valsalva, indicated by arrows, have been superimposed on this picture of the short axis of the normal heart viewed from the atrial aspect.

Less commonly, the non-coronary aortic sinus is involved. The left coronary aortic sinus is rarely involved. Aneurysms of the right coronary aortic sinus usually prolapse into the right ventricle or right atrium, and those from the non-coronary sinus into the right atrium. Aneurysms of the left coronary aortic sinus prolapse into the left ventricle. The most common aneurysm, from the right coronary aortic sinus prolapsing into the right ventricle, may be associated with a ventricular septal defect.

As indicated, the aneurysms may rupture, this occurring during childhood or adolescence, and most frequently into the right rather than the left chambers. As expected from their position, aneurysm of the right sinus of Valsalva may rupture into the right ventricle or the right atrium, while those involving the non-coronary sinus tend to rupture into the right or left atrium, and those involving the left coronary aortic sinus rupturing into the left ventricle or the left atrium (Fig. 50-19).^{106–108} Rupture can also occur through the septal leaflet of the tricuspid valve, producing an acquired atrioventricular septal defect.¹⁰⁹ There is an increased incidence of rupture when an aneurysm occurs in the presence of a doubly committed subarterial ventricular septal defect. Rupture in these cases may occur into the right ventricular outflow tract.¹¹⁰ Aneurysms occurring in the setting of Marfan's syndrome are considered as a separate entity. Other associated lesions include an aortic valve with two leaflets, and aortic coarctation. Rupture has also been reported in a patient with Behçet's disease,¹¹¹ and as a late complication after repair of dissection of the ascending aorta.¹¹²

Clinical Features

When the aneurysm has not ruptured, it usually produces no symptoms. It may only be discovered as a chance finding on echocardiography, or angiography, performed during

interrogation of another lesion, such as ventricular septal defect. The natural history of unruptured aneurysms is not known. Although rupture has been reported in the neonatal period,¹¹³ it occurs more frequently in the third or fourth decade of life. When the aneurysm ruptures, the majority of the patients become symptomatic. Rupture may produce central precordial chest pain, along with sudden dyspnoea, because of a large left-to-right shunt combined with aortic regurgitation. Very occasionally, rupture may not produce any symptoms. Even rarer still is rupture into the pericardial cavity.¹¹⁴ Unruptured aneurysms may cause angina, which may be intractable, especially when the aneurysm causes distortion of the origins of the coronary arteries.¹¹⁵ Myocardial infarction may be the consequence of compression of the coronary arteries, and may occasionally be fatal.^{116,117} Other possible complications include transient ischaemic attacks and cerebral embolism.^{118–120} Physical examination may reveal a wide pulse pressure and left or right ventricular overactivity. The murmurs vary, with ejection systolic combined with early but long diastolic murmurs, or continuous murmurs heard at the right or left lower sternal borders. Obstruction of the right ventricular outflow tract has occasionally been reported, with or without the presence of a ventricular septal defect.^{121,122}

Investigations

The electrocardiogram usually shows left ventricular hypertrophy, occasionally with biventricular hypertrophy. Cross sectional combined with colour Doppler echocardiography is helpful in making the diagnosis,¹²³ and frequently shows dilation of the aortic root and left ventricular volume overload. A ruptured right coronary aortic sinus may protrude anteriorly, caudally, and leftwards. Severe aortic regurgitation may be present, with turbulent flow into the right ventricle or right atrium seen on colour Doppler.¹⁰⁷ Echocardiography will also show the presence or absence of a ventricular septal defect. Transoesophageal echocardiography shows the anatomy in more detail, and is perhaps superior to the transthoracic approach.¹²⁴ Frequently, surgery can be performed without the need for cardiac catheterisation.^{119,125} Cardiac catheterisation and angiography merely confirm the echocardiographic findings, albeit often showing the deformity of the aortic sinus more convincingly. Although filling of the right heart chambers, into which the aneurysm may have ruptured, is frequently seen, occasionally the rapid heart rate and the high cardiac output prevent their opacification. Apart from conventional echocardiography, contrast imaging has also been used for non-invasive diagnosis.^{126,127}

Management

The conventional treatment is surgical, although transcatheter approaches have increasingly been used in recent years.^{128–130} If the surgical approach is chosen, it is performed on cardiopulmonary bypass. Direct closure can be carried out through an aortotomy, through the right ventricle, or via the right atrium. Sometimes both the aorta and the chamber of entry need to be explored to achieve effective repair.^{131,132} Surgical repair may then involve closure of both ends of the aneurysm with patches. If a ventricular septal defect is present, it too should be closed. The aortic

valvar leaflets may need resuspension in order to reduce the severity of aortic regurgitation, which may determine the outcome. Even after successful surgical repair, the prognosis is guarded. Recurrence, or an increase, of aortic regurgitation may be seen, and require further surgery. It is debatable whether an aneurysm discovered incidentally in an asymptomatic child should be surgically repaired. Surgical repair can now be achieved without mortality, even though it may be necessary to replace the aortic valve.¹³³ A more recent surgical experience¹³⁴ reported overall survival of 95% at 20 years. In the latter series, reoperation was needed in one-sixth of the patients for replacement of the aortic valve, recurrence of the fistula, or recurrence of a ventricular septal defect.

Transcatheter closure of a ruptured aneurysm of the sinus of Valsalva was first reported in 1994, using a Rash-kind umbrella to close the defect.¹²⁸ Since then, different devices have been used, and the transcatheter experience has increased.^{129, 135} To achieve success, the point of origin of the ruptured sinus needs to be clear of an orifice of a coronary artery by at least half a centimeter. The procedure is usually performed under general anaesthesia, using femoral venous and arterial access, and incorporating selective coronary angiography and an aortogram to delineate the anatomy. Having established an arterio-venous circuit, it is important to size the defect. When the size is uncertain, a balloon can be passed over the guidewire to provide increased accuracy. As discussed, a variety of devices, such as Amplatzer ductal occluder or the device designed for closure of muscular ventricular septal defects, have been used to occlude the ruptured sinus (Figs. 50-20 and 50-21). Having inserted the device, selective coronary angiography is performed to ensure that the aortic end of the device has not encroached on the origin of the coronary arteries.

Figure 50-20 An aortogram in the right anterior oblique projection shows a ruptured right sinus of Valsalva draining into the right atrium (Courtesy of Dr Grazyna Brzezinska-Rajszys, Warsaw, Poland.)

Figure 50-21 A cine frame of an aortogram in the same patient shown in Figure 50-20 showing an Amplatzer duct occluder used to close the ruptured sinus of Valsalva aneurysm. (Courtesy of Dr Grazyna Brzezinska-Rajszys, Warsaw, Poland.)

Insertion of the device should produce complete occlusion of the defect. Haemolysis can occur if there is a significant residual flow, so selection of the most appropriate device is crucial. Reported results have thus far been good.^{128–130}

AORTOPULMONARY WINDOW

The aortopulmonary window is an abnormal communication between the intrapericardial components of the ascending aorta and the pulmonary trunk, but in presence of two patent arterial valves. It is a rare defect,¹³⁶ and is differentiated from common arterial trunk by the presence of the separate arterial valves arising from discrete subaortic

and subpulmonary outflow tracts (Fig. 50-22). The window is usually found between the left lateral wall of the aorta and the right wall of the pulmonary trunk. It can be variable, its dimensions determining the magnitude of the shunt, the pulmonary arterial pressures, and the clinical features.

Morphology

Most frequently the defects are either circular, and positioned midway between the arterial valves and the bifurcation of the pulmonary trunk, helical and in similar position, or large and lacking obvious posterior or distal borders.¹³⁷ More rarely, the defect can be tunnel-like.¹³⁸ The window is an isolated lesion in about half the patients, but can be found in association with a ventricular septal defect, anomalous origin of the right or left coronary arteries from the pulmonary trunk, aortic coarctation, interruption of the aortic arch (Fig. 50-23), aortic origin of the right pulmonary artery, and in the setting of tetralogy of Fallot or other ventriculo-arterial connections.^{139–156} It is unusual, however, to find windows in association with Di George syndrome. An iatrogenic window has now been described following inappropriate balloon dilation of pulmonary arterial stenosis.¹⁵⁷

Clinical Features

The lesion produces left-to-right shunting comparable to that produced by a large patent arterial duct. The haemodynamic findings are similar to those found in patients with common arterial trunk. Congestive cardiac failure may occur in neonates or infants, with signs suggestive of a persistent patency of the arterial duct, but with a clinical suspicion of common arterial trunk. As the pulmonary vascular resistance falls during the first few weeks of life, the left-to-right shunt through the window increases. Pulmonary hypertension is a frequent complication, depending on the size of the window. The peripheral pulses are bounding, and because of the high pulmonary arterial pressures, there may be a systolic murmur at the base, rather than a continuous murmur.

Figure 50-22 These images show a circular aortopulmonary window between the ascending portions of the aorta and the pulmonary trunk. The left panel shows the external features. Note the separate nature of the arterial roots, with a tissue plane between the proximal parts of the aorta and the pulmonary trunk. The right panel shows the view of the window from the pulmonary aspect. Note the separate nature of the pulmonary valve.

Figure 50-23 The external features of this specimen show an aortopulmonary window in the setting of interruption of the aortic arch at the isthmus. The persistently patent arterial duct is feeding the descending aorta.

When the shunt is large, there is often a mid-diastolic murmur as a result of increased flow across the mitral valve. The pulmonary component of the second sound is frequently accentuated. If the window is small, there may be a continuous murmur similar to that generated by an arterial duct. If uncorrected, pulmonary vascular disease may develop within the first few years. Concomitant reversal of the shunt through the window may then cause cyanosis.

Investigations

The electrocardiogram may show left atrial hypertrophy resulting from increased flow. Frequently there is biventricular hypertrophy. The chest radiograph may show generalised cardiomegaly, with plethoric lung fields in those with large windows, but may be normal in those with small windows. The diagnosis is usually easily made with cross sectional echocardiography.^{150,158} Parasternal long- and short-axis views usually identify two arterial valves, thus excluding a common arterial trunk. A high left parasternal long-axis view will demonstrate the presence of an arterial duct, as seen in association with interruption of the aortic arch. In between these views, a high parasternal short-axis view will show the window when the transducer is tilted superiorly (Fig. 50-24). Although it is often possible to see the sharp margins of the window on echocardiography, colour Doppler is an essential complementary technique that confirms flow of blood through the window.

Cardiac catheterisation is not usually needed unless there is some doubt about the presence of pulmonary vascular disease, it is performed to delineate other additional

Figure 50-24 The high parasternal short-axis cross sectional echocardiogram shows the morphology of an aortopulmonary window (APW). AO, aorta; MPA, pulmonary trunk.

defects, or transcatheter closure is to be attempted. If the window is small, the pressures in the right side of the heart may be normal. They may be equal to systemic pressures if the window is large. In these patients, operability may need to be determined by calculation of the pulmonary vascular resistance in air and 100% oxygen. Aortography in the antero-posterior and lateral projections usually demonstrates the window. Other angiograms may be needed to confirm other additional defects, such as anomalous origin of one of the coronary arteries. Magnetic resonance imaging, however, seems a better alternative method for diagnosing additional defects.¹⁵⁵

Management

Treatment is usually surgical, and there is general agreement that surgery should be performed as early as possible, before the onset of pulmonary vascular disease. The first surgical repair was reported as long ago as 1952.¹⁵⁹ Early experience reported mortality of up to one-fifth,¹⁵² but results have now increased markedly,¹⁵⁶ and deaths after repair are now unexpected. The historical risk factors for death included high pulmonary vascular resistance. Some patients may survive to early adult life without surgery, but will almost certainly have established pulmonary vascular disease. On presentation nowadays, medical treatment is initially needed to control congestive cardiac failure. If cardiac failure cannot be controlled, there is no need to delay surgery. When the window is large, surgery should be carried out at presentation in the first few months, and preferably before 6 months of age.

Repair can usually be performed with cardiopulmonary bypass via a thoracotomy or a sternotomy.^{152,156,160,161} Technically, the windows are easy to repair by direct suture when small, or with a patch if large. Direct suture is usually achieved using a transpulmonary approach, while a patch is inserted via either the transpulmonary or a transaortic approach.^{152,156} An inverted flap of pulmonary trunk has also been used to repair the window.¹⁶² Repair

Figure 50-25 A digital subtracted aortogram in the left anterior oblique projection showing opacification of the pulmonary trunk from a small aortopulmonary window. (Courtesy of Dr Mehnaz Atique, Karachi, Pakistan.)

can also be achieved without cardiopulmonary bypass, the window being ligated with a clip.¹⁶¹ When associated with other complex defects, then primary repair of the additional defects, along with the closure of the window, is usually undertaken in the neonatal period or in early infancy.^{143,144,146,148,149,151,152,154,156,163} It is essential to evaluate the coronary arterial anatomy pre-operatively in order to avoid missing anomalous origin of either coronary artery from the pulmonary trunk. This association may have an important influence on the outcome.¹³⁷

Transcatheter techniques can now be used to close some but not all windows, experience with this method currently being limited. Closure has been performed using a double umbrella, but only for small windows.^{164,165} Other devices, such as the Amplatzer variety of devices, have been used, and are a good option for windows of small to medium size (Figs. 50-25 and 50-26).^{166,167} Before proceeding with transcatheter closure, it is necessary to make a detailed evaluation of the relationships of the arterial valves, the origins of the coronary arteries, and the positions of the right and left pulmonary arteries. Aortic root angiography is needed to delineate the size of the defect. The defect should be crossed from either the ascending aorta, or from the venous side, but the device is usually delivered from the venous side. After successful closure, anti-platelet agents are given for 6 months.

PULMONARY ARTERIO-VEINUS MALFORMATIONS

Pulmonary arterio-venous malformations are congenital malformations providing an abnormal communication between a pulmonary artery and vein that bypasses the normal pulmonary capillary bed. They may occur as an isolated anomaly or as multiple lesions. Rarely, such

Figure 50-26 A cine frame from an aortogram from the same patient shown in Figure 50-25 showing complete occlusion of the aortopulmonary window with an Amplatzer duct occluder. (Courtesy of Dr Mehnaz Atique, Karachi, Pakistan.)

abnormalities can be acquired, but are then described not as pulmonary arterio-venous malformations, but as arterio-venous fistulas. Interest in the pulmonary arterio-venous malformations has increased since the mid 1980s with the realisation that they cause more clinical problems, and a greater morbidity, than had been previously recognized. The emergence of transcatheter embolisation as an effective and safe alternative therapy to surgery has also contributed to the increased interest.¹⁶⁸⁻¹⁷¹

Incidence

Pulmonary arterio-venous malformations are rare.^{172,173} In a survey at the Hospital for Sick Children in Toronto, only 6 cases were found in more than 15,000 cases of congenital cardiac disease.¹⁷⁴ This may well be an underestimate, as small lesions may easily be missed at postmortem, as well as on routine investigations. It is now realised that relatives of patients with known pulmonary arterio-venous malformations, even in the absence of hereditary haemorrhagic telangiectasia, can have incidental and asymptomatic pulmonary arterio-venous malformations.

The malformations may occur as isolated vascular anomalies, or in association with hereditary haemorrhagic telangiectasia, the latter association being more common in some reported series,^{171,175} but sporadic cases forming the majority in other series.¹⁷² Now that the relatives of patients with such malformations are being actively screened, it appears that they, too, are commonly afflicted with hereditary haemorrhagic telangiectasia.^{171,176} The association with hereditary haemorrhagic telangiectasia is more common in the setting of multiple malformations.^{172,177} An incidence of up to one-third has been described in those with hereditary haemorrhagic telangiectasia, and there is also an increased incidence in the apparently unaffected relatives of these patients.

Figure 50-27 Pulmonary arterio-venous malformations can be considered simple (A) or complex (B). A, In the most common form, a large single feeding pulmonary artery (PA) is seen with a single pulmonary vein (PV) draining the non-septated malformation. B, In the less common complex type, multiple arteries and veins supply and drain from the septated malformation.

It follows, therefore, that the malformations can be solitary, multiple of varying size, multiple of uniform size, or diffuse.¹⁷⁸ Classification on the basis of structure¹⁷⁹ is simpler, and more appropriate for assessment and evaluation prior to embolisation. Based on angioarchitectural criteria, four-fifths consist of a single pulmonary artery communicating directly with a vein via the malformation, which is usually aneurysmal and non-septated (Fig. 50-27A). This so-called simple type (Figs. 50-28 and 50-29) can usually be cured by embolisation of this single feeding artery. The remaining one-fifth of the lesions are complex (Figs. 50-27B, 50-30 and 50-31), consisting of two or more connecting pulmonary arterial branches feeding aneurysmal and septated malformations, often cirroid, with two or more draining veins. The malformations more rarely are diffuse, with most of the lungs containing multiple small arterio-venous communications (Figs. 50-32 and 50-33). In the setting of diffuse hepatic disease, such as cirrhosis, right-to-left shunting has sometimes been associated with multiple very small arterio-venous fistulas.¹⁸⁰ It is now well established that similar multiple fistulas can develop after construction of cavopulmonary connections that exclude hepatic flow from the lungs.¹⁸¹

Most commonly, the malformations are found in the lower lobes or the right middle lobe, being more common in the right lung.^{182,183} They do not generally show much of a tendency to increase in size, albeit that long-term follow-up is not available. Studies using CT scans, however, together with serial measurements of arterial blood gases, have shown that there is little change in the degree of right-to-left shunting, or in the size of the malformations, over a period

Figure 50-28 A selective injection into the left pulmonary artery shows a pulmonary arterio-venous malformation supplied by a single large feeding artery. The draining vein has not yet opacified (the same patient is shown in Figures 50-29 and 50-35).

Figure 50-29 The angiographic anatomy of the simple type of pulmonary arterio-venous malformation is best shown on this film with the injection directly into the feeding artery. Despite a collection of coils immediately proximal to the malformation, and further coils within it, the malformation has not been occluded. Note the artery (*black arrow*) supplying normal lung immediately proximal to the coils and the single large vein draining to the left atrium (same patient as in Figures 50-28 and 50-35).

Figure 50-30 Selective injection into the right pulmonary artery shows a complex type of pulmonary arterio-venous malformation with multiple feeding arteries.

of 3 to 4 years.^{176,184} Anecdotal experience has shown a gradual increase in size, but at different rates in the two lungs,¹⁸⁵ while several reports have described increases in size during pregnancy, or else the occurrence of significant complications.¹⁸⁶⁻¹⁸⁸ Because of this, it is suggested that young female relatives of affected patients, or members of families with hereditary haemorrhagic telangiectasia, should be screened to exclude asymptomatic malformations, and that this should be carried out before puberty.¹⁸⁸

Figure 50-31 A more selective injection into the malformation shown in Figure 50-30 reveals the presence of several feeding arteries.

Figure 50-32 A 35-year-old patient with hereditary telangiectasia also had very extensive pulmonary arterio-venous malformations, revealed by an injection into the left descending pulmonary artery.

Figure 50-33 A super-selective injection into a branch of the pulmonary artery shows that there are relatively normal appearing arteries arising side by side with abnormal arteries to small pulmonary arterio-venous malformations. This would make selective embolisation very difficult, as normal branches would also be occluded.

Clinical Presentation

Patients with the malformations present very rarely as neonates and infants, but in this setting cyanosis, respiratory distress, and severe cardiac failure can be found.^{189,190} Echocardiography is then needed to rule out congenital cardiac disease. More commonly, presentation is in later childhood, although it is quite common for the malformations to go undetected until mid-adult life. Sometimes the diagnosis is made as an incidental finding on a routine chest X-ray or CT scan (Fig. 50-34). Patients may present with symptoms of dyspnoea and fatigue, which may have been present for some years, even from childhood. Often there is a history of cyanosis on exercise, sometimes with surprisingly good exercise tolerance. A quite common presentation is for a patient to first present with neurological problems.^{171,191} This is now recognized to be a major cause of morbidity. It is the single most important reason why such malformations should be actively sought and treated in patients with hereditary haemorrhagic telangiectasia.¹⁷⁶ Some form of cerebrovascular accident, such as a stroke or transient ischaemic attack, may be the initial presenting feature. It has been suggested that up to half of patients are at risk either from some form of paradoxical embolism leading to transient ischaemic attacks or strokes, or from an intracerebral abscess.^{176,192} Such an ischaemic episode may be caused by thrombosis associated with polycythaemia or may be caused by a paradoxical embolism related to venous thrombosis and right-to-left shunting. The presence on CT scans of evidence of strokes is not necessarily associated with any symptoms. Haemoptysis rarely occurs from rupture of a malformation, or alternatively may be caused by bleeding from telangiectasia involving the airways.¹⁹³ Haemothorax is another rare form of presentation. Bleeding from hereditary haemorrhagic telangiectasia involving

Figure 50-34 Chest radiograph of a 45-year-old man shows a smooth oval density on the left upper zone. It was barely possible to see a tubular structure connecting this with the hilum, suggesting the diagnosis of a pulmonary arterio-venous malformation.

the nose and lips may result in an iron deficiency anaemia, and such lesions can affect other parts of the body, including the gut and abdominal organs.

The clinical examination may reveal central cyanosis and clubbing. In the presence of anaemia, the cyanosis may not be obvious. Evidence of hereditary haemorrhagic telangiectasia may be seen involving the nails, skin, and mucous membranes of the mouth, but such changes are rare in children. Examination of the heart and chest will be normal, except that a murmur may be heard associated with a large superficially placed pulmonary arterio-venous malformation. The murmur is usually systolic or continuous.

Screening

Hereditary haemorrhagic telangiectasia is a disorder of vascular development characterised by vascular malformations occurring in the gastrointestinal tract, respiratory system, and the cerebral, hepatic and pulmonary circulations. More than seven-tenths of pulmonary arterio-venous malformations are associated with this condition, and pulmonary arterio-venous malformations occur in one-third of patients with hereditary haemorrhagic telangiectasia. It is important, therefore, that patients with hereditary haemorrhagic telangiectasia are screened for pulmonary arterio-venous malformations.¹⁹⁴ As clinically significant malformations may occur in the absence of dyspnoea, and with normal resting arterial saturations of oxygen, it is important that these patients undergo some form of screening. The accuracy of non-invasive screening tests have been compared against the gold standards of CT angiography or pulmonary angiography.¹⁹⁴ The best test proves to be contrast echocardiography. This reflects the presence of very small microscopic pulmonary arterio-venous malformations that are not detected by CT angiography. A combination of a chest X-ray and contrast echocardiography now permits exclusion of the diagnosis of pulmonary arterio-venous malformations with total confidence.

Should these tests be positive, then CT of the chest should be performed

Investigations

The electrocardiogram is usually normal except in infancy. The echocardiogram, which may also be normal, is important to exclude any intracardiac disease. In many instances, a chest X-ray will either diagnose or strongly suggest the diagnosis. The heart is usually of normal size, and the malformations may be seen in the lungs. Typically they are round, well-defined, homogeneous opacities, often situated peripherally (see Fig. 50-34). Though not always obvious, especially when at the bases of the lungs and behind the heart, abnormal vessels connecting the malformation to the hilum can usually be discerned. Sometimes the chest radiograph is normal when small pulmonary arterio-venous malformations are not visible or, rarely, in the presence of diffuse and very small lesions.^{195,196} CT is currently the best modality for demonstrating the malformations.^{184,197} If the diagnosis is in doubt, then CT with intravenous contrast will confirm the diagnosis. High-resolution scans through the lungs, and the availability of fast spiral scanners, will now mean that more, and even very small, lesions will be demonstrated.¹⁸⁴ If obvious lesions are seen on the chest radiograph, and the clinical diagnosis is not in doubt, there would seem little point in doing any further tomography, as detailed angiography is necessary to plan for any embolisation of the larger lesions. When a malformation is diagnosed, or strongly suspected, the measurement of arterial blood gases is useful to confirm the presence of hypoxaemia, and to quantify any right-to-left shunting.^{168,171,176} The arterial saturations of oxygen should be measured with the patient breathing room air in the erect or sitting position and, after 20 minutes, while breathing 100% oxygen.¹⁹⁸ Orthodeoxia is the term to describe a significant drop in arterial saturations of oxygen in the standing or sitting positions. This is related to the predominantly basal location of pulmonary arterio-venous malformations, and the gravitational shifts of flow that result, as well as the increase in lung volume. Quantitative assessment of the degree of right-to-left shunting can be made from nuclear medicine studies.^{199,200} This technique can be used to assess the effectiveness of embolisation, particularly when there are multiple malformations. A further technique to detect right-to-left shunting is to use echocardiography to look for evidence of microcavitation in the left atrium after a peripheral injection of saline.²⁰¹

Pulmonary Angiography

It makes sense to perform angiography and embolisation on the same occasion, especially if there are multiple lesions that may need several attempts at embolisation. Detailed pulmonary angiography is necessary to demonstrate clearly the angioarchitecture of the malformations. Initially, selective right or left pulmonary angiograms are performed (see Figs. 50-28 and 50-30). Selective catheterisation is then needed to demonstrate the feeding artery and its relationship to the adjacent normal pulmonary arterial branches (see Figs. 50-29 and 50-33). Locating the feeding artery may be difficult, especially in the lower zones where many vessels are closely related. Specialised catheter

techniques, together with digital angiography, are essential requirements. Injections in varying degrees of obliquity may be needed to show the arterial anatomy.

Treatment

Until 1978, the only treatment available was surgery. The various operations performed included pneumonectomy, transection of the pulmonary trunk, lobectomy, segmentectomy, ligation of feeding vessels, intra-aneurysmal obliteration of the malformations, and wedge resection.^{193,202-205} The aim was to be as conservative as possible, for at least two reasons. First, any lung tissue removed is likely to have normal function. Second, the greater the amount of the normal pulmonary circulation that is obliterated, the greater the flow to the rest of the lungs. It is possible that such high flows then cause enlargement of other malformations.²⁰⁶ Complications of surgery were unusual, even in children.^{169,204,205} As the techniques and devices for embolisation have evolved, however, there is now no real role for surgery.

Transcatheter occlusion, or embolisation, of a pulmonary arterio-venous malformation was first described in 1977.²⁰⁷ Many series have now confirmed the initial encouraging response.^{169-171,175,197} There is no place now for diagnostic arteriography alone, as the diagnosis, as well as the number and size of the malformations, will have been usually made on CT scans. Thus, arteriography is performed as a prelude to embolisation. Whenever embolisation is planned, it is essential to obtain informed consent and to detail possible risks. If multiple pulmonary arterio-venous malformation are present, it is advisable to also explain that more than one procedure may be necessary. The aim is to occlude either the feeding artery or the malformation itself (Figs. 50-35 and 50-36). It is vital that techniques are used that prevent any possibility of the material used for embolisation passing through the malformation and ending up in the systemic circulation. Embolisation should not be attempted unless the operator is experienced with embolisation elsewhere in the body. Embolisation of the pulmonary arteries is unique in that, unlike systemic arterial embolisation, where the lungs act as very effective filters for any material that crosses to the venous circulation, the consequences can be catastrophic with a pulmonary arterio-venous malformation. Even with all the necessary precautions, there has to be a very small risk of some systemic embolism, and the patient should be warned of this. If polycythaemia of significant degree is present, then venesection should be performed prior to embolisation. It is also advisable to give a bolus of heparin, approximately 5000 units, at the start of the procedure.

All symptomatic pulmonary arterio-venous malformations, and those associated with hypoxia in the sitting or standing position, should be treated. The risk of paradoxical embolism in small pulmonary arterio-venous malformations in the absence of these problems is very difficult to predict. It has been suggested that, if the feeding artery is greater than 3 mm in diameter on CT, that embolotherapy should be advocated, but this will be influenced by the age of the patient. Embolisation was first described in 1977 using stainless steel coils. In the early experience, detachable balloons and metallic coils were used, but developments with coils and other devices have now rendered balloons obsolete.¹⁷⁰

Figure 50-35 A pulmonary arterio-venous malformation is supplied by a single large feeding artery (see earlier catheterisation in the same patient shown in Figure 50-28). At this second embolisation procedure, further coils have been positioned more proximally in the feeding artery. This has occluded the pulmonary arterio-venous malformation, but at the cost of occluding also a small branch supplying normal lung.

Figure 50-36 Multiple pulmonary arterio-venous malformations in the right lower lobe. These malformations were separately embolised with coils. The film taken after the procedure confirms occlusion of the malformations.

In simple malformation with a single feeding artery, the aim should be to occlude the artery just before it enters the aneurysmal part of the malformation (see Fig. 50-29). More proximal occlusion will be more likely to occlude branches supplying normal lung parenchyma, and result in some pulmonary infarction.¹⁸⁴ It is important to assess the diameter of the artery, as this must not be bigger than the diameter of the coil or occluding device used to occlude it. Too small a coil or device could pass through the malformation and into the single draining vein, which is usually larger than the artery. Whatever technique is used, it is important that the tip of the catheter is precisely placed and that, prior to detaching a balloon or pushing out a coil, this position and its relationship to the feeding artery is confirmed, and also that it is stable. Coils have been most commonly used for occlusion. Until recently, the range of coils was limited, but now platinum microcoils with complex helical shapes and of large diameter are available. There is now a large range of coils available that are detachable or controlled release. This allows the coils to be fully deployed and then retrieved if their position is not optimal. The coil can be repositioned, and only then released or detached when its position is considered satisfactory. Large arteries may need multiple coils to effect occlusion. If occlusion is going to occur, it will usually occur within 15 to 20 minutes of insertion. A large vessel may need several coils of larger diameter to form an anchor point on which several smaller coils can then be trapped to form a nest (see Fig. 50-35). If coils are placed without achieving a critical mass, an artery permitting high flow may not be occluded. A recent development has been to coat coils with a hydrogel polymer. This coating expands five times in about 20 minutes after deployment, thus achieving greater stability, and producing more total mass with fewer coils. Very large diameter coils, up to 2 cm, are now also available. The technique can be varied to place coils directly into the aneurysmal part of the malformation (see Fig. 50-35) rather than in the feeding artery.²⁰⁸ If the malformation itself is occluded, there is then no risk of revascularisation from opening of unseen small branches. Moreover, no branches to normal lung parenchyma would then be occluded. A theoretical disadvantage of the use of coils is that, when a coil partially occludes the feeding artery, thrombus may form that could embolise into the systemic circulation. There is little evidence to suggest that this occurs. A further significant advance has been the development of vascular plugs, such as the Amplatzer Vascular Plug. Such plugs are attached to a nitinol wire. Like the detachable coils, they are retrievable, and are only detached when their position is optimal. A minor disadvantage is that they need to be passed through a slightly larger catheter. A second generation device has now been developed.²⁰⁹ The feeding artery to a pulmonary arterio-venous malformation will also supply some normal lung parenchyma. Even with very careful and precise embolisation, there is the likelihood of a small amount of normal lung being infarcted (see Figs. 50-33 and 50-35). The more proximal the occlusion, the greater the amount of infarction that will occur.

Pulmonary arterio-venous malformations are not common, and there are few detailed results.²¹⁰ In early experiences,¹⁷⁵ failure to restore the arterial oxygen saturations to normal values resulted from persistence of residual malformations too small to be considered for occlusion. Patients with multiple malformations will sometimes have

a small lesion that is jointly supplied with a segment of normal lung parenchyma. Occluding the malformation would mean losing that segment of normal lung. In the simple type of malformation, be they single or multiple, embolisation is an effective technique that is safe and usually curative. Embolisation is now the treatment of choice, and surgery should be reserved for those very rare occasions when embolisation is felt to be not technically possible, or when embolisation has failed. Unlike arterio-venous malformations elsewhere in the body, these lesions do not recanalise. In the more complex and diffuse pulmonary arterio-venous malformations, it is much more difficult to eradicate completely all the lesions. By embolising the larger ones, nonetheless, significant clinical improvement can be achieved (see Fig. 50-32). It is always possible to repeat embolisations with no increased risk. Careful monitoring of the effects of embolisation by measuring blood gases and, possibly, by nuclear medicine studies is essential.

Cardiac Tumours

ELISABETH BÉDARD, ANTON E. BECKER, and MICHAEL A. GATZOULIS

Cardiac tumours in infants and children are rare. Their atypical clinical presentation prevented timely diagnosis in the past, when cardiac tumours were often a postmortem finding. The widespread use of echocardiography, and other non-invasive diagnostic methods, in recent years has resulted in a marked increase in the detection of cardiac tumours during childhood, when the patients are often asymptomatic, and also in fetal life.^{1,2} In turn, early recognition of cardiac tumours has resulted in better understanding of their natural history and, combined with advances in surgical techniques, an improved overall outcome.^{1,3}

It is difficult to ascertain the true incidence of cardiac tumours because of the tendency to base estimates on postmortem studies, case reports, and experiences of single institutions. The lack of non-invasive diagnostic imaging in earlier reports was another limiting factor. In the general population, and based on the data of 22 large autopsy series, the incidence of cardiac tumours was reported at around 0.02%.⁴ The reported incidence in infants and children varied from 0.027% as assessed from autopsy records,⁵ to 0.49% in the clinical series analysed in the New England Regional Infant Cardiac Program.⁶ Another analysis² showed that the incidence of cardiac tumours in children had seemingly increased from 0.06% over the period 1980 to 1984, to 0.32% for the period 1990 to 1995. Review of data from the Armed Forces Institute of Pathology, combined with personal experience from the Cardiovascular Pathology Registry in the Academic Medical Center, Amsterdam, shows that, among a total of 386 primary tumours of the heart collected between 1976 and 1993, only 55 occurred in infants and children below the age of 16 years (Table 51-1).⁷ Of these, one-fifth were considered malignant. Table 51-2 shows a detailed breakdown of the types of tumours reported in stillbirths, fetuses, and neonates.¹

CLINICAL SIGNS AND SYMPTOMS

Although cardiac tumours are usually benign in children, they may induce even life-threatening symptoms. Their clinical manifestations are often non-specific. They may mimic many other diseases of the heart and lungs. Classically, the clinical presentation is divided according to whether it is the consequence of systemic, embolic, or cardiac effects (Table 51-3).

Systemic Manifestations

The systemic manifestations of tumours of the heart are manifold, and include findings such as fever, general malaise, loss of weight, and fatigue. Digital clubbing,

Raynaud's phenomenon, myalgia, and arthralgia are usually associated with myxomas. All these features can mimic infective endocarditis, collagen vascular disease, rheumatic heart disease, or malignancy.⁸ The constitutional symptoms disappear when the tumour is removed.⁸ During the last 15 years, much evidence has accrued to suggest that inflammatory and autoimmune manifestations, seen in the presence of myxomas, may be the result of the production and release of the cytokine interleukin-6 by the tumour.⁸⁻¹¹

Embolic Manifestations

Embolic signs are not an uncommon manifestation of cardiac tumours, being reported in three-tenths of patients with left atrial myxomas.¹² Embolism is also well described in children,¹³ but is infrequent during fetal life or the neonatal period.¹ There can be embolisation of either fragments of the tumour itself (Fig. 51-1), or thrombus aggregated at the surface of the tumour (Fig. 51-2). The distribution of such emboli depends largely on the localisation of the primary tumour itself, along with the presence or absence of additional cardiac malformations, such as additional shunts or abnormal patterns of flow. Embolisation of tumour fragments occurs only when the tumour itself has an intracavitary extension. Thromboembolic formation, however, can occur also with primary intramural tumours that compromise the endocardium of the cardiac chamber, either by mechanical compression or

by inducing a functional disturbance. Generally speaking, left-sided tumours embolise to the systemic circulation. Hence, they may affect almost any organ, even the heart itself.¹⁴ Sudden occlusion of a peripheral artery should always alert to the possibility of embolisation from a primary intracardiac tumour, and should alert to the possibility of cerebral embolism.¹³ Moreover, multiple systemic embolisation may mimic systemic vasculitis or infective endocarditis, particularly when producing systemic manifestations.

Primary tumours in the right heart chambers may cause pulmonary embolism.¹⁵ This may be indistinguishable from pulmonary embolism secondary to venous thromboembolism. Perfusion defects in the lung due to embolisation from a tumour do not usually resolve within a few weeks, as they do with venous embolisation. Embolisation from a tumour may also be suggested by complete absence of flow to one lung in the presence of a normal perfusion scan on the opposite lung. This is most unusual in patients with recurrent pulmonary venous thromboembolism.

Cardiac Manifestations

The cardiac events are largely dependent on the location and the extent of the tumour within the heart. Tumours that are localised within the myocardium may occasionally pass unnoticed clinically. They may be discovered as incidental findings at echocardiography or postmortem. Detection of a cardiac mass on routine obstetric sonographic scan is often the initial finding in fetuses.¹

Arrhythmias

Disturbances of cardiac rhythm can be the first manifestation of a primary cardiac tumour.¹⁶ Should the tumour be located in the region of the atrioventricular node or conduction axis, even small tumours may produce disturbances of atrioventricular conduction. Complete atrioventricular block and sudden death are seen as the extreme clinical manifestation, especially for rhabdomyomas.¹ Moreover, the intramural location of primary tumours may underlie a wide variety of disturbances of rhythm, including atrial fibrillation or flutter, paroxysmal atrial tachycardia, atrioventricular junctional rhythm, Wolff-Parkinson-White

TABLE 51-3

CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Symptoms/Signs	Remarks
1. Systemic	
Fever	May mimic endocarditis or malignant disease
General malaise	
Weight loss	
Fatigue	
Digital clubbing	May mimic collagen, rheumatic or malignant disease
Raynaud's phenomenon	
Myalgia and arthralgia	
2. Embolic	
Systemic embolism	May affect almost any organ Caused by embolisation of left-sided tumour fragments or thrombi aggregated at its surface
Pulmonary embolism	Caused by embolisation of right-sided tumours
3. Cardiac	
Arrhythmias	Almost any arrhythmias can occur Complete atrioventricular block and sudden death are seen as the extreme
Cardiac failure	May mimic dilated, restrictive, or hypertrophic obstructive cardiomyopathy May present with cardiomegaly, respiratory distress, hydrops, pulmonary oedema, cyanosis
Pericardial effusion and tamponade	Seen mainly in teratoma, malignant tumours, and secondary lesions
Obstruction	May cause outflow tract or atrioventricular valve obstruction and mimic valvar disease May present with new murmur, syncope, sudden death, or acute pulmonary oedema Symptoms and murmur may relate to the patient's position
Tumour plop	Is almost the only specific sign (with the postural variation of a murmur) Results from sudden tension on the stalk of the tumour as it prolapses during diastole into the left ventricular cavity with the possible impact of the mass on the ventricular wall

syndrome, atrial and ventricular premature beats, ventricular tachycardia, and ventricular fibrillation.^{16–19}

Cardiac Failure and Pericardial Effusion

Infiltrative tumours of the myocardium can cause haemodynamic compromise. This tends to occur late in the clinical course when there is substantial involvement of the myocardium or pericardium (Fig. 51-3), producing symptoms of cardiac failure consequent to systolic and/or diastolic dysfunction.¹ In some instances, the clinical presentation may mimic that of dilated, restrictive, or hypertrophic obstructive cardiomyopathy.^{20,21} Pericardial exudates, eventually with cardiac tamponade, may be the first symptom of the epicardial location of a tumour.^{22,23} This is mainly seen with teratomas, malignant tumours, and secondary lesions.

Obstruction

Primary cardiac tumours with intracavitary extension may cause obstruction, or may interfere with valvar closure (Fig. 51-4).^{1,3} The signs and symptoms are then highly

Figure 51-1 The illustration shows a left ventricular myxoma in an adult. It is easy to see how parts of the tumour can fragment and embolise to the systemic circulation.

Figure 51-2 The slide shows a section across an intramural coronary artery that is completely occluded by a thrombus detached from the surface of an intracardiac myxoma.

dependent upon the chamber involved, and the size of the tumour. The embolic effects, which are a frequent complication, similarly relate directly to the site of the tumour. Left atrial tumours may produce mitral stenosis (see Fig. 51-4) or insufficiency, and may mimic valvar disease, with new murmurs as a frequent presenting sign in infants and children.^{1,24} Intracavitary left ventricular tumours may also

Figure 51-3 The heart is shown from the left side. A huge rhabdomyoma has grown in the antero-superior wall of the left ventricle, compromising the ventricular cavity, and producing cardiac failure.

Figure 51-4 The opened left atrioventricular junction in this adult heart is completely blocked by a left atrial myxoma. Note the different colouration of the components of the tumour located in the left atrium and ventricle.

cause inflow or outflow obstruction, or atrioventricular valvar insufficiency, along with the anticipated accompanying signs and symptoms. All these obstructive manifestations may have a sudden onset, particularly in the case of a pedunculated highly mobile left atrial tumour, which can cause syncope, sudden unexpected death, or acute pulmonary oedema.^{1,3} Such findings are often intermittent, and may relate to the posture of the patient.

Location of Tumour within the Heart

Intracavitary tumours within the right atrium frequently produce symptoms of right-sided cardiac failure.²⁵ The manifestations may result from either obstruction of the tricuspid orifice or tricuspid valvar insufficiency, the latter

secondary to interference with valvar closure. Caval venous obstruction may be seen as a leading feature.²⁶ Right ventricular intracavitary tumours may similarly produce signs and symptoms of tricuspid valvar obstruction, but can also produce outflow obstruction or atrioventricular valvar insufficiency.^{24,27–30} Right-sided failure is often the leading manifestation. As with all cardiac tumours, the physical signs may vary considerably, depending upon their site and size. As stated before, the picture may be further complicated by pulmonary embolism and secondary pulmonary hypertension. Tumours in the right ventricle, therefore, may mimic congenital pulmonary stenosis, restrictive cardiomyopathy, or even cyanotic cardiac disease, especially in the neonate.¹ Atypical chest pain may occur. This is caused by coronary arterial obstruction, either from compression by the tumour itself, or because of coronary arterial embolism (see Fig. 51-2).¹⁴ Hence, intracavitary left ventricular tumours may mimic other conditions, such as aortic and subaortic stenosis, asymmetric septal hypertrophy, and endocardial fibroelastosis.^{31–35}

PHYSICAL EXAMINATION

Physical examination is, in general, non-conclusive. Murmurs, when present, are in themselves non-specific, but certain atypical findings may suggest a cardiac tumour rather than primary valvar or myocardial disease. Such findings include postural variation in the intensity of the murmur, and the presence of a so-called tumour plop. The plop has been described particularly in patients with left atrial myxoma, being characteristic of a pedunculated and highly sessile tumour. The plop was heard in one-sixth of the patients in one large series.¹² It most likely results from sudden tension on the stalk of the tumour as it prolapses during diastole into the left ventricular cavity, along with the possible impact of the mass on the ventricular wall.³⁶

INVESTIGATIONS

Laboratory Studies

These are non-specific (Table 51-4). Abnormal findings include an elevated erythrocytic sedimentation rate, and increased levels of C-reactive protein in the serum, along with hypergammaglobulinaemia, thrombocytosis or thrombocytopenia, polycythaemia, leucocytosis, and anaemia.

Electrocardiography

The electrocardiogram is also non-specific. All kinds of disturbances of rhythm and conduction, and abnormalities of voltage and the ST-T segments, may be seen.^{1,16} The electrocardiogram may also display the typical pattern of atrial dilation or ventricular hypertrophy.^{1,12} Incidental low-voltage complexes may be registered, indicating possible pericardial involvement. Occasionally, it is possible to find the pattern of ventricular pre-excitation.¹ This is particularly the case when the accessory muscular atrioventricular pathways are composed of the intracardiac tumour.^{37,38}

Chest Radiography

Cardiac tumours may alter the contours of the heart, but the changes in themselves are most often non-specific. The cardiac contour may be normal, or may display enlargement of

TABLE 51-4

MERITS OF POTENTIAL INVESTIGATIONS IN PATIENTS WITH CARDIAC TUMOURS

Investigation	Remarks
Blood	Non-specific May include elevated erythrocytic sedimentation rate and serum C-reactive protein, hypergammaglobulinaemia, thrombocytosis or thrombocytopenia, polycythaemia, leucocytosis, and anaemia
Electrocardiogram	Non-specific All kinds of rhythm and conduction disturbances or voltage and ST-T wave segmental abnormalities may be seen
Chest radiograph	Non-specific May show abnormal contours of the heart Signs of pulmonary venous obstruction may occur with obstructive left-sided tumours Possible to show calcification of the tumour
Echocardiogram	Main diagnostic modality Allows accurate determination of the size, shape, texture, location, attachment, mobility, and haemodynamic consequences of the tumour
Magnetic resonance imaging	Allows a better soft tissue contrast, and offers a larger field of view, demonstrating the extension to the adjacent structures Requires sedation in children to suppress deep respiration and movements

either the entire heart or any particular chamber.^{39–41} Gross and bizarre distortions of the cardiac contour occasionally occur that are then suggestive of a tumour. The overall picture may be further complicated by the presence of pericardial fluid. Radiographic signs of pulmonary venous obstruction with left atrial enlargement may be observed in patients with obstructive left-sided tumours. Calcification of a primary tumour may occasionally be so intense that it can be noted on the chest radiograph (Fig. 51-5).^{39,40}

Echocardiography

Echocardiographic examination is now universally established as the main, and usually the only, diagnostic modality required for children. It allows accurate determination of the size, shape, texture, location, attachment, mobility, and haemodynamic consequences of the tumour. For most patients, it obviates the need for cardiac catheterisation and angiography.^{2,3,42,43} Use of the technique, in some hands,⁴⁴ has resulted in dramatic increase in the annual incidence of cardiac neoplasms over a period of 5 years, combined with an equally dramatic reduction in unexpected intra-operative findings. Echocardiography is also the method of choice for follow-up, as spontaneous regression of tumours diagnosed during infancy is frequent.⁴⁵ The diagnostic sensitivity of transthoracic and transoesophageal approaches has been reported to be 93.3% and 96.8%, respectively.⁴⁶ The sensitivity is greatest for endocardial lesions, where the contrast between tumour and an echolucent cavity is most apparent, permitting characterisation of the size and mobility of the masses. In contrast, echocardiographic assessment of the pericardial tumours

Figure 51-5 This right atrial myxoma from an adult heart is extensively calcified, as shown in the inset, which is a postmortem radiograph. Calcification of this extent can also be seen on chest radiographs during life.

may be limited because of the echo density and their frequent position in the echocardiographic farfield. While involvement of the pericardium, and the extracardiac mediastinum, by the tumour may be revealed by scanning from multiple positions, this being mandatory when assessing any pericardial effusion of unknown aetiology, magnetic resonance imaging is a more capable and reliable technique for this task. Texture may be inferred by the gray-scale appearance, although interpretation remains subjective.⁴⁷ Colour processing of the cross sectional gray-scale image has also been applied to distinguish tumour mass from endocardium.^{48,49} In recent years, contrast

echocardiography has been shown to provide better visualisation of the interface between myocardium and blood.⁵⁰ Contrast perfusion imaging of cardiac masses with gray-scale power modulation also facilitates the differential diagnosis.⁵¹ Echocardiography also gives information as to whether the tumour is encapsulated, and whether it is solid or cystic.⁵² Cardiac tumours have the tendency to occur at multiple sites. Hence, echocardiographic evaluation should be thorough, encompassing the whole heart and pericardium.³

Transoesophageal echocardiography can be a useful adjunct to transthoracic imaging, notably in patients with suboptimal transthoracic windows. It is ideally suited for the examination of suspected tumours involving the atriums, interatrial septum, caval veins, atrioventricular valves, and, to a lesser extent, the great arteries.⁵³ Another important application is the differentiation of true pathology from normal, or variants of normal, anatomy. For example, a prominent terminal crest may simulate a mass during transthoracic imaging of the morphologically right atrium. Transoesophageal echocardiography can demonstrate this to be a normal structure. In addition, transoesophageal imaging can be used intra-operatively to assist with surgical excision of cardiac tumours, or to guide transvenous biopsy.^{3,54} Dynamic three-dimensional echocardiography allows a view of the contents of an intracardiac tumour.⁵⁵ It is a valuable way of defining the morphological and spatial characteristics of cardiac and paracardiac tumours, establishing their relationships with adjacent structures, and might be superior to transthoracic echocardiography in the evaluation of the size of intracardiac masses (Fig. 51-6).^{42,55-58} When used preoperatively, it may yield important additional information and improve the operative planning.⁵⁹ Prenatal echocardiographic screening (Fig. 51-7), performed usually for the assessment of intra-uterine growth, or occasionally as part of investigations for fetal arrhythmias or non-immune hydrops and high-risk pregnancies, has permitted fetal tumours to be diagnosed as early as 19 weeks of gestation,^{1,60-62} with two-thirds of the tumours being rhabdomyomas.¹ Prior knowledge of the existence of the tumour in some circumstance has permitted life-saving interventions, such as intra-uterine pericardiocentesis, or even intra-uterine surgery. Prenatal diagnosis

Figure 51-6 Dynamic three-dimensional echocardiography showing a myxoma in a 12-year-old boy, originating in the left atrium and attached to the atrial septum in the region of the oval fossa. The tumour is protruding into the atrioventricular orifice during ventricular diastole. (Courtesy of Dr Jan Marek, Great Ormond Street Hospital, London, United Kingdom.)

Figure 51-7 This massive right-sided heart tumour (arrow) was diagnosed during fetal echocardiography at 21 weeks of gestation. The neoplasm, which is primarily extracardiac, may have an intracardiac extension, and appears to have limited the effective right ventricular cavity, causing some obstruction of the right ventricular outflow tract. A teratoma was suspected, and confirmed at pathology. (Courtesy of Dr Julene Carvalho, Royal Brompton Hospital, London, United Kingdom.)

certainly permits optimisation of postnatal care.^{61–64} Spontaneous regression of even symptomatic tumours has also been described when diagnosed during fetal life.¹

Magnetic Resonance Imaging and Computed Tomography

Since the mid-1980s, magnetic resonance imaging has been increasingly used for the detection and diagnosis of cardiac neoplasms, with various studies comparing its value to transthoracic echocardiography.^{40,65–67} Resonance imaging shows better the contrast with soft tissue, and offers a larger field of view, showing the extent of the tumour relative to the adjacent mediastinum, lungs, or vascular structure (Figs. 51-8 and 51-9).^{65–70} The inherent natural contrast between the intracardiac and vascular spaces and the surrounding walls of cardiovascular structures enables sharp delineation of the myocardium, with negligible interference by bony or lung tissue.⁷¹ Resonance imaging is unquestionably the superior investigative approach in pericardial lesions, and provides information on the haemodynamic consequences of the tumour. Contrast-enhanced imaging with paramagnetic agents and radio-frequency labelling permits further differentiation of tumour from viable myocardium.⁷² With the recent improvement in pulse sequences for cardiac imaging, the motion artefact has been reduced, giving an even better quality to the images.⁶⁸ Spin-echo and cine-gradient-echo techniques provide additional valuable information concerning mobility, site of attachment,

Figure 51-8 Cardiac magnetic resonance imaging showing an angiosarcoma in the free wall of the right atrium in a 45-year-old female. A, A spin-echo image in a four-chamber view and the corresponding inversion recovery gradient-echo image acquired 1 min (B) and 15 min (C) after intravenous injection of gadolinium DTPA. The spin-echo image depicts the anatomical details of the right atrial mass and its relation to surrounding structures. Early and late enhancement (B and C) indicate increased vascularity, and necrosis and scarring, respectively. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Courtesy of Dr Raad Mohiaddin, Royal Brompton and Harefield NHS Trust, London, United Kingdom.)

Figure 51-9 Cardiac magnetic resonance imaging of an atrial myxoma. Diastolic frame from dynamic cine studies acquired in the left ventricular horizontal long axis (A) and in the short axis of the left atrium (B). A solid mass attached to the interatrial septum is clearly seen (arrow). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Courtesy of Dr Raad Mohiaddin, Royal Brompton and Harefield NHS Trust, London, United Kingdom.)

and effects on myocardial and valvar function.⁷³ The use of resonance imaging in children, nonetheless, is not free of limitations. Heavy sedation is often required to suppress deep respiration and other movements. In those with arrhythmias, interference can still cause significant motion artefact despite electrocardiographic gating, thus compromising the quality of imaging.⁶⁸ Furthermore, in contrast to echocardiography, the machine is not portable, and is not suitable for patients requiring intensive care. The technique is also incapable of demonstrating the presence of calcium.⁶⁸ Computed tomography, in contrast, is able to detect calcification, of value in the differential diagnosis of cardiac tumours.⁶⁷ Computed tomographic scanning is also faster and easier to perform than magnetic resonance imaging.⁶⁷ Recently, multi-slice computerised tomography has emerged, permitting detailed delineation of intra- and pericardial masses.⁷⁴

Catheterisation and Angiocardiography

Once accepted as the gold standard for diagnosis, angiocardiography has waned in importance as a result of the availability and reliability of the non-invasive methods of imaging discussed above. One of the last indications remaining is to eliminate the presence of coronary arterial diseases in adults with cardiac tumours.^{3,75} Angiocardiography does not demonstrate extension of tumour into the ventricular walls but only the presence of the tumour within the cavities, as demonstrated by filling defects. The possibility of diagnosis by endomyocardial biopsy has been suggested,⁷⁶ and may still be used in certain circumstances.⁷⁷ This is hardly ever necessary nowadays, as a firm diagnosis can be established using non-invasive imaging. If necessary, diagnosis can be confirmed by peri-operative biopsy should surgical excision of the tumour be justified. Pressure measurements can be obtained with catheterisation, although this has the inherent risk of placing a catheter near or across a friable tumour, a process that may lead to embolisation.⁷⁸

Transthoracic echocardiography, therefore, constitutes the procedure of choice when screening for cardiac tumours. Magnetic resonance and transoesophageal echocardiographic imaging clearly complement one another, and the choice between these techniques depends upon various factors, including the transthoracic echogenicity of the patient, the site of the possible tumour, the availability of these methods, cost, and the physical state and age of the patient.

TYPES OF TUMOUR

Rhabdomyomas

Rhabdomyomas are by far the most frequent tumours found in fetuses, infants and children. They occur almost exclusively in patients under the age of 15 years, and about three-quarters are seen in patients under 1 year of age.¹ They most likely represent hamartomas rather than true neoplasms, being composed of overgrown cardiac muscle.^{1,34} They may present as circumscribed non-encapsulated lesions, varying in size from a few millimetres to several centimetres. Occasionally, the lesion may outgrow the size of the heart (see Fig. 51-1). Rhabdomyomas are usually multiple, and have a distinct preference

for the ventricular septum and the adjacent ventricular walls (Fig. 51-10).^{1,7,34,79} The lesions may be limited to the myocardium, often leading to compression and deformity of the cardiac chambers. Alternatively, they may extend from their intramural location to occupy an intracavitary position (see Fig. 51-10). Nearly half of patients have an intracavitary rhabdomyoma, with marked obstruction to flow of blood in at least one cardiac chamber.¹ Histologically, the lesions are characterised by grotesquely swollen myocytes, which present an almost empty cytoplasm traversed by tiny strands of cross-striated sarcoplasm. The nucleus may thus appear suspended within the cell, giving rise to the so-called spider cell (Fig. 51-11). Spontaneous regression is possible, occurring in most neonates during the first year of life.¹ Echocardiographic follow-up has shown regression within a period as short as 6 weeks.^{45,80-83} Tuberous sclerosis is present in over half of those found to have rhabdomyomas. When the tumours are multiple, up to four-fifths have the disease.^{1,34}

It is possible to distinguish two main clinical categories. In some patients, the rhabdomyoma is an incidental post-mortem finding.¹ In other patients, however, the tumour is the immediate cause of morbidity and/or mortality. In some, it may have led to stillbirth, or death within a few days of birth. In others, the rhabdomyoma may become clinically manifest, usually because of cardiomegaly, intracardiac obstruction, a murmur, congestive cardiac failure, cyanosis, or cardiac arrhythmias, and death may occur suddenly and unexpectedly.^{1,7,34,84} Seizures, hydrops, and polyhydramnios have also been described.³⁴

The prognosis of children with rhabdomyomas has improved significantly over recent decades due to advances in diagnosis and treatment.¹ Meta-analysis suggests mortality of 25.4%.³⁴ This, however, is almost certainly an over-estimation of the real rate of death, since not all cases are reported. Indeed, survival in some series has been greater than 80%.^{1,80,84,85} Once symptoms have appeared suggestive of arrhythmias, obstruction to the outflow tracts, or

Figure 51-10 These multiple rhabdomyomas, occupying an intracavitary position, are growing from the wall of the right ventricle and the adjacent right atrium.

Figure 51-11 This histological section of a rhabdomyoma shows the typical features of the so-called spider cell.

valvar dysfunction, the prognosis becomes worse.¹ It has been suggested, with good reason, that the demonstration of an intracardiac mass in a symptomatic child less than 5 years of age strongly suggests the diagnosis of rhabdomyoma. Since most infants with rhabdomyomas will show a spontaneous regression during the first year of life, surgical intervention should be recommended only in the presence of severe haemodynamic disturbances or persistent arrhythmias.¹ While the cardiac prognosis for fetuses or infants with rhabdomyomas is generally good, concerns are raised because of their common association with tuberous sclerosis. Recent studies suggest that patients with tuberous sclerosis carry a poor neurological prognosis with many of them suffering epilepsy and mental/behavioural disability in childhood and later life.^{86,87}

Fibromas

Cardiac fibromas, found in one-quarter of cases, ranked second in frequency amongst tumours identified at post-mortem in hearts of children between 1 and 15 years of age (see [Table 51-1](#)).⁷ The reported prevalence in clinical series has been higher, at one-quarter to one-fifth.⁸⁸ These tumours are seen throughout childhood, although they are less common in fetuses and newborns. The gross appearance of cardiac fibromas is relatively uniform. They present as solid, firm, whitish lesions, with a distinct fibromatous architecture when seen in cut sections ([Fig. 51-12](#)). They may vary in size from 1 to 9 cm.¹ Those producing functional impairment are usually several centimetres in size. Their circumscript appearance suggests an encapsulated nature, but microscopic studies reveal intermingling of

Figure 51-12 The cut edge of this resected fibroma shows the typical fibromatous architecture.

the tumour with the adjacent myocardium.^{1,7} Moreover, satellite nodules may be present. Calcification within the lesions is not uncommon.¹ Cardiac fibromas, in practical terms, are slow-growing, solitary, but potentially aggressive lesions. Spontaneous regression has not been observed, and surgical excision is often required. Signs and symptoms are largely dependent on the location of the tumour. There is a distinct predilection for the ventricular septum and left ventricular wall. This preference may underlie the presentation of cardiac fibromas with sudden and unexpected death.^{89,90} Cardiac arrhythmias and atrioventricular conduction disturbances can occur. The position within the ventricular septum may also lead to compression of the cardiac chambers and, hence, may cause obstruction. Cardiomegaly is often the leading sign when the lesion is localised in the ventricular or atrial free wall. As fibromas and rhabdomyomas may have similar appearances on imaging, complete evaluation for tuberous sclerosis is warranted. In one-twentieth of cases, cardiac fibromas have been associated with the naevoid basal cell carcinoma syndrome, known as Gorlin's syndrome.^{1,91} Successful surgical excision of large tumours has been reported in children of all ages, with no recurrence of disease over follow-up of several years, even if the resection was not complete.^{7,24,81,88,92,93} Successful transplantation of the heart has also been reported for children with cardiac fibromas.^{88,94,95}

Myxomas

Myxomas are the most common type of cardiac tumours in the overall population. They make up approximately one-quarter of all primary tumours of the heart, but their incidence is much lower in infants and children (see [Table 51-1](#)).^{1,7} They may have a familial trait in perhaps one-twentieth of instances, but most cases are sporadic.^{1,8,96} Patients with familial myxomas are younger at the time of diagnosis, and have associated syndromes with mucocutaneous anomalies and endocrinopathy.^{7,8,96} Cardiac myxomas are usually attached to the atrial septum in the region of the oval fossa, with three-quarters originating in the left atrium.^{8,96} The remaining myxomas arise from the right or left ventricular endocardium with almost equal incidence. Myxomas are multiple in about one-twentieth of cases, most often in those which are familial.

Figure 51-13 The histological section of this myxoma shows the polygonal myxoma cells embedded with a mucoid ground substance rich in glycosaminoglycans.

The tumours typically form a pedunculated mass extending into a cardiac chamber, either with a villous surface (see Fig. 51-1), or with a smooth and lobulated surface (see Fig. 51-5). The friable appearance of the villous surface (see Fig. 51-1) may easily cause detachment and embolisation of either myxomatous fragments or thrombus adherent to the surface.¹¹ Highly sessile atrial tumours may protrude into the atrioventricular orifice during ventricular diastole, sometimes producing valvar stenosis (see Fig. 51-4). The stalk usually contains vessels of large calibre, which can occasionally be seen on coronary angiograms. Histologically, the tumours are composed of polygonal myxoma cells, embedded within a mucoid ground substance rich in glycosaminoglycans (Fig. 51-13). The cellular make-up within the tumour is quite variable, and they often contain haemorrhagic foci and cysts.⁸ Myxomas are thought to originate from multipotential subendocardial mesenchymal cells.^{1,8,96} Their content of abnormal deoxyribonucleic acid suggests a potentially neoplastic nature.¹¹

The systemic, embolic, and cardiac manifestations, as previously described, may dominate the clinical profile, although most experience in this respect is based on adults rather than children. In general terms, the signs and symptoms relate directly to their site and size. In overall series, signs and symptoms of mitral valvar disease dominate the clinical presentation. Other features, such as embolic phenomena, signs and symptoms of tricuspid valvar disease, sudden and unexpected death, pericarditis, myocardial infarction, atrial fibrillation, signs and symptoms of pulmonary valvar disease, and constitutional manifestations such as fever of undetermined origin, may also be the leading manifestation. In a proportion of patients, there are no

cardiac symptoms. The tumour may then be detected as an incidental finding. In infancy, cyanosis, cardiomegaly, murmur, and hydramnios have been reported as the presenting feature.¹ Even though myxomas are considered benign, their consequences, such as embolisation or obstruction to flow, can potentially be lethal.¹¹ Their possible recurrence, local invasion, or extension is also suggestive of a malignant character.⁹⁶ The risk of recurrence is less than 1 in 20 for the sporadic myxomas, but 1 in 5 for the familial cases.^{8,96} Removal of the tumour is the preferred therapeutic option. The stalk should also be removed completely to reduce the risk of recurrence. Follow-up evaluation for recurrence is warranted.

Teratomas

Most of the studies on primary cardiac tumours place teratomas second or third in frequency, albeit rare in children (see Table 51-1 and Fig. 51-7).^{1,7} Most are extracardiac and intrapericardial. They are located at the base of the heart, usually being attached to the root of the arterial pedicle. Intracardiac teratomas do occur, but are exceptionally rare. When found, they can obstruct the ventricular outflow tracts.²⁸ On gross pathology, teratomas are composed of multilocular cysts separated by solid areas. Microscopically, teratomas contain, by definition, elements derived from all three germ layers of the body.

Infants with intrapericardial teratomas frequently present with tamponade and cardiovascular collapse. The teratomas may grow to bizarre dimensions, leading to impaired cardiac function with or without congestive cardiac failure, or to compression of the airways with respiratory distress. Sudden deaths, severe encroachment by the tumour on the heart and great vessels, and infectious pericarditis have all been reported.⁹⁷ The tumours most often present on imaging studies, or because of pericardial effusions when present in fetuses and neonates.¹ Cyanosis, respiratory distress, fetal hydrops, and stillbirth have also been described.¹

Early and accurate diagnosis is of paramount importance in such critically ill patients, as surgical excision and decompression of the pericardial effusion can be achieved successfully. Furthermore, diagnosis during fetal life allows prompt postnatal, or even prenatal, intervention to the development of cardiopulmonary distress.^{61-64,98} In older, asymptomatic children, surgical removal of the tumour is recommended because of the risk of sudden death, and its potential for malignant transformation.

Vascular Tumours

Vascular primary cardiac tumours, such as haemangiomas, represent a heterogeneous group, and can have various pathological characteristics.⁹⁹ Vascular tumours arising from the heart are extremely rare, having been documented in less than one-tenth of all primary cardiac tumours seen in children.⁹⁹ They occur in the atrial walls, especially of the right atrium (see Fig. 51-8), and may cause haemopericardium and tamponade.^{99,100} Intracardiac haemangiomas may also occur.¹⁰¹ Clinical presentation may be diverse, ranging from no manifestations, or an asymptomatic murmur, to cardiomegaly with pericardial effusions and congestive cardiac failure. When diagnosed after infancy, they rarely present with symptoms.⁹⁹

Gross inspection will usually readily identify the true nature of the lesion. On histology, various vascular lesions can be found, with the most common described as capillary and cavernous types.^{1,7} Cardiac vascular tumours are most often diagnosed by echocardiography, but magnetic resonance imaging may provide better tissue characterisation.^{101,102} Those presenting in infancy may regress spontaneously, or with anti-angiogenic therapy such as corticosteroids or interferon-alpha.⁹⁹ This is not the case in older children. Symptomatic tumours of this type seen in older children should be resected, and do not then seem to recur.⁹⁹

Tumours of the Atrioventricular Node

Cystic tumours of the atrioventricular node, also called mesotheliomas of the atrioventricular node, are exceedingly rare. They are the smallest tumours associated with sudden death, and most of the cases are diagnosed at autopsy.³ Immunocytochemical studies have demonstrated an epithelial pattern of differentiation, suggesting that the term mesothelioma is incorrect. The cyst wall is covered by a single layer of cuboidal epithelioid cells, and is composed of fibrous connective tissue showing focuses of chronic inflammation. Within the fibrous tissue are smaller cysts lined by similar cuboidal cells, which contain hyaline eosinophilic material.^{3,103–105} The majority of patients have partial or complete atrioventricular block, and often die either of complete heart block or of ventricular fibrillation. Cystic tumours of the atrioventricular node have been described as occurring at almost any age, from newborn to 86 years, with a mean age at presentation of 38 years and a ratio of females to males of 3 to 1.^{3,103} The tumours, although small, can be detected by echocardiography or magnetic resonance imaging.^{103,105} In symptomatic patients with heart block, a pacemaker can be implanted, albeit that pacing has not always prevented death.¹⁰³ Indeed, it is not always well tolerated, and ventricular fibrillation may ensue.¹⁰⁵ For these reasons, cystic tumours of the atrioventricular node have recently been surgically excised with success.^{103,105}

Purkinje Cell Tumours

These tumours are known under a variety of terms, including oncocytic cardiomyopathy, histiocytoid cardiomyopathy, foamy myocardial transformation, infantile xanthomatous cardiomyopathy, and focal lipid cardiomyopathy.^{1,7} They are rare, and to date, less than 100 cases have been described.¹ Most cases were reported in infants under 2 years old, with more than three-quarters found in females.¹⁰⁶ They are associated with tachyarrhythmias, and may give rise to incessant ventricular tachycardia or sudden death. The aetiology remains controversial. It has been proposed that they might arise from a disorder of mitochondrial metabolism. Also, because of the association between histiocytoid cardiomyopathy and an X-linked chromosomal disorder, including microphthalmia with linear skin defect, an abnormality in the p22 region of the X chromosome has been suggested.¹⁰⁶

Pathological examination of the tumour is characterised by the presence of subendocardial nodules that may be discrete or diffuse throughout the ventricles, with

increased weight of the heart.¹⁰⁷ The tumours involve most frequently the conduction system and the left ventricle. Histopathology reveals clusters of vacuolated histiocytoid-like cells with decreased bundles of myofibril.^{1,106,107} Ultrastructurally, the cells contain an increased number of mitochondria.

The most common clinical presentation is with arrhythmia and sudden death.^{1,108} Ventricular fibrillation, ventricular tachycardia, Wolff-Parkinson-White syndrome, premature ventricular beats, supraventricular tachycardia, and heart block have all been described.^{1,107} Involvement of other organs has been reported. Extracardiac and cardiac malformations, such as ventricular and atrial septal defects, endocardial fibroelastosis, and hypoplastic left heart syndrome, have also been described.¹⁰⁶

Diagnosis may be difficult, but should be suspected in female infants with tachyarrhythmias, especially if echocardiography reveals nodular deposits on the ventricular endocardium or valves.¹ Accurate examination of the cardiac conduction system is paramount to find the mechanisms responsible for sudden cardiac death in infancy.^{1,108} Without treatment, the tumours usually result in death by the age of 2 years.^{1,106} When the tumour is resectable, surgical excision has been performed with success.^{1,106}

Primary Malignant Tumours

Primary malignant tumours of the heart are extremely rare in infancy and childhood (see [Table 51-1](#)). Rhabdomyosarcoma is the leading type.¹ They are characterised clinically by a rapidly downhill course, with death occurring shortly following the onset of symptoms. This is caused by the rapid growth of the tumour, systemic dissemination, and unfavourable response to medical or surgical treatment.^{1,24} The tumours have a tendency to invade the myocardium, and to extend within the cardiac chambers. They are difficult to excise completely.¹⁰⁹ Metastasis to the lungs, thymus, and regional lymph nodes can occur.¹ Early, aggressive surgical excision, most often in conjunction with adjunctive chemotherapy and radiation therapy, might result in longer survival in some patients.^{1,24,95} This approach, nonetheless, remains palliative because malignant tumours are almost invariably fatal.^{1,24} Cardiac transplantation has been performed in a limited number of patients with inconsistent results.^{95,110}

Secondary Cardiac Tumours

These are also very rare in children, but are more frequent than the primary type. The clinical picture is nearly always dominated by the underlying disease, albeit that occasionally the cardiac symptoms constitute the basis for the presenting complaints. Cardiac involvement occurs secondary to either direct extension, haematogenous or lymphatic spread, or via extension from the inferior caval vein.³ Lymphoma is the most common underlying disease in children, followed by Wilms' tumour. Other solid neoplasms, such as malignant hepatic tumour, may also metastasise or grow into the heart.^{111,112} The symptoms produced by the metastatic lesions depend on the site and extent of the tumour. Pericardial involvement may give rise to pericardial effusion, which is often blood stained. Cardiac compression may be caused by either an effusion or a solid tumour

encasing the heart. Post-operative outcome in patients with secondary cardiac tumours is poor. Surgery should, thus, be reserved for cases with haemodynamic compromise.¹¹¹

SURGICAL THERAPY

The planning of surgical treatment must be based on the accurate assessment of the number, location, size, and extent of the tumour or tumours, on the haemodynamic state of the patient, and on the histological nature of the lesion. Cross sectional echocardiography provides most of this information. Although endomyocardial biopsy has been promoted as a means of histological diagnosis, in most cases the histological nature of the tumour may be predicted accurately from the non-invasive investigations. In infants, multiple nodules nearly always point to a rhabdomyoma, by far the most common tumour of the heart seen in children. The presence of tuberous sclerosis in the infant, or in the family, confirms the diagnosis. A large and well-circumscribed tumour in the septum or ventricular wall is likely to be a fibroma or an intracardiac teratoma.

Because of evolutions in cardiac surgery, complete resection of virtually all primary cardiac tumours is now possible.²⁴ As a result, the prognosis of children with primary cardiac tumours improved significantly in recent decades. Surgical resection is indicated in all symptomatic patients, in those with significant obstruction of either the ventricular inlet or outlet, or in the setting of life-threatening arrhythmias.⁸¹ Single lesions amenable to surgical resection, especially fibromas, should be considered for removal because of the possibility of arrhythmias, and even sudden cardiac death. If feasible, the aim must be complete resection, but in some series, even incomplete resection of benign tumour has led to good results without recurrence.^{24,113} In the setting of myxomas, surgery should be undertaken urgently because of the potential for catastrophic embolisation. Careful examination of the entire heart is necessary to remove concurrent sites of myxomatous tissue. Partial resection for relief of obstruction and amelioration of an increase in chamber size may be indicated when there are significant haemodynamic alterations. Incomplete removal may result later in arrhythmias, and the potential for sudden death will remain. In the presence of multiple lesions, or if there is extensive myocardial involvement, and in the absence of symptoms, surgery is better postponed. Since most rhabdomyomas undergo spontaneous regression, surgical intervention is no longer indicated unless there are significant clinical manifestations.^{1,7,24}

OTHER TREATMENTS

When the anatomical location of the tumour precludes curative resection, cardiac transplantation may be considered if there is obstruction to the flow of blood or severe arrhythmias.⁹⁵ This option should be considered on a case-by-case basis because of the limited experience to date.⁹⁵ Vascular tumours in infants may be treated with

anti-angiogenic therapy, such as corticosteroids or interferon-alpha.⁹⁹ Very little data is available on chemotherapy or radiation in children with cardiac sarcomas. These therapies, in general, do not appear efficacious.^{1,24}

ACKNOWLEDGEMENTS

We thank Drs Julene Carvalho and Raad Mohiaddin, from Royal Brompton Hospital, and Dr Jan Marek, from Great Ormond Street Hospital, for their contribution with illustrations. Dr Bédard has received financial support from the Cardiology Institute of Quebec, Laval University, and the Cardiologists Association of the province of Quebec. Professor Gatzoulis and the Royal Brompton Adult Congenital Heart Center receive support from the British Heart Foundation.

Kawasaki Disease

JANE NEWBURGER

Kawasaki disease was first described in 1967, by a Japanese paediatrician, Tomisako Kawasaki.¹ He characterised the illness, then termed mucutaneous lymph node syndrome, as including high fever, non-exudative conjunctivitis, inflammation of the oral mucosa, rash, cervical adenopathy, and findings in the limbs, including swollen hands and feet, red palms and soles, and, later, subungual peeling. At the time, the disease was thought to be self-limited, without long-term consequences. Later, Kawasaki disease was shown to cause coronary arterial aneurysms, which may cause complications of angina, myocardial infarction, and sudden death. Although the disease continues to have the highest relative risk in children of Japanese ancestry, it has been described worldwide in children of all races and ethnicities. In the United States of America, where more than 4000 children with Kawasaki disease are hospitalised annually,² Kawasaki disease has surpassed rheumatic fever as a cause of acquired cardiac disease in children. In this chapter, I will summarise current knowledge about the aetiology and pathogenesis, diagnosis, treatment in the acute phase, and natural history of Kawasaki disease.

EPIDEMIOLOGY

The incidence of Kawasaki disease differs according to race and ethnicity. In Japan, Kawasaki disease has an incidence of approximately 138 cases for each 100,000 children under the age of 5 years.³ In the United States of America, Kawasaki disease has been reported to be most common among Asians and Pacific Islanders, with an incidence of 32.5 cases for each 100,000 children under the age of 5 years, intermediate in non-Hispanic African Americans, where the number is 16.9, and Hispanics, at 11.1 cases, and lowest in Caucasians, with 9.1 cases in each 100,000 children under the age of 5 years.² Previous smaller state-based studies suggested similar prevalence according to race.^{4,5}

Kawasaki disease is most common in children younger than age 5 years, but one-quarter of cases in the United States of America occur in older children.² Young infants have the highest rate of formation of coronary arterial aneurysms, and often present with incomplete features. Children older than age 8 years also have a higher rate of coronary arterial involvement.⁶⁻⁹ In contrast to young infants, older children generally present with typical findings, but suffer an increased incidence of coronary arterial aneurysms, in part because of delayed diagnosis by physicians, who mistakenly believe that Kawasaki disease only occurs in very young children. Males are affected more than females by a ratio of approximately 1.5 to 1, and the illness is most common during the winter and early

spring months.^{2,10} Data linking Kawasaki disease to antecedent exposure to carpet cleaning, or to viral infections of the respiratory tract, have been inconsistent.^{4,5,11-14} Other studies have suggested that Kawasaki disease is associated with residence near a standing body of water,¹⁵ antecedent eczema,¹⁶ and use of humidifiers.¹⁴

In Japan, the rate of recurrence of the disease is approximately 3%,¹⁷ and the proportion of cases with a positive family history is approximately 1%.^{17,18} Siblings have a relative risk that is 10-fold that of the normal Japanese population, with half developing the disease within 10 days of the first case.¹⁹ The risk of occurrence in twins may be as much as 100-fold higher than in the general population.^{19,20} Parents of Japanese children with Kawasaki disease, compared to the general population, have a two-fold higher risk of having had Kawasaki disease themselves in childhood.¹⁹⁻²² Of note, in the United States, the familial incidence of Kawasaki disease is believed to be far lower than in Japan.

Coronary arterial disease is responsible for almost all deaths in patients with Kawasaki disease.²³ The case fatality rate is 0.08% in Japan.¹⁷ In the United States, reported in-hospital mortality for Kawasaki disease has varied from 0% to 0.17%.^{2,24} Although the highest risk of myocardial infarction and death occurs in the first months after illness onset,²⁵ sudden death from ischaemic heart disease may occur many years later in patients with coronary arterial aneurysms and stenoses.²⁶

AETIOLOGY AND PATHOGENESIS

The cause of Kawasaki disease remains unknown, despite decades of investigation and spirited controversy. For many reasons, an infectious cause or trigger seems most likely. The illness is self-limited, and usually non-recurring. Its clinical signs and symptoms overlap with those in known toxin-mediated or viral infections. Its predilection for young children, with rare occurrence in neonates and adults, suggest that immunity is acquired. An infectious agent is further suggested by winter-spring seasonality, outbreaks in the community, and occasional epidemics. Person-to-person transmission does not occur, but infection with a common agent could produce asymptomatic disease in most children, and recognisable signs and symptoms of the disease in a tiny subset of susceptible individuals. It has not been linked to exposure to drugs or to environmental pollutants.

A number of investigations, including reports of selective expansion of V β 2 and V β 8 T-cell receptor families in the acute stage of the disease, have suggested that the illness may be caused by bacterial superantigens.²⁷⁻³⁰

The prevalence of toxin-producing strains was similar, nonetheless, in patients with the disease and febrile controls in a prospective, multi-centre study.³¹ Other investigations have suggested that the immune response in the disease is evoked by a conventional antigen.^{32–34} Recently, a cytoplasmic antigen, bound by a synthetic IgA antibody, has been observed in the proximal bronchial epithelium and coronary arteries of the majority of postmortem specimens from children with the disease, but not in postmortem control patients. The nature of the antigen is as yet undetermined.³⁵ The data suggests that the disease may be caused by a respiratory infectious agent with tropism for vascular tissue.³⁵ It is also possible that it may be triggered by more than one microbial agent in a susceptible host.

The importance of genetic factors in susceptibility is supported by the influence of race and family history on its incidence (see Epidemiology above). In addition, an increasing literature has explored the association of genetic polymorphisms to susceptibility to the disease, or to development of aneurysms.^{22,36–45}

The pathogenesis includes marked immune activation, with release of pro-inflammatory cytokines and growth factors, activation of endothelial cells, and infiltration of coronary arteries and other medium-sized extraparenchymal arteries by CD68+ monocyte/macrophages, CD8+ cytotoxic lymphocytes, and oligoclonal IgA plasma cells.^{33,46–55} The integrity of the arterial wall may be disrupted by infiltration of macrophages and release of matrix metalloproteinases.⁵⁶

PATHOLOGY

Mortality peaks between 15 and 45 days after onset of fever, when patients are in a hypercoagulable state and have thrombocytosis and disrupted vascular endothelium.⁵⁷ Mortality declines significantly beyond the first year after the onset of the illness. Because of progressive coronary arterial stenosis, however, myocardial infarction may occur many years later. An increasing literature has shown that when diagnosis is not made in childhood, the disease can cause myocardial infarction in young adults.⁵⁸

Because few patients die in the acute phase of the disease in the current era, much of our knowledge about its pathology derives from early studies in Japan.^{23,59} In the first 9 days of illness, findings include acute perivascularitis and vasculitis of the microvessels and small arteries, as well as acute perivascularitis and endarteritis of the three major coronary arteries, with influx of neutrophils. Inflammation in the pericardium, myocardium, atrioventricular conduction system, and endocardium are also present. Deaths in this early period are caused by myocarditis and abnormalities of conduction. In the second through fourth weeks of the disease, the coronary arteries are affected by panvasculitis, and aneurysms form, with coronary arterial thrombosis. The cells infiltrating the arterial wall range from neutrophils to large mononuclear cells, and include lymphocytes and plasma cells. At this stage, the internal elastic lamina shows segmental destruction. Pericarditis, myocarditis, inflammation of the atrioventricular conduction system, and endocarditis with valvitis, continue to be present. Mortality in these weeks is most likely to be secondary to ischaemic heart disease, rupture of aneurysms, and myocarditis, including lesions of the conduction system. After

1 month, active inflammation begins to be replaced by progressive neointimal proliferation, neoangiogenesis, and fibrosis with formation of scars. Late deaths are characterised by severe coronary arterial stenosis.

Aneurysms produced by the disease occur in locations that are similar to those of atherosclerotic lesions, that is, in the proximal segments and branches of the coronary arteries, suggesting a role for shear stress in both types of coronary lesions. In addition, growth factors are prominently expressed at the inlets and outlets of the aneurysms, these also being sites of high shear stress.⁶⁰ Aneurysms can occur in medium-sized extraparenchymal arteries other than the coronary arteries. In particular, the coeliac, mesenteric, femoral, iliac, renal, axillary, and brachial arteries can be affected.⁵⁹ Peripheral arterial aneurysms, however, never occur in the absence of aneurysms involving the coronary arteries.

CLINICAL DIAGNOSIS

General Aspects of Initial Diagnosis

Diagnostic criteria are summarised in Table 52-1.⁶¹ The epidemiologic definition for diagnosis includes fever for 4 days with at least four principal clinical criteria, or fever and fewer than four principal criteria in the presence of coronary arterial abnormalities. By convention, the first day of the disease is considered to be the day on which the fever initially occurs. All clinical features are rarely present at the same time, so the diagnosis requires sequential evaluation of the patient. In the absence of treatment, the mean duration of fever is 11 days, and fever rarely persists beyond 4 weeks. The principal clinical findings are not pathognomonic, so other diseases with similar clinical features should be excluded (Table 52-2).

A diagnosis of incomplete disease may be made in patients who do not fulfill the classic criteria outlined in Table 52-1, whereas the term atypical disease refers to patients who have features not generally seen, for example those presenting with haemophagocytic syndrome, or renal failure. Because coronary arterial disease is now well recognised to occur in children with incomplete or atypical features, and treatment with immunoglobulins must be started early to be effective, a new algorithm for evaluation and treatment of the child with suspected disease was recently developed (Fig. 52-1).⁶² The diagnosis may be based upon abnormalities of the coronary arteries by echocardiography when the classic epidemiologic definition is not fulfilled. Because young infants are most likely to have incomplete criteria, and also have the highest risk of aneurysms, echocardiography is recommended for infants less than age 6 months with a fever lasting for 7 or more days without other explanation, in whom there is elevation of either C-reactive protein or the rate of erythrocytic sedimentation.

Laboratory features are reflective of an acute inflammatory response. Virtually all patients at presentation have elevation of the rate of erythrocytic sedimentation or C-reactive protein.⁶³ The average level of haemoglobin at the time of presentation is two standard deviations below the mean for age, with the anaemia being normocytic and normochromic. The number of white blood cells is generally increased, at a median of 15,000/mm³, with a leftward shift. The platelet count is usually normal in the

TABLE 52-1

CLINICAL AND LABORATORY FEATURES OF KAWASAKI DISEASE**Epidemiologic Case Definition (Classic Clinical Criteria)**

- Fever of at least 5 days' duration
- Presence of at least four of the following principal features:
 - Changes in extremities
 - Polymorphous exanthem
 - Bilateral conjunctival injection
 - Changes in the lips and oral cavity
 - Cervical lymphadenopathy
- Exclusion of other diseases with similar findings (see Table 52-2)

Other Clinical and Laboratory Findings

- Cardiovascular findings
 - Congestive heart failure, myocarditis, pericarditis, or valvular regurgitation.
 - Coronary artery abnormalities
 - Aneurysms of medium-sized non-coronary arteries
 - Raynaud's phenomenon
 - Peripheral gangrene
- Musculoskeletal system
 - Arthritis, arthralgia
- Gastrointestinal tract
 - Diarrhea, vomiting, abdominal pain
 - Hepatic dysfunction
 - Hydrops of the gallbladder
- Respiratory tract
 - Pulmonary nodules and interstitial infiltrates
 - Pleural effusion
- Central nervous system
 - Extreme irritability
 - Aseptic meningitis
 - Peripheral facial nerve palsy
 - Sensorineuronal hearing loss
- Genitourinary system
 - Urethritis/meatitis
 - Testicular swelling
- Other findings
 - Erythema and induration at Bacille Calmette-Guerin (BCG) inoculation site
 - Anterior uveitis
 - Desquamating rash in groin

Laboratory Findings in Acute Kawasaki Disease

- Neutrophilia with immature forms
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
- Elevated serum α -l-antitrypsin
- Anemia
- Hypoalbuminaemia
- Thrombocytosis after first week
- Sterile pyuria
- Elevated serum transaminases
- Pleocytosis of CSF
- Leukocytosis in synovial fluid

first week of the illness, peaking in the third week of the illness to values sometimes higher than 1,000,000/mm³. After the seventh day of illness, counts are usually at least 450,000/mm³. Plasma gammaglutamyl transpeptidase, transaminases, and bilirubin, are frequently elevated.^{64,65}

TABLE 52-2

DIFFERENTIAL DIAGNOSIS OF KAWASAKI DISEASE

- Viral infections including measles and adenovirus
- Scarlet fever
- Staphylococcal scalded skin syndrome?
- Toxic shock syndrome
- Bacterial cervical lymphadenitis
- Drug hypersensitivity reactions
- Stevens-Johnson syndrome
- Juvenile rheumatoid arthritis
- Rocky Mountain spotted fever
- Leptospirosis
- Mercury hypersensitivity reaction (acrodynia)

Reprinted with permission from Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771.

Synthesis of albumin is decreased in the acute phase, and hypoalbuminaemia is common. Microscopic evaluation of the urine may reveal an elevated count of white blood cells with no identified infectious agent, so-called sterile pyuria. Cerebrospinal fluid contains an increased number of white blood cells, predominantly mononuclear cells, with normal levels of glucose and protein.⁶⁶ Serum cardiac troponin^{67–69} and brain natriuretic factor⁷⁰ may also be elevated in the acute phase of the disease.

Cardiac Findings

The acute phase of the disease may be associated with myocarditis, pericarditis, valvitis, and inflammation in the coronary arterial wall. Cardiac auscultation typically reveals a hyperdynamic praecordium, tachycardia, and a gallop rhythm, even in the absence of fever. Almost all children have an innocent flow murmur related to anaemia and fever. In addition, some children with significant mitral regurgitation have a pansystolic regurgitant murmur at the apex. The disease may occasionally present with low cardiac output syndrome or shock. Electrocardiography may show arrhythmia, prolonged PR interval, or nonspecific ST and T wave changes.

At the time of acute presentation, the maximal z scores for the coronary arteries normalised to body surface area are greater than in the general afebrile population. A maximal z score for the proximal segments of the right or anterior interventricular arteries is at least 2.5 in approximately one-quarter of patients.⁷¹ Coronary arterial dimensions then diminish in the majority of patients treated with immunoglobulins within the first 10 days of illness.

Coronary arterial aneurysms are the most serious long-term complications of the disease. Approximately one in five children who are not treated with high doses of immune globulin given intravenously within the first 10 days of illness develops coronary arterial ectasia or aneurysms. The aneurysms may be detected by echocardiography beginning 7 days after the first appearance of fever, with their diameter usually peaking around 4 weeks after onset of the illness. Independent predictors of development have included age less than 1 year, male gender, delayed treatment with immunoglobulins, persistent or

Figure 52-1 Evaluation of suspected incomplete Kawasaki disease (KD). The numbers 2 to 8 in the figure refer to the issues highlighted in the legend. (1) In the absence of gold standard for diagnosis, this algorithm cannot be evidence-based but rather represents the informed opinion of the expert committee. Consultation with an expert should be sought anytime assistance is needed. (2) Infants younger than 6 months old on the seventh day of fever without other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, an echocardiogram, even if the infants have no clinical criteria for diagnosis. (3) Characteristics suggesting Kawasaki disease are listed in Table 52-1. Characteristics suggesting disease other than Kawasaki disease include exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, or generalised adenopathy. Consider alternative diagnoses (see Table 52-2). (4) Supplemental laboratory criteria include levels of albumin less than 3.0 g/dL, anaemia for age, elevation of alanine aminotransferase, more than 450,000 platelets per mm³ after the seventh day, a white blood cell count of greater than 15,000/mm³, and more than 10 white blood cells per high-power field in the urine. (5) Can treat before performing echocardiogram. (6) Echocardiogram is considered positive for purposes of this algorithm if any of three conditions are met: z score for the anterior interventricular or right coronary artery of greater than 2.5, coronary arteries meet Japanese Ministry of Health criteria for aneurysms, or there are more than three other suggestive features, including perivascular brightness, lack of tapering, decreased left ventricular function, mitral regurgitation, pericardial effusion, or z scores for the anterior interventricular and right coronary arteries between 2 and 2.5. (7) If the echocardiogram is positive, treatment should be given to children within 10 days of the onset of fever, and those beyond the tenth day with clinical and laboratory signs of ongoing inflammation. (8) Typical peeling begins under nail bed of fingers and then toes. CRP, C-reactive protein; FSR, erythrocyte sedimentation rate; f/u, follow-up. (Reprinted with permission from Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747-2771.)

recrudescent fever after immunoglobulins, so-called immunoglobulin resistance, and laboratory measures suggesting worse inflammation.⁷¹⁻⁷⁷ Asian/Pacific Islander race and Hispanic ethnicity are also risk factors.⁷⁸ Sociodemographic factors appear to play an important role in delayed diagnosis.⁷⁹

Aneurysms are considered to be saccular when their axial and lateral diameters are nearly equal. Fusiform aneurysms occur when there is symmetric dilation, with gradual proximal and distal tapering. Coronary arteries are considered to be ectatic when the dimension is dilated without a segmental aneurysm. Aneurysms are classified as giant when the internal diameter is at least 8 mm.^{61,80}

Depression of myocardial function is common in the acute phase of the disease. Endomyocardial biopsies have suggested that myocarditis is a universal feature of Kawasaki disease, and myocardial inflammation is present in from

half to three-quarters of patients based upon nuclear imaging. Fortunately, myocardial function usually improves rapidly after administration of intravenous immune globulin, and long-term, clinically significant abnormalities of systolic function are uncommon in the absence of ischaemic heart disease secondary to coronary arterial aneurysms.

In the acute phase, mitral regurgitation may result from valvitis, or from transient dysfunction of the papillary muscles. More than one-quarter of children have mitral regurgitation at the time of presentation.⁸¹ Late mitral regurgitation is usually the result of ischaemic disease. Aortic regurgitation, presumably secondary to valvitis, is infrequently detected by echocardiography in the acute phase.⁸¹ Only rare instances of late mitral regurgitation unrelated to ischaemia or late aortic regurgitation of clinical significance have been reported.⁸²⁻⁸⁴

Figure 52-2 The cross sectional echocardiogram shows a giant aneurysm of the right coronary artery (RCA). Ao, aorta.

Echocardiography

Echocardiographic imaging of the coronary arteries is essential in the evaluation of all patients with definite or suspected disease (Fig. 52-2). Its sensitivity and specificity for the detection of dilation of the proximal coronary arterial segments are high when performed with appropriate transducers by experienced sonographers in cooperative or sedated children. Because aneurysms also occur in the absence of the classic criteria, echocardiography has an important role in evaluation of children with protracted fever and some findings consistent with features of Kawasaki disease. Additional echocardiographic features in the acute phase include coronary arterial ectasia, lack of tapering, and perivascular brightness. Left ventricular contractility may also be diminished, and mild valvar regurgitation, particularly mitral regurgitation, is relatively common.⁸¹ Although pericardial effusions may occur, they are infrequently significant in size.⁸¹

Echocardiography should be performed shortly after diagnosis to provide a baseline examination of coronary dimensions, left ventricular function, valvular regurgitation, and pericardial effusion. In children whose fever resolves after initial treatment with intravenous immune globulin, and who remain afebrile, echocardiography should be repeated at 2 weeks, and again at approximately 6 to 8 weeks after onset of the illness. Children at higher risk, that is those with recrudescence fever, baseline coronary arterial abnormalities, diminished left ventricular function, or pericardial effusion, should undergo more frequent echocardiographic evaluation to guide the need for additional therapies.

Cross sectional echocardiographic imaging should be performed with the transducer of the highest frequency available, and recorded in a dynamic video or digital cine format. The imaging planes and transducer positions required for optimal visualisation of the coronary arterial segments are depicted in Table 52-3. Whenever possible, all major coronary arterial segments should be visualised. The most common site for formation of aneurysms are the proximal segments of the anterior interventricular and right coronary arteries, followed in descending order by the main stem of the left coronary artery, the circumflex artery and the distal part of the right coronary artery, and the junction between the right coronary artery and inferior interventricular artery. Measurements are made from inner edge to inner edge, excluding points of branching.

TABLE 52-3

ECHOCARDIOGRAPHIC VIEWS OF CORONARY ARTERIES IN PATIENTS WITH KAWASAKI DISEASE

- Left main coronary artery: Praecordial short-axis at level of aortic valve; precordial long-axis of left ventricle (superior tangential); subcostal left ventricular long-axis
- Left anterior descending coronary artery: Praecordial short-axis at level of aortic valve; precordial superior tangential long-axis of left ventricle; precordial short-axis of left ventricle
- Left circumflex: Praecordial short-axis at level of aortic valve; apical four-chamber
- Right coronary artery, proximal segment: Praecordial short-axis at level of aortic valve; precordial long-axis (inferior tangential) of left ventricle; subcostal coronal projection of right ventricular outflow tract; subcostal short-axis at level of atrioventricular groove
- Right coronary artery, middle segment: Praecordial long-axis of left ventricle (inferior tangential); apical four-chamber; subcostal left ventricular long-axis; subcostal short-axis at level of atrioventricular groove
- Right coronary artery, distal segment: Apical four-chamber (inferior); subcostal atrial long-axis (inferior)
- Posterior descending coronary artery: Apical four-chamber (inferior); subcostal atrial long-axis (inferior)

Statistics about the prevalence of aneurysms are based upon criteria set forth by the Japanese Ministry of Health in 1984. These classify coronary arteries as abnormal if the internal luminal diameter is greater than 3 mm in children less than 5 years of age, or 4 mm in children at least 5 years of age, if the internal diameter of a segment measures at least 1.5 times that of an adjacent segment, or if the coronary arterial lumen is clearly irregular.⁸⁵

Because normal dimensions are related to body size, dimensions may also be expressed as units of standard deviation, or z scores, adjusted for body surface area (Fig. 52-3).⁸⁶ Use of such z scores has suggested that the criteria adopted by the Japanese Ministry of Health may result in under-diagnosis and under-estimation of the true prevalence of arterial dilation in the first weeks of the illness. Some limitations should be noted. There is no normative data for febrile patients with other diseases. Z scores are available only for the main stem of the left coronary artery and the proximal segments of the anterior interventricular and right coronary arteries. For this reason, the criterion of size 1.5 times that of the surrounding segment is still useful for diagnosis of aneurysms in peripheral sites. Imaging of the coronary arteries may also reveal lack of normal tapering and perivascular echogenicity or brightness, but these qualities are difficult to quantitate and verify.⁸⁷

Stress Testing

Children with aneurysms should undergo periodic stress testing, with assessment of myocardial perfusion or function. Most methods of stress testing used in adult cardiology have been reported in small series of children with Kawasaki disease.⁸⁸⁻⁹⁸ Because the sensitivity and specificity of tests to provoke myocardial ischaemia have been exhaustively studied in adults with coronary arterial disease, adult guidelines should be followed to choose the best test based upon specific characteristics of the patients.⁹⁹ Additional factors in the choice of

Figure 52-3 Mean and limits for prediction for 2 (solid purple and blue lines) and 3 (dotted purple and blue lines) standard deviations for the size (red solid line) of (A) the anterior interventricular artery, (B) the proximal right coronary artery (RCA) and (C) the main stem of the left coronary artery (LMCA) according to body surface area for children below the age of 18 years. Z scores for the main stem should not be based on the dimension at the arterial orifice nor its immediate vicinity. Enlargement of the main stem secondary to Kawasaki disease usually is associated with ectasia of the anterior interventricular or circumflex arteries, or both arteries. (Reprinted with permission from Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771.)

modality for testing include institutional expertise with particular techniques, and the age and ability of the child to cooperate with exercise. False positive tests are more likely in patients with a low prior probability of coronary arterial disease. I do not recommend performing stress tests in patients without a history of coronary arterial enlargement.

Other Noninvasive Methods for Imaging the Coronary Arteries

In selected patients, noninvasive imaging methods other than echocardiography may be needed for assessment of the coronary arterial anatomy. In particular, ultrafast computerised tomography, and magnetic resonance imaging and angiography, may provide valuable noninvasive imaging data in patients whose coronary arteries cannot adequately be imaged by echocardiography (Fig. 52-4).^{100–104} In addition to imaging, cardiac resonance tests can be performed together with pharmacologic stress, and may allow assessment of myocardial infarction using delayed enhancement (Fig. 52-5).

Figure 52-4 The magnetic resonance image shows a giant segmented aneurysm of the anterior interventricular artery, which arises directly from the aortic root. The segments of the aneurysm are depicted by the arrows. Ao, aorta.

Figure 52-5 Myocardial delayed enhancement imaging shows a large area of nearly transmural hyperenhancement (arrows) consistent with an antero-septal myocardial infarction, becoming transmural at the apex. LA, left atrium; LV, left ventricular.

Ultrafast computerised tomography has been shown to have excellent sensitivity for detection of coronary arterial stenoses in patients with the disease.¹⁰⁵ Because the technique is associated with relatively high doses of ionising radiation,^{106,107} this test should be reserved for use in circumstances when other non-invasive tests are inadequate for imaging.

Coronary Angiography

Cardiac catheterisation and coronary angiography provide the gold standard for imaging, against which other methods are assessed (Fig. 52-6). Indeed, almost all reports on the natural history of the disease are based upon angiographic studies. In addition to providing better delineation of the distal coronary vasculature than noninvasive tests, angiography is the most reliable method by which to assess coronary arterial stenosis or thrombotic occlusion and the presence of collateral vessels.

Because selective coronary angiography has greater risks than noninvasive imaging, its use should be restricted to selected patients with coronary arterial aneurysms, clinical signs, noninvasive studies indicating myocardial ischaemia, or those in whom noninvasive methods fail to provide adequate images. Angiography is usually performed 6 to 12 months after the onset of the illness in patients with significant aneurysms who have no signs or symptoms of ischaemic heart disease. Angiography can be helpful in guiding anti-thrombotic therapy when proximal aneurysms have regressed, but the distal parts of the coronary arteries cannot be imaged by noninvasive means. Some cardiologists follow patients who have undergone surgical revascularisation or catheter intervention by cardiac catheterisation to evaluate the efficacy of their treatment. To evaluate whether peripheral arterial aneurysms are present,¹⁰⁸ abdominal aortography and subclavian arteriography should be

Figure 52-6 The coronary angiogram demonstrates a giant aneurysm of the right coronary artery, with obstruction and bridging collateral arteries in a 4-year-old boy.

performed in patients undergoing coronary arteriography for the first time.

NATURAL HISTORY

Patients with Kawasaki disease have had careful follow-up only for the past three decades. It is clear, however, that long-term outcomes are related to the extent of dilation of the coronary arteries in the first month of the illness. Aneurysms reach their peak diameter in the first 4 to 6 weeks after onset of the illness. After this time, a myointimal proliferation results in regression of approximately half to two-thirds of aneurysmal segments.^{83,109} The likelihood of regression is primarily determined by the peak luminal diameter, with larger aneurysms being less likely to regress.^{110,111} Other factors that predict greater likelihood of regression are younger age, distal location, and fusiform shape.¹⁰⁹ Aneurysms that persist may develop significant stenoses secondary to myointimal proliferation at either end of the aneurysm, calcification, tortuosity, or thrombotic occlusion. Rupture of an aneurysm is rare, and generally occurs early after onset rather than as a late complication.

In patients with persistent aneurysms, the prevalence of coronary arterial stenosis increases over time,^{83,108,112} with the highest incidence occurring in patients with giant aneurysms.¹¹² The principal cause of death is myocardial infarction produced by thrombotic occlusion in a coronary arterial segment with an aneurysm and/or stenosis.²⁵ The highest risk of myocardial infarction occurs in patients with giant aneurysms, related to sluggish flow in a huge vascular space, often in combination with stenosis at its distal end. Although myocardial infarction occurs most frequently in the first year after onset, patients with aneurysms and/or stenoses have a life-long increased risk for ischaemic events. Indeed, previously undiagnosed Kawasaki disease may become apparent in adulthood at the time of presentation with myocardial infarction.^{113,114} Fatalities from myocardial infarction are most likely with obstruction in the main stem of the left coronary artery, or in the proximal segments of both the right and anterior interventricular arteries.²⁵ Thrombosis of the right, compared to the left, coronary artery is more likely to be silent and to recanalise.

Patients with aneurysms have been found to have stiff and thickened carotid arteries 6 to 20 years after onset, and these changes occur independent of dyslipidaemia.¹¹⁵ The presence of carotid atherosclerosis suggests that the coronary arteries may be similarly affected. Patients with persistent aneurysms also have been found to have higher levels of high sensitivity C-reactive protein than those without aneurysms or normal children.^{116,117} Low-grade ongoing inflammation thus appears to be a late effect in patients with coronary arterial aneurysms.

Regression of the aneurysms restores the internal luminal diameter to normal. The arterial wall, however, shows fibrous intimal thickening on histopathologic examination. Intravascular ultrasound in coronary arteries with regressed aneurysms is characterised by marked symmetric or asymmetric myo-intimal thickening.^{118–120} In patients with regressed coronary aneurysms studied by intravascular ultrasound at least 10 years after onset, greater thickening of the intimal and medial layers was significantly associated with larger initial diameter of the coronary arteries.¹¹⁹

Regressed aneurysms also have abnormalities of function. Pharmacologic testing with intracoronary arterial

administration of isosorbide dinitrate has shown that vascular reactivity is reduced in arterial segments with regressed aneurysms when compared to normal vessels. Vasodilation is progressively impaired as the interval from onset lengthens. In addition, endothelial dysfunction in regressed aneurysms is indicated by constriction of the arteries subsequent to administration of acetylcholine.^{120–123} Despite abnormalities of structure and function, children with regressed aneurysms rarely have clinical symptoms or events within the first two decades of follow-up.

Children in whom aneurysms were never detected have normal cardiopulmonary fitness, and careful follow-up in Japan over the past three decades shows that they have no greater likelihood of cardiac or other diseases. Research studies suggest, however, that they should be monitored as an at-risk population. Vascular inflammation is diffuse during the acute disease, and lipid metabolism after the disease is altered for years after resolution of acute symptoms, with a pattern similar to that seen in other vasculitides.^{124–126} Increased arterial stiffness in children who never had coronary arterial dilation is suggested by higher mean pulsed wave Doppler velocity in the brachial and radial arteries.^{126,127} Coronary physiology may also be disturbed, with lower myocardial flow reserve and higher total coronary arterial resistance found in children with a history of Kawasaki disease in whom coronary dilation was never detected compared to normal controls.¹²⁸ Endothelium-dependent brachial arterial reactivity, which often mirrors coronary arterial reactivity, has been reported to be abnormal among children without a history of aneurysms.¹²⁹ Reports on endothelial function in the epicardial coronary arteries, as assessed by infusion of acetylcholine, have varied in their findings.^{130,131}

TREATMENT

Treatment of the disease in the first weeks after onset is aimed at lowering fever for comfort, reducing inflammation and shear stress in the arterial wall, and preventing thrombosis. To reduce shear stress, children in whom coronary aneurysms are developing should undergo transfusion of red blood cells if they are profoundly anaemic, ideally to achieve a haematocrit of at least 30%, and β -blockers should be administered to reduce myocardial consumption of oxygen. Among patients with aneurysms, prevention and, if needed, treatment of coronary thrombosis are key components of therapy. Patients with coronary arterial stenosis or occlusion and evidence of reversible ischaemia are candidates for interventional catheterisation and surgical procedures. Specific therapies are detailed below.

Anti-inflammatory Therapies in the Acute Phase of Illness

Aspirin

Although aspirin does not affect the prevalence of coronary arterial aneurysms,¹³² it has been a cornerstone of therapy because of its anti-pyretic and anti-platelet effects. The agent is given in high doses, 80 mg/kg/day, divided into four daily doses, and this regime is used until the child has been afebrile for at least 48 hours, after which the dose is lowered to 3 to 5 mg/kg/day for its anti-platelet effects. Aspirin in low doses is continued for approximately

6 weeks, and then discontinued in patients without coronary arterial aneurysms. In children with coronary arterial abnormalities, aspirin is continued indefinitely at low doses, and may be used together with other anti-thrombotic therapies, such as clopidogrel or warfarin, in children with coronary arterial lesions placing them at high risk.

Reye syndrome has been reported in children with the disease who are taking aspirin in high doses. Although this syndrome has not been associated with use of aspirin in low doses, annual vaccination against influenza is recommended for all children on chronic treatment with aspirin. When a child medicated on a chronic basis with aspirin develops a flu-like illness, aspirin should be withheld transiently and, if necessary, another anti-platelet medication, such as clopidogrel, should be substituted until resolution of the illness. Because ibuprofen antagonises the inhibitory effect of aspirin on platelets, sustained therapy with ibuprofen should be avoided in children who are taking aspirin in low doses for prophylaxis of coronary arterial thrombosis.¹³³

Intravenous Immunoglobulin

Control of inflammation decreases the likelihood of aneurysmal formation, and is the most important aim of therapy in the acute phase of illness. Among the armamentarium of anti-inflammatory agents that have been used, only intravenous immunoglobulin in high doses has been demonstrated to be effective in multiple randomised, multi-centre trials with blinded echo interpretation.⁶² When administered in the first 10 days, and ideally within the first 7 days, of illness, intravenous immunoglobulin reduces the prevalence of aneurysms approximately fivefold, to less than 5%. Treatment with intravenous immunoglobulin is also beneficial for children beyond the tenth day of illness in whom fever persists, or who have coronary arterial abnormalities together with persistent clinical and laboratory evidence of inflammation.¹³⁴ The standard dosage is 2 g/kg, administered over 8 to 12 hours. In patients who present with diminished left ventricular function, the agent should be administered more slowly, because it provides a considerable volume load. Meta-analyses have demonstrated a dose-response effect,¹³² with this data underscoring the current practice of administering a second infusion to the 15% of children who have persistent or recrudescing fever at least 36 hours after completion of the first infusion. For children who defervesce with a second infusion, but in whom fever recurs, a third infusion may be administered. Some children have persistent fever, and develop coronary arterial aneurysms despite treatment, indicating resistance to intravenous gamma globulin. These children should receive alternative anti-inflammatory therapy.

Other Therapies

Corticosteroids are the mainstay of therapy for many childhood vasculitides, and they have been administered to children with Kawasaki disease, both as primary and rescue therapies. Uncontrolled case series, and one open and unblinded multi-centre randomised trial, have suggested that primary treatment may be beneficial.^{135–141} In a recent randomised, multi-centre placebo-controlled and blinded trial, primary therapy with pulsed-dose intravenous methylprednisolone did not improve outcomes with regard to coronary arterial lesions in patients who also received standard therapy with immunoglobulins and aspirin.⁸¹

More often, corticosteroid therapy is administered to the patient resistant to intravenous immune globulin, in whom at least two courses of immunoglobulins are unsuccessful in controlling fever. Once again, retrospective studies and case series suggest that treatment with steroids improves fever and the inflammatory response.^{142–146} In a randomised trial in patients with persistent fever after two treatments with immunoglobulins, patients randomised to pulse steroids, compared to those treated with immunoglobulins given at 1 g/kg, had fevers of shorter duration, and reduced length of stay in hospital, but no difference in the incidence of coronary arterial aneurysms.¹⁴⁶ Based upon the currently available literature, treatment with pulse steroids should be reserved for children who have persistent or recrudescent fever despite at least two courses of intravenous gamma globulin given at 2 g/kg.

Abciximab, a murine monoclonal antibody to the platelet glycoprotein IIb/IIIa receptor, has been reported in a single-center case series with historical controls to promote regression in the maximal diameter of the aneurysms.¹⁴⁷ This salutary effect is presumed to be secondary to promotion of vascular remodeling through the anti-inflammatory effects of abciximab.

Infliximab, a chimeric monoclonal antibody to TNF- α , is being used increasingly as rescue therapy in those patients who are resistant to immunoglobulins.^{148,149} Its efficacy in reducing the prevalence and severity of coronary arterial aneurysms is unknown.

Plasma exchange has been reported to lower the incidence of aneurysms in uncontrolled studies.^{150–152} Because this therapy is technically complex to administer, it should be used only when other methods have failed. Rarely, cytotoxic agents have been used to treat refractory patients with acute disease,^{145,153} but the risks of such therapies exceed their benefits for the majority of patients.

Prevention of Coronary Arterial Thrombosis

The risk of thrombosis depends upon the size of the coronary arterial aneurysm, as well as the presence of coronary arterial stenosis. Thus, the types of agents used for prophylaxis of thrombosis are tailored to the extent and severity of arterial involvement.⁶² Because randomised trials of anti-thrombotic regimes have not been performed, the choice of agents is derived primarily from experience in adults with atherosclerotic disease, including aneurysms, as well as case series and consensus of experts. Patients with small aneurysms are treated with aspirin in doses sufficient to produce an anti-platelet effect (see above). At the other end of the spectrum, giant aneurysms, with a diameter of greater than 8 mm, are characterised by stagnant flow, so anticoagulation with warfarin or low-molecular weight heparin is added to aspirin therapy. For most patients, the international normalised ratio is maintained between 2.0 and 2.5. Patients with giant aneurysms and a history of coronary arterial thrombosis may benefit from treatment similar to that used in patients after replacement of the mitral valve, using, for example, warfarin to maintain the international normalised ratio between 2.5 and 3.5 along with aspirin. The optimal anti-thrombotic regimen for patients with aneurysms intermediate in size between small and giant is controversial. Clopidogrel¹⁵⁴ or

anti-coagulation may be added to treatment with aspirin, depending upon the individual situation. For example, treatment of a 3-month-old infant with an aneurysm of 6 mm, with characteristics of flow similar to a giant aneurysm, usually includes anticoagulation together with aspirin. The same-sized aneurysm in an adolescent weighing 80 kg might warrant only anti-platelet therapy. Thus, it is important to consider the z scores, although guidelines for their use in choice of an anti-coagulation regimen have not been developed.

Treatment of Coronary Arterial Thrombosis

Thrombolytic therapy in children with coronary arterial thrombosis is primarily guided by studies in adults with acute coronary syndromes. The most common agent used in children is tissue plasminogen activator, at doses of 0.1 to 0.5 mg/kg/hr for 6 hours, administered together with aspirin and heparin or low-molecular-weight heparin.⁶² The burden of thrombus in a giant aneurysm is large, and some children have rebound of thrombosis after cessation of thrombolytic therapy. For this reason, treatment may occasionally involve a combination of tissue plasminogen activator and abciximab, given as a bolus of 0.25 mg/kg over 30 minutes, followed by an infusion of 0.125 μ g/kg/minute for 12 hours. Mechanical restoration of myocardial perfusion by means of interventional cardiology may be used in patients whose vessels are large enough to accommodate adult-sized catheters.

Interventional Catheterisation Procedures

The indications for interventional catheterisation procedures have not been assessed in randomised trials in children and adults with coronary arterial stenoses secondary to Kawasaki disease. Most of the techniques used in adults with atherosclerotic coronary arterial disease have been applied to the population of children with Kawasaki disease. These include percutaneous transluminal coronary angioplasty, rotational atherectomy, and placement of stents.¹⁵⁵ To provide practical interim suggestions for clinicians until evidence-based guidelines are available, the Research Committee of the Japanese Ministry of Health, Labor and Welfare published recommendations for conditions under which catheter intervention should be considered in such patients.¹⁵⁵ These include presentation with ischaemic symptoms, presence of reversible ischaemia on stress testing, or presence of at least 75% stenosis of the anterior interventricular coronary artery. Contraindications to catheter intervention include severe left ventricular dysfunction, and coronary arteries with multiple, ostial, or long-segment stenoses.

Longer-term results for catheter interventions have now been published with a median follow-up of 3.6 years.¹⁵⁶ For vessels in which angioplasty was used, the early success rate was 86%. For rotational atherectomy, the figure was 96%, and for placement of stents, 90%. At the latest follow-up, stenoses had recurred in 29% of arterial segments in which angioplasty had been performed: in 28% of segments following rotational atherectomy, and in 8% of segments following placement of a stent. Neoaneurysms were noted in 7% of segments treated with angioplasty and rotational ablation, likely related to the high pressure of

inflation needed to relieve stenoses in stiff coronary arteries. Procedures are best performed by a multi-disciplinary team that takes advantage of the technical expertise and knowledge of adult cardiologists, working together with paediatric cardiologists, anaesthesiologists, and nurses.

Surgery

As with interventional catheterisation procedures, the indications for bypass grafting in children with Kawasaki disease are based upon experience in adult patients and consensus of experts. Coronary arterial bypass surgery is performed with the goal of improving symptoms of angina, enhancing myocardial perfusion, and lowering the future risk of myocardial infarction or sudden death.^{157,158} Children with reversible ischaemia on stress-imaging tests are generally considered for intervention, be it transcatheter or surgical. In addition, high-grade obstructions in at least two major coronary arteries, or in the main stem of the left coronary artery, are indications for surgery because these findings predict a high risk of myocardial infarction. Some experts also consider high-grade stenosis in the anterior interventricular artery to be an indication for intervention. Bypass grafting is contraindicated when there is arterial disease distal to the planned anastomosis, or nonviable myocardium in regions supplied by the affected vessel.¹⁵⁹ Competing flow into arteries supplied by a graft causes a string sign, and may result in occlusion.

Although saphenous venous grafts were used in the earliest surgical series, they are rarely used today because of poor long-term patency in children.¹⁶⁰ Instead, arterial grafts, such as those provided using the internal mammary, radial, and gastroepiploic arteries, have better long-term patency, enlarge in length and diameter as the child grows, and improve myocardial perfusion.¹⁵⁸

Coronary arterial bypass procedures in children have low morbidity and mortality.¹⁵⁷ In a national survey of such grafting in Japan,¹⁵⁷ long-term rates of patency were shown to be affected by the age of the patient at the time of the graft. Specifically, when performed in children at least 12 years of age, internal mammary arterial grafts had patency rates of 95%, 91%, and 91% at 1, 5, and 15 years after surgery. Lower patency was seen in those who underwent surgery at ages younger than 12 years, at 93%, 73%, and 65%, respectively. Left ventricular ejection fraction of less than 40% was a risk factor for mortality. A recent small series suggests that the use of percutaneous transluminal balloon angioplasty for anastomotic stenosis after bypass grafting improves the long-term patency in small children to rates similar to those in older children.¹⁶¹

Cardiac transplantation can be performed in children with Kawasaki disease who have end-stage ischaemic cardiomyopathy in whom severe coronary arterial lesions cannot be treated further with interventional catheterisation or coronary arterial bypass procedures.¹⁶²

RECOMMENDATIONS FOR LONG-TERM FOLLOW-UP

The frequency of follow-up, types of testing, and specific recommendations regarding medications, exercise restrictions, and anticoagulation are summarised in [Table 52-4](#).¹⁶³

Certain principles for long-term management are common to patients with all levels of risk. Because the future risk of atherosclerotic coronary disease may be higher in children who have had Kawasaki disease, all children should undergo periodic assessment and counseling about known risk factors.¹⁶⁴ All patients and families should be counseled regarding a heart-healthy diet, the importance of exercise, and the risks of smoking. They should be encouraged to limit adverse effects from passive smoking, so a smoke-free home should be advised. A lipid profile should be obtained approximately 1 year after the onset of the illness. New recommendations from the American Heart Association have established the thresholds at which pharmacologic management of hyperlipidaemia and hypertension should be started, depending upon the severity of coronary arterial disease.¹⁶⁴ Paediatric cardiologists should strive to balance the need for preventive counseling for exercise and a heart healthy diet against the production of cardiac non-disease.

Regular aerobic exercise should be strongly encouraged in all patients to the extent advised in the recommendations of the 36th Bethesda Conference for their level of coronary arterial disease.¹⁶⁵ Those with arteries that were always normal, or only transiently dilated, have no need to restrict their exercise. In patients with coronary arterial disease, participation in competitive sports is guided by the results of non-invasive assessment of left ventricular function and exercise testing with myocardial perfusion imaging. Even patients at the highest categories of risk can participate in some types of competitive sports if they have normal left ventricular function and exercise tolerance, and no evidence of either reversible ischaemia or exercise-induced arrhythmias. Patients taking anti-platelet or anti-coagulant medications should be discouraged from sports involving collisions or high impacts because of the risk of bleeding.

IMPLICATIONS IN ADULT LIFE

Excellent follow-up of patients with Kawasaki disease has occurred only in the last three decades, so data are limited on its implications for life into adulthood. The standardised mortality ratio for males with cardiac complications has been reported to be 2.35, with 95% confidence intervals from 0.96 to 5.19, after long-term follow-up in Japan.¹⁶⁶ The failure of this finding to reach statistical significance may reflect the excellence of therapies for coronary arterial disease, and the rarity of severe coronary arterial aneurysms. Management of anti-coagulation in pregnancy be similar to that in the obstetric patient with a prosthetic valve,¹⁶⁷ and women should have reproductive counseling when they reach childbearing age. The largest series on pregnancy and delivery in women with coronary arterial aneurysms due to Kawasaki disease included 46 deliveries in 30 patients.¹⁶⁸ No patients had coronary arterial complications. To date, patients whose coronary arteries were always normal, or only transiently dilated, have not been found to suffer a higher incidence of cardiac or other diseases in follow-up. Japanese cohorts, nonetheless, will need to be followed into middle age before it is known whether even these patients are at risk for premature atherosclerosis. Continuing surveillance of such patients will be necessary to fully understand the implications of the disease for long-term

TABLE 52-4

RISK STRATIFICATION

Risk Level	Pharmacological Therapy	Physical Activity	Follow-up and Diagnostic Testing	Invasive Testing
I (no coronary artery changes at any stage of illness)	None beyond initial 6–8 weeks	No restrictions beyond initial 6–8 weeks	Cardiovascular risk assessment and counseling at 5-year intervals	None recommended
II (transient coronary artery ectasia that disappears within initial 6–8 weeks)	None beyond initial 6–8 weeks	No restrictions beyond initial 6–8 weeks	Cardiovascular risk assessment and counseling at 3- to 5-year intervals	None recommended
III (small to medium solitary coronary artery aneurysm)	Low-dose aspirin (3–5 mg/kg aspirin per day), at least until aneurysm regression is documented.	For patients in first decade of life, no restriction beyond initial 6–8 weeks. For second decade, physical activity guided by stress testing every other year. Contact or high-impact sports discouraged for patients on anti-platelet agents.	Annual cardiology follow-up with echocardiogram and ECG, combined with cardiovascular risk assessment and counseling. Stress testing with radio-isotope perfusion scan or stress echocardiogram every other year.	Angiography, if non-invasive test suggests ischemia
IVa (one or more large or giant coronary artery aneurysms), or IVb (multiple or complex aneurysms, without obstruction)	Long-term anti-platelet therapy and warfarin (target: INR 2.0–2.5) or LMW heparin (target: antifactor Xa level 0.5–1.0 unit/mL) should be combined in giant aneurysms.	Contact or high-impact sports, isometrics, and weight training should be avoided because of the risk of bleeding. Other physical activity recommendations guided by outcome of stress testing or myocardial perfusion scan.	Biannual follow-up with echocardiogram + ECG. Annual pharmacological or exercise stress testing.	Initial angiography at 6–12 months. Repeated angiography if non-invasive test, clinical or laboratory findings suggest ischemia. Elective repeated angiography under some circumstances (see text)
V (coronary artery obstruction)	Long-term low-dose aspirin. Warfarin or LMW heparin if giant aneurysm persists. Use of β -blockers should be considered to reduce myocardial oxygen consumption	Contact or high-impact sports, isometrics, and weight training should be avoided because of the risk of bleeding. Other physical activity recommendations guided by outcome of stress testing or myocardial perfusion scan.	Biannual follow-up with echocardiogram and ECG. Annual pharmacological or exercise stress testing.	Angiography is recommended to address therapeutic options.

This manuscript provides the classic description of pathology of the heart in fatal Kawasaki disease in a series of 20 hearts. The authors classify cardiac lesions according to the duration of illness at the time of death. Within the first 9 days of illness, the predominant findings were acute perivasculitis and vasculitis of the microvessels (arterioles, capillaries, and venules) and small arteries, and acute perivasculitis and endarteritis of the three major coronary arteries. Additional findings included pericarditis, myocarditis, inflammation of the atrioventricular conduction system, and endocarditis with valvitis. In the period from 12 to 25 days after illness onset, coronary aneurysms appeared. After 28 days, inflammation in the microvasculature disappeared and coronary arteries began to granulate. In the latest stage, 40 days to 4 years, aneurysms showed scarring with severe stenosis.

- Kato H, Ichinose E, Kawasaki T: Myocardial infarction in Kawasaki disease: Clinical analyses in 195 cases. *J Pediatr* 1986;108:923–927.

This manuscript provides the largest series of patients with myocardial infarction resulting from Kawasaki disease. The authors summarise cases in 195 patients with myocardial infarction from 74 hospitals in Japan. Approximately three-quarters of myocardial infarctions occurred within the first year after illness onset. The majority of myocardial infarctions (63%) occurred during sleep or at rest. The most common symptoms included shock, unrest, vomiting, abdominal pain, and chest pain; not surprisingly, older children were much more likely to report chest pain. Almost 40% of patients who suffered myocardial infarctions did not recognise or report symptoms at the time. The mortality rate from the first myocardial infarction was 22%, and 16% of patients had a second myocardial infarction. Fatalities were most likely to occur in those with left main disease or with coronary obstruction in both the proximal right coronary artery and the left anterior descending coronary artery. Survivors were more likely to have single vessel involvement of the right coronary artery.

- Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 2004;110:2747–2771.

This scientific statement prepared on behalf of the American Heart Association provides recommendations for the initial evaluation, treatment in the acute phase, and long-term management of patients with Kawasaki disease. It includes a new algorithm to guide clinicians in deciding which children with fever for greater than 5 days, and four or more classic criteria, should undergo echocardiography, receive intravenous gamma globulin, or both, for Kawasaki disease.

- Kato H, Sugimura T, Akagi T, et al: Long-term consequences of Kawasaki disease: A 10- to 21-year follow-up study of 594 patients. *Circulation* 1996;94:1379–1385.

This elegant study followed a cohort of 594 consecutive children with acute onset of Kawasaki disease between 1973 and 1983 for 10 to 21 years, with a mean of 13.6 years. All children had coronary angiography after recovery from the acute phase of the disease. Coronary arterial aneurysms initially were present in 146 patients (25%). By approximately 2 years later, 55% of aneurysms had shown regression. Regression was not seen, however, in giant coronary aneurysms. Coronary arterial stenosis increased progressively over time. Among the 448 patients with normal findings at the first angiogram, none developed any cardiac abnormalities over time. Systemic arterial aneurysms occurred in 2% of patients, and valvular heart disease in 1%. During the period of follow-up, 5% of patients developed ischaemic heart disease, and 2% had a myocardial infarction. The mortality rate was 0.8%.

- Tsuda E, Kamiya T, Kimura K, et al: Coronary artery dilatation exceeding 4.0 mm during acute Kawasaki disease predicts a high probability of subsequent late intima-medial thickening. *Pediatr Cardiol* 2002;23:9–14.

The authors correlated the maximal coronary arterial diameter in 28 patients during the acute phase of Kawasaki disease with the extent of intima medial thickening by intravascular ultrasound at a mean of 15 years later. The initial coronary arterial diameter was significantly related to late intima medial thickness in the right coronary, the anterior interventricular, and the circumflex arteries. Abnormal intima medial thickness was defined as being equal to or greater than 0.40 mm. Initial coronary arterial dilation exceeding 4.0 mm in any of the main coronary arteries predicted a high likelihood of late abnormalities in intima medial thickness, defined as greater than 0.40 mm, in the corresponding coronary arterial segment at late follow-up.

- Cheung YF, Yung TC, Tam SC, et al: Novel and traditional cardiovascular risk factors in children after Kawasaki disease: Implications for premature atherosclerosis. *J Am Coll Cardiol* 2004;43:120–124.

The authors studied a cohort of 102 subjects, 37 having Kawasaki disease with coronary arterial aneurysms, 29 subjects with Kawasaki disease and normal coronary arteries, and 36 healthy age-matched children. The subjects with coronary arterial aneurysms had lower high density lipid cholesterol and levels of apoA-I, and higher levels of apoB and pulse wave velocity than did the control subjects. Those with Kawasaki disease but without aneurysms had higher levels of apoB and pulse wave velocity than did control subjects, but similar levels of high density lipids and apoA-I. These data suggest that children with a history of Kawasaki disease may have an adverse cardiovascular risk profile, as characterised by a proatherogenic alteration of the lipid profile and increased arterial stiffness. Compared to the patients with Kawasaki disease but without aneurysms, those with coronary arterial aneurysms have a worse profile. This study raises concerns that children with a history of Kawasaki disease may be predisposed to premature atherosclerosis later in life.

- Ishii M, Ueno T, Akagi T, et al: Guidelines for catheter intervention in coronary artery lesion in Kawasaki disease. *Pediatr Int* 2001;43:558–562.

This manuscript from the Research Committee of the Ministry of Health, Labour, and Welfare in Japan provides guidelines for catheter intervention in those with coronary arterial lesions in Kawasaki disease. The guidelines review the background and natural history of coronary arterial abnormalities; indications and types of interventional cardiology procedures; and recommendations for management after the procedures.

- Tsuda E, Kitamura S: National survey of coronary artery bypass grafting for coronary stenosis caused by Kawasaki disease in Japan. *Circulation* 2004;110(11, suppl 1):II61–II66.

These authors provide information from a national survey of coronary arterial bypass grafting in Japan in calendar year 2002. Among 323 institutions returning the survey instrument, 244 patients who underwent bypass grafting since 1975 were identified. Median age at surgery was 11 years, median interval from onset of Kawasaki disease to surgery was 8 years, and median duration from surgery to follow-up was 5 years. More than one in four patients had had a myocardial infarction prior to surgery. In children whose bypass grafting was performed at an age of at least 12 years, patency rates for internal mammary artery grafting at 1, 5, and 15 years of follow-up were 95%, 91%, and 91%, respectively. The corresponding results for children younger than 12 years at surgery were 93%, 73%, and 65%. Of the children, 6% underwent reoperation. Among 14 late deaths, 9 were sudden. The mortality rate was especially high, at 75%, among children with ejection fraction less than 40%.

- Kavey RE, Allada V, Daniels SR, et al: Cardiovascular risk reduction in high-risk pediatric patients: A scientific statement from the American Heart Association Expert Panel on Population and Prevention Science; the Councils on Cardiovascular Disease in the Young, Epidemiology and Prevention, Nutrition, Physical Activity and Metabolism, High Blood Pressure Research, Cardiovascular Nursing, and the Kidney in Heart Disease; and the Interdisciplinary Working Group on Quality of Care and Outcomes Research: Endorsed by the American Academy of Pediatrics. *Circulation* 2006;114:2710–2738.

This scientific statement prepared on behalf of the American Heart Association emphasises that children with certain diagnoses, including Kawasaki disease, are at risk for premature cardiovascular disease, and provides practical recommendations for management of cardiovascular risk. Thresholds for pharmacologic treatment of hyperlipidaemia and hypertension in children with Kawasaki disease are stratified according to whether a child has current coronary arterial aneurysms, regressed aneurysms, or no history of coronary arterial abnormalities.

- Tsuda E, Kawamata K, Neki R, et al: Nationwide survey of pregnancy and delivery in patients with coronary arterial lesions caused by Kawasaki disease in Japan. *Cardiol Young* 2006;16:173–178.

The authors provide a survey of pregnancy and delivery in patients with a history of Kawasaki disease in Japan, analysing 46 deliveries in 30 patients from 16 institutions. Coronary arterial bypass grafting had been performed in 4 patients, and 16 patients were receiving low-dose aspirin. No cardiac complications occurred in any patient. The authors recommend that the mode of delivery should be determined primarily by obstetrical considerations, rather than the coronary arterial disease.

Non-rheumatic Inflammatory Diseases of the Heart

EDWARD J. BAKER

In this chapter, I will discuss inflammatory diseases of the heart, excluding rheumatic fever (see Chapter 54), Kawasaki disease (see Chapter 52), and infectious endocarditis (see Chapter 55). Although the heart may be the primary target organ, inflammatory disease of non-rheumatic origin is often more generalised in nature. Usually such diseases affect various structures of the heart in combination. Only rarely will they be limited to the endocardium, the myocardium, or the pericardium. To clarify the discussion, however, I will distinguish between myocarditis and pericarditis.

MYOCARDITIS

Myocarditis is defined as an inflammatory response within the myocardium. Its aetiology and pathogenesis are very variable. In many patients, the precise mechanisms involved still remain unclear. The clinical consequences of myocarditis are largely determined by the degree and extent of myocardial injury. The disease may first present with pump failure, or with abnormalities of rhythm and conduction. In the acute stage, sudden death may occur, often before the diagnosis is made.

The heart is often dilated, with histological studies revealing myocardial necrosis, with accompanying inflammatory reactions (Fig. 53-1). The degree and extent of myocardial necrosis may vary considerably, as may the type of

inflammation. Usually, neither one of these histological findings is diagnostic as far as aetiology and pathogenesis are concerned. In more advanced stages of the disease, part of the damaged myocardium may be replaced by scar tissue. Eventually, the histology of the affected heart may be dominated by interstitial fibrosis. In such instances, the condition is often described as chronic myocarditis. Various schemes for the histological grading of myocarditis have been described, most notably the Dallas criteria.¹ Recently, it has been established that the use of these criteria is unreliable when assessing endomyocardial biopsies to diagnose myocarditis.² The myocardial changes are not uniform, and the findings depend on the site of sampling. Furthermore, there are significant differences in interpretation of the histology between histopathologists. It is now established that virus may be present in the myocardium without the Dallas criteria for myocarditis being fulfilled.³ Most importantly, the Dallas classification does not predict prognosis, nor response to immunosuppressive therapy.

Myocarditis may be associated with a variety of aetiological factors including infections, ischaemia, and generalised inflammatory conditions. In children, two main classes of non-rheumatic myocarditis can be recognised: the infectious and generalised autoimmune variants.

Infectious Myocarditis

Infectious myocarditis can occur as a complication of almost any infectious disease. Viral infections are by far the most important in the industrialised Western world, but in other parts of the world, protozoal infections may rank highest. Many acute bacterial infections can result in myocarditis. It can occur as a complication of tuberculosis, Lyme disease, and haemolytic uraemic syndrome.^{1,4-6} Infectious myocarditis is a frequent complication of opportunistic infections in patients with immune deficiencies, either primary or secondary, such as those that occur in patients treated with immunosuppressive drugs. Obviously, therefore, the type and incidence of infectious myocarditis will vary considerably from one part of the world to another. Moreover, its true prevalence in any given population is, as yet, unknown. This is because the disease may take a subclinical course in many patients, and, hence will go undetected. In others, the presence of an infectious myocarditis may be completely masked by the more overt signs and symptoms of other affected organs. Depending on the histological criteria used, evidence of myocarditis has been found in up to one-twentieth of postmortems.⁷ It has been demonstrated to be present in approximately one in ten

Figure 53-1 The slide shows the typical histologic features of viral myocarditis. There is heavy lymphocytic infiltration with myocardial cell degeneration and necrosis. (Courtesy of Professor Sebastian Lucas, Guy's and St Thomas's Hospital, London, United Kingdom.)

sudden deaths in young adults, and a similar proportion of patients with dilated cardiomyopathy.⁸

Viral Myocarditis

The majority of the cases of myocarditis seen in the West are of viral origin. Almost any viral disease can be complicated by myocarditis. Hence, the clinician should always be alert to this possibility. Viral myocarditis can present with ventricular dysfunction of rapid onset, or with progressive ventricular dysfunction and dilation. Viruses are known to be present in the myocardium of many patients with dilated cardiomyopathy even when the histological criteria for myocarditis are not evident. Enteroviruses, particularly those of Coxsackie group B, have been considered important causes, but molecular studies using the polymerase chain reaction have shown that adenoviruses are more commonly found in the myocardium in patients with clinical myocarditis.⁹ Cytomegalovirus, echovirus, hepatitis C, respiratory syncytial virus, and the viruses producing influenza, mumps, and rubella have also been implicated.^{10,11} Human immunodeficiency virus also commonly infects the heart.¹² In children, it can cause myocarditis and pericarditis, often presenting with the picture of a dilated cardiomyopathy.^{13,14}

The viral infection may be acquired transplacentally or postnatally. The infection may present in neonates and infants, with myocarditis as the leading abnormality. Infections in older children often cause pericarditis as the dominant feature. The mechanisms involved in producing the myocardial injury are complex. Invasion of the myocardial cells by viruses, or elaboration of toxins, may play an important role. Alternatively, cellular immune mechanisms and circulating autoantibodies may be of great importance. A combination, which may vary considerably between individual patients, of viral infection and subsequent abnormal immune response, causing either ineffective viral clearance or autoimmune myocyte damage, seems to underlie the clinical manifestation of the disease. Persistence of the virus, or continuing immune reactions after the viral infection has cleared, may produce chronic myocardial damage and present as chronic dilated cardiomyopathy.

Clinical Features

The clinical onset of myocarditis usually occurs after a latent period following the onset of a systemic viral infection. The signs and symptoms of myocarditis are highly variable, but are principally the result of cardiac failure or disturbances of rhythm. It is understandable, therefore, that there is no single characteristic clinical profile for myocarditis. Indeed, a whole spectrum of abnormalities may exist. At the one end, a child may develop an infectious myocarditis that remains completely unnoticed. At the other end, a child may become acutely ill with signs of both left- and right-sided cardiac failure and low cardiac output, often further complicated by disturbances of rhythm and sudden death.

All signs and symptoms, even the most subtle ones, which indicate failing pump function or abnormalities in rhythm and conduction, should alert the physician to a cardiac complication. This is particularly so when noticed in the setting of a viral disease. In this respect, the important

features that may give a clue to the diagnosis are cardiac enlargement, cardiac failure, tachycardia, gallop rhythm, tachypnoea, dyspnoea, fatigue, and the appearance of an apical murmur indicating mitral insufficiency. There may be chest pain from accompanying pericarditis. Non-specific symptoms, such as fever, diarrhoea, problems with feeding, pallor, mild jaundice, and lethargy, often mark the clinical onset of the principal disease. Occasionally, the clinical picture may be dominated by severe respiratory distress secondary to left ventricular failure, so much so that initially a respiratory infection is mistakenly diagnosed. The clinical picture of cardiac failure in a previously well child with often a minor, preceding viral infection is typical.

Laboratory Findings

The sedimentation rate is usually elevated but may be normal. The level of C-reactive protein may also be elevated, and this may be of prognostic significance.¹⁵ The white cell count is variable, as are the levels of the cardiac enzymes, all depending on the severity of the disease and the nature of the infection. Levels of troponin are frequently, but not invariably, elevated.

All available diagnostic procedures should be used, including close collaboration with the bacteriological laboratory, in an attempt to identify an infectious agent. Despite all studies, however, the diagnosis of a viral origin is often based on circumstantial evidence, along with the exclusion of other possible aetiologies, rather than positive identification of an aetiological agent.

Investigations

Radiology

The size of the heart may be normal, particularly in the early period of the disease. More frequently, the heart will be enlarged, with normal lung fields. Occasionally, pulmonary venous congestion will be evident.

Electrocardiography

Electrocardiographic abnormalities are common in myocarditis, but are non-specific (Fig. 53-2). There is often a sinus tachycardia, with lowering of the QRS complexes in the standard leads and/or precordial leads, flattening or inversion of the T waves, and changes in the ST segment. Arrhythmias are often present and may lead to unexpected death. Occasionally, disturbances of conduction are seen, with varying degrees of heart block. Complete atrioventricular block is rare. The QRS complexes may be broadened, with left or right bundle branch block configuration. The electrocardiographic changes may disappear during the course of the disease, or they may show a progressive evolution to overt abnormalities. The abnormalities may persist after the patient has recovered clinically, most likely because of myocardial fibrosis.

Echocardiography

Echocardiography may demonstrate important, albeit non-specific, features. There is usually dilation of the heart chambers, usually predominantly the left ventricle. When the onset is rapid, producing so-called fulminant myocarditis, there may be ventricular dysfunction without dilation. Ventricular dysfunction is usually much more evident in the left ventricle than in the right, and may be either

Figure 53-2 The electrocardiogram is from a 9-year-old boy with viral myocarditis. The electrocardiogram on admission (A) showed first-degree atrioventricular block with broad QRS complexes. There is an infarction pattern with QS complexes in all precordial leads. After 30 days, the electrocardiogram had normalised (B), but there was left-axis deviation with slightly broadened QRS complexes, indicative of incomplete left bundle branch block. After 4 years the electrocardiogram had not changed in any important way.

global or segmental. The left atrium may also be enlarged, especially in the presence of mitral insufficiency (Fig. 53-3). The motion of the ventricular septum, and of the ventricular walls, may be reduced and abnormal, while the ejection fraction may be decreased. Echocardiographic tissue characterisation, tissue Doppler imaging, and measurements of myocardial velocity have been shown to differentiate myocarditis from other causes of ventricular dysfunction, albeit that further work will be needed to determine their value in a clinical setting.

The echocardiogram is of great importance in demonstrating or excluding a pericardial effusion and intracardiac thrombosis, and for excluding structural causes of ventricular dysfunction. Identical echocardiographic findings are found in chronic myocarditis and dilated cardiomyopathy.

Other Imaging Techniques

Radionuclide scans have been used for the detection of myocarditis, using either gallium-67 scans or indium-111-labelled monoclonal antimyosin antibody.¹⁶ In practise, the most valuable role of radionuclide imaging is the serial measurement of left ventricular function, where it provides a more reproducible measurement of function than does echocardiography.

Early studies with contrast-enhanced magnetic resonance imaging have shown considerable promise in detecting myocarditis. Focal myocardial enhancement correlates with myocardial injury and histological changes. This has been used to guide biopsy of affected regions, improving the accuracy of histological diagnosis.¹⁷

Endomyocardial Biopsy

The place of routine endomyocardial biopsy in suspected myocarditis is still unclear. The histological changes of myocarditis are patchy, and so there can never be total confidence that a negative biopsy excludes myocarditis. There is little evidence that biopsy is of value in determining prognosis, or in helping further management.¹⁸ The risk of the biopsy procedure is highest in the acutely unwell young child with severe ventricular dysfunction.¹⁹ After many years of pursuing a policy of routine biopsy in suspected cases, in our own centre we have been unable to demonstrate any benefit, and have abandoned the practise. It is increasingly being used to enable identification of the viral aetiology by analysis of the polymerase chain reaction.⁹ Biopsy may be justified in selected cases with unusual or

rapidly progressive presentation, or where histology is used to guide therapy.⁸

Treatment

If an infectious agent has been identified as the cause of the myocarditis, and a specific treatment is available, then that should be started. In most cases, the causative agent is not identified. Treatment will then be non-specific, aiming at lowering the cardiac pre- and afterload, and at preventing and controlling complications such as cardiac failure and disturbances of rhythm.

Bedrest is advised for at least 14 days in the acute stage in order to reduce the workload of the heart. A good response is characterised by a sleeping pulse rate of less than 100 beats per minute in children, and of less than 120 beats per minute in infants. Restlessness and hypoxic stress should be avoided. If necessary, oxygen is administered.

Diuretics and inotropic agents may well need to be given intravenously in the initial stages of treatment. In a minority of patients, ventilation and circulatory support may be needed. The place of extracorporeal membrane oxygenation is not well established. As the ventricular function can recover, it should be considered in critically ill patients. Cardiac failure should be treated with diuretics, inhibitors of angiotensin-converting enzyme, and β -blockade.

Patients should be closely monitored for the occurrence of arrhythmias. When present, these disturbances should be treated if they have a deleterious haemodynamic effect. Many antiarrhythmic drugs will further depress myocardial contractility and should be used with care.

Thrombosis can occur in those with very dilated atrial and ventricular chambers. In such patients, transoesophageal echocardiography is needed to exclude intracardiac thrombosis with confidence. Anticoagulation should always be considered in these circumstances. If evidence of intracardiac thrombosis is seen echocardiographically, anti-coagulation should be continued until the left ventricular function has improved.

The value of prescribing drugs that suppress the inflammatory reaction is unclear.²⁰ Immunosuppression is used more commonly in children than in adults with myocarditis. There is no scientific justification for this diversity of approach. It was advocated in the expectation that

Figure 53-3 These cross sectional echocardiograms are from a child with acute myocarditis, with subcostal (A), parasternal short-axis (B), parasternal long-axis (C), and apical long-axis (D) views. The images show dilated cardiomyopathy, each view being dominated by the globular, dilated, left ventricular cavity. Function was very poor, with an estimated left ventricular ejection fraction of 15%. There was moderate mitral incompetence on colour Doppler.

immunosuppressive therapy would resolve the cellular infiltrate in the myocardium and, hence, reduce mortality and morbidity. The use of corticosteroids is advocated for patients with biopsy-proven disease who fail to respond to conventional therapy.²¹ Steroids have been reported to help in the treatment of heart block or ventricular tachycardia brought on by myocarditis.²² Despite this anecdotal evidence, a trial has shown no benefit from the routine use of prednisolone combined with either cyclosporin A or azothioprine.²³ Immunosuppression has been shown to be of value in a rare histological variant of myocarditis—giant cell myocarditis.²⁴ Immunoglobulin given intravenously in high doses may be beneficial in improving the recovery of ventricular function.²⁵ It is widely used in children, but clinical trials have not yet shown that it improves the recovery of left ventricular function or the long-term outcome.²⁶

Children may die during the acute phase of the illness. In those whose left ventricular function is poor, failing to improve and remaining dependent on diuretics or inotropic agents given in high doses intravenously to control cardiac failure, or in those who develop intractable life-threatening

arrhythmias, the option of cardiac transplantation should be considered. Transplantation may also be necessary for those who recover from the acute phase of myocarditis but continue to have poor left ventricular function over the longer term.

Prognosis

Many children make a full recovery from myocarditis. Older children, and those with a lower ejection fraction at presentation, have a worse prognosis.²⁷ The clinical signs and symptoms usually subside within a few weeks or months. It may take a little longer for the size of the heart and the electrocardiogram parameters to normalise. In some patients, this may take a year or more. Occasionally, the heart may remain enlarged, or episodes of cardiac failure may recur after an initial favourable response. The prognosis in these patients is usually poor. One recent large study showed that two-thirds of children presenting with cardiac myocardial failure were alive without cardiac transplantation at 1 year. Including the patients that had transplantation, more than

four-fifths were surviving at 1 year, albeit that most were still on medication 1 year after presentation.²⁸ A further study showed an overall incidence of dilated cardiomyopathy in children under 18 years of 0.57 cases per 100,000. Of these almost half were diagnosed as myocarditis, three-tenths had died or required transplantation at 1 year, and only just over half were alive at 5 years.²⁹

Differential Diagnosis

Myocarditis needs to be distinguished from other anomalies that present with signs and symptoms of acute cardiac failure early in life. A variety of metabolic diseases may present with dilated cardiomyopathy in infancy, and these should be excluded (see Chapters 49 and 57). When the left coronary artery arises anomalously from the pulmonary trunk, the characteristic features are the electrocardiographic signs of an anterolateral myocardial infarction. The diagnosis can be confirmed echocardiographically, or by angiocardigraphy. Enlargement of the heart and cardiac failure may also be caused by longstanding and severe anaemia of various causes. Dilation of the heart may occur also as a secondary phenomenon in patients with systemic arterio-venous fistulas. Occasionally, a child may present with all the signs and symptoms of dilated cardiomyopathy without a history of an acute disease. Acute cardiac failure accompanied by mitral insufficiency is often the leading symptom. From a clinical viewpoint, there is no difference from chronic myocarditis.

GENERALISED AUTOIMMUNE MYOCARDITIS

Generalised autoimmune myocarditis encompasses a heterogeneous group of diseases. Some cause myocarditis as the dominant feature, while others have an arteritis as the leading pathology. These diseases are also known as collagen, connective tissue, diseases. I discuss here only the cardiac aspects of the two most important diseases relevant to children.

Systemic Lupus Erythematosus

In systemic, or disseminated, lupus erythematosus, the myocardial lesions consist mainly of fibrinoid changes in the connective tissue with a cellular reaction. Similar changes may affect the valves, notably the mitral and aortic valves. The lesions may heal leaving fibrous scars. Libman and Sacks³⁰ described the distinctive type of valvar and mural endocarditis that occurs in this condition. It is characterised by verrucous lesions along the line of closure of the valves, as well as along the ventricular surface of the leaflets extending onto the mural endocardium. The disease usually has a systematised character and involves many systems, including the heart. Cardiovascular manifestations are infrequent in children.

Cardiac Manifestations

The dominating cardiac feature is pericarditis. A pericardial friction rub is often present, and the chest radiograph will show an enlarged heart. Myocardial involvement may underscore cardiac failure. The latter feature may be complicated further by valvar dysfunction, either as part of the disease or secondary to the ventricular volume overload and accompanying dilation of the chambers. Mitral

insufficiency is the most frequent valvar abnormality, although significant aortic insufficiency has been described. The electrocardiogram will usually show non-specific changes of the ST segment. Disturbances of rhythm and conduction are frequent.

Treatment

The treatment of choice is corticosteroids, which also have a favourable effect on the management of cardiac dysfunction. Deleterious effects on the heart have been described, nonetheless, from chronic administration of suppressive doses of prednisone.

Dermatomyositis

Pathology

Dermatomyositis is a multi-systemic disease of uncertain aetiology. It is characterised by diffuse non-suppurative inflammation of striated muscle and skin. Initially, there is oedema of the subendothelial connective tissue, with collection of inflammatory changes round cells in both skin and muscle. Hyalinised material is found in the media of the arterioles, with inflammatory reaction in and around the vessels. In the phase of healing, there may be deposition of calcium salts in skin, subcutaneous tissues, and interfascial planes of muscle. The myocardium may show loss of striations, fragmentation, and vascularisation of myocytes. The interstitial tissues of the heart may also show swelling and oedema.

Cardiac Involvement

Tachycardia is the most common finding. The electrocardiogram may be normal, although occasional abnormal T-waves may be encountered. Complete heart block and arrhythmias have been reported. Murmurs are heard in about one-tenth of cases. Cardiac enlargement and cardiac failure are uncommon. Acute myocarditis, and pericarditis with a pericardial friction rub, have been described.

Treatment and Prognosis

In most instances, long-term treatment with prednisone is beneficial. Other immunosuppressive agents are rarely required. Most children will recover, and medication can be discontinued over 1 or 2 years.

PERICARDITIS

Pericarditis is defined as an inflammatory reaction of the pericardium in response to injury, whether infectious or non-infectious in nature. Its precise incidence is unknown, but there is evidence that, clinically, pericarditis may often pass unnoticed. Indeed, clinical recognition will depend heavily upon the type and severity of the pericardial reaction. When limited, it may easily resolve without attracting notice. It often co-exists with myocarditis. As with myocarditis, the aetiology of pericarditis differs considerably from one part of the world to another. Infectious causes, such as tuberculosis, and pericarditis caused by a generalised autoimmune disease, such as rheumatic fever, are rare in the West. They still form a major threat in other parts of the world.

Pathophysiology

The pericardium is a double-layered sack lined by mesothelial cells and lubricated by a thin film of fluid. This construction enables the heart to move freely without friction.

An accumulation of fluid within the sack, however, may cause cardiac dysfunction, particularly when it occurs over a short period of time. Likewise, a fibrous change within the pericardial layers may have an effect upon cardiac function.

An inflammatory response of pericardium may cause exudation as part of the reaction. This may lead, in turn, to an excessive accumulation of fluid within the pericardial sack. This can cause a rise in intrapericardial pressure. Compression of the heart by the pericardial fluid can cause a decrease of cardiac output, stroke volume, and systolic arterial pressure, resulting in cardiac tamponade. The pericardium is relatively inelastic, and as a result, the pressure-volume relationship of the heart has a progressively rising slope. An initial increase in intrapericardial fluid does not result in a substantial rise in pressure, whereas additional accumulation of fluid will very soon result in a significant elevation of pressure. Likewise, in patients with signs and symptoms of cardiac tamponade owing to excessive intrapericardial fluid, evacuation of a small amount may cause a marked decrease in pressure.

The time during which the fluid accumulates plays a major role. Slow accumulation of fluid will stretch the pericardium gradually. This is much better tolerated than conditions that lead to a rapid increase, and hence equally rapid build-up of pressure. In more severe forms of pericarditis, the increased pressures will lead to impaired venous return during ventricular diastole. This results in a decline in cardiac output. During inspiration, the blood pressure may abnormally fall by more than 10 mm Hg, leading to the so-called paradoxical pulse. In its most severe form, no further filling of the cardiac chambers is possible, and the patient will die with signs of electro-mechanical dissociation. Acute cardiac tamponade is rare in infants and children.

In patients with a haemodynamically significant build-up of pressure within the pericardial sack, several compensatory mechanisms develop in an attempt to maintain an adequate cardiac output. An increase in heart rate, together with peripheral vasoconstriction, increases the afterload of the heart. This results in a higher mean pressure at the expense of a narrow pulse pressure. These compensatory mechanisms are vital. They should not be corrected, as cardiac output may then drop even further. Injudicious use of diuretics in such circumstances can make matters worse rather than better. Constrictive pericarditis was once most commonly seen as a complication of tuberculous pericarditis. Acute viral or idiopathic pericarditis is now a more common antecedent.³¹ It is uncommon in childhood.

Clinical Features

In adults with acute fibrinous pericarditis, precordial pain is often the dominant symptom. In childhood, this symptom is less important. When it does occur, the site, radiation, severity, and character of the pain are highly variable. The discomfort may be diminished by sitting up and leaning forward. Other manoeuvres, such as inspiration, deep breathing, and coughing, may increase the sensation of discomfort. At this stage, the pericarditis does not necessarily interfere with the circulation.

At physical examination, the friction rub is the most typical and diagnostic finding, although its absence does not exclude the presence of pericarditis. The rub is maximal along the left sternal border but is often audible over the

entire precordium. It is best heard with the patient sitting up or leaning forward. When the pericardial effusion increases, the friction rub may be heard intermittently, or it may disappear totally. The presence of a pericardial rub, however, does not exclude the presence of a large effusion. With marked effusions, the heart sounds are often muffled, and they may become extremely faint. The development of a pericardial effusion does not always produce symptoms. Hence, it may escape clinical notice.

With an increase of fluid, cardiac tamponade will develop. This is characterised by a rise in venous pressure, an enlargement of the liver, and the presence of peripheral oedema. The systolic blood pressure is low, and the pulse pressure is narrow. A paradoxical pulse is often present. The patient usually appears sick, anxious, and distressed, and is cyanosed and dyspnoeic. Moreover, fever, tachycardia and tachypnoea are commonly present. Signs and symptoms of toxicity are often present when the pericarditis is caused by bacterial infection. This condition should be considered an emergency, requiring prompt medical or surgical treatment. A large pericardial effusion can compress the lower part of the lung. This can result in dullness on percussion and bronchial breathing laterally and at the back, a combination known as Ewart's sign.

Investigations

Echocardiography

Cross sectional echocardiography is the most important diagnostic technique. If a pericardial effusion is suspected as a cause of haemodynamic compromise, the examination should be undertaken urgently. In the normal heart, the pericardial sack is hardly identified. The anterior right ventricular wall of the heart is in direct contact with the anterior chest wall, and the inferior and posterior left ventricular walls are in direct contact with the diaphragm, the posterior mediastinal structures, and the pleura. A pericardial effusion will widen the space because of the accumulation of fluid, which does not reflect ultrasound (Fig. 53-4). Echocardiography will show this echo-free space around the heart. Thickening of the pericardium is an uncommon finding. Cross sectional echocardiography permits an approximate estimation of the quantity of the collected fluid.

The majority of patients with small-to-moderate effusions demonstrate essentially normal cardiac motion. Patients with an acute small-volume tamponade produced by a small volume of fluid may demonstrate a limited motion of the cardiac walls. In the presence of large effusions, excessive cardiac displacement may occur. This is observed mainly in benign viral pericarditis and malignancies, but it is rare in children. Cardiac tamponade is a clinical and not an echocardiographic diagnosis.³² The echocardiographic differentiation of a haemodynamically insignificant effusion from one with tamponade is not easy, but the findings indicating tamponade are diastolic collapse of the right atrial, right ventricular, and left atrial walls.³³ In addition, when there is tamponade, Doppler interrogation of the superior caval vein will show an absence of diastolic flow.³⁴

Radiology

The cardiac silhouette may be normal as long as a sizeable effusion is absent. Fluid in the pericardial sack manifests itself radiologically as an enlarged silhouette. In borderline

Figure 53-4 The cross sectional echocardiograms show a pericardial effusion. The parasternal long-axis view (A) shows a small posterior effusion behind the left ventricular free wall, between the two cross hairs. There is also a collection anterior to the right ventricle. The subcostal view (B) shows a large anterior collection of fluid extending from around the right atrium and ventricle to the apex of the heart (between cross hairs). At the level of the right atrium, it measured over 8 mm in width.

cases, comparison with a previous radiograph can be most helpful. As fluid accumulates, the cardiac silhouette increases. This manifests as blunting of the cardiophrenic angles, and disappearance of the sharp angulations between contiguous structures of the heart and great vessels. Changes in the configuration of the cardiac silhouette are occasionally observed when the patient is changed from a recumbent to an upright position. In children, this is not a very reliable finding.

Electrocardiography

Sequential electrocardiographic changes are observed in most patients with pericarditis³⁵ (Fig. 53-5). They are the result of subepicardial myocardial damage. In the initial stage of the disease, the ST segment is elevated in almost all leads except for leads V₁ and aVR, which often remain unaltered. After a few hours to days, the ST segments may return to the baseline, and the T waves may become flat (Fig. 53-6). In a later stage, the T waves may become inverted. The electrocardiogram may return to normal during convalescence, although the T waves may remain inverted for several months. They may occasionally remain in this form as a permanent change.

Figure 53-5 The electrocardiograms are from a 7-year-old boy with pericarditis. On the first day of fever, when he suffered precordial pain, there is ST elevation in nearly all leads (A). After 4 weeks (B), there are negative T waves, especially in the leads I, II, V₁-V₆. After 1 year (C), the electrocardiogram is nearly normal, but there is still a flat T wave in lead I.

In patients with pericardial effusion, the electrocardiogram may have a generalised low voltage. Sinus tachycardia unrelated to fever or other cardiac problems may be present in the initial phase. Supraventricular tachycardias, and ventricular ectopic beats, are a regular phenomenon. None of these changes, however, can be considered specific for pericarditis. Indeed, the electrocardiogram may occasionally remain completely normal.

Pericardiocentesis

Where there is tamponade, or when the pericardial fluid needs to be drained for diagnostic reasons, the choice is between percutaneous aspiration and surgical evacuation. The echocardiographic appearances are of critical importance in determining the correct approach. Where there is tamponade, with a large, tense collection of non-loculated fluid, aspiration is usually the quickest and safest approach.

Figure 53-6 The electrocardiogram is taken from a 14-year-old girl with pericarditis. On admission, 1 week after onset of the disease (A), the T waves are flat in the leads I, II, V₁, and V₆ and negative in II, III, ACF, and V₄. After 4 weeks (B), the electrocardiogram has normalised.

This should always be done with echocardiographic guidance. Screening with X-ray and electrocardiographic guidance are also of value. The safest approach is subxiphoid. Ideally, the patient should be tilted head up, thus encouraging the pericardial fluid to collect anteriorly and inferiorly. Under local anaesthesia, a needle is inserted at about 45 degrees to the abdominal wall. It should be angled cranially, and slightly toward the left. The needle is aspirated as it is advanced. As the pericardium is entered, it is felt to give, and the pericardial fluid will fill the syringe. If the needle is connected to the V lead of an electrocardiogram, the signal will indicate if it has been advanced too far and touched the heart. Radiography can be used, or echocardiographic contrast can be injected, if there is doubt about the position of the tip of the needle.

Once the pericardium is entered, it is best to exchange the needle for a soft pigtail catheter over a wire. The pericardial fluid can then be aspirated. In the setting of recurrent accumulations of fluid, the pigtail catheter can be left in place as a pericardial drain. The fluid should be sent for bacteriologic and cytologic examination. Percutaneous aspiration is a straightforward and safe procedure where there is a large anterior collection of fluid. When the collection is small, or predominantly posterior, aspiration is more difficult and more dangerous. Under these circumstances, or when the fluid is loculated or the accumulation is recurrent, surgical evacuation with the creation of a pericardial window should be considered.

Specific Syndromes

Acute Bacterial Pericarditis

Since the introduction of antibiotics, the incidence of acute bacterial pericarditis has declined drastically. In the West, it has become a rare condition. It remains an important disease, nonetheless, from the point of view of therapy and prognosis. In most instances, bacterial pericarditis is caused by septicaemia, or direct spread from another site of infection, although such a primary site may pass unnoticed. Well-known sources for bacterial pericarditis are pyelonephritis, osteomyelitis, tonsillitis, bacterial pneumonia, and left-sided empyema. Pericarditis may complicate a bacterial endocarditis. It is then usually caused by direct spread from the valvar lesions into the epicardium (see Chapter 55).

The microorganisms most commonly involved are *Haemophilus influenzae*, *Staphylococcus*, *Pneumococcus*, *Meningococcus*, and *Streptococcus* species. Almost any microorganism, however, may cause pericarditis.³⁶ In children in particular, involvement of the pericardium used to be a most hazardous complication of the tuberculous infection.

Usually the disease has an acute onset with pain, high fever, tachycardia, and tachypnoea. The children often present with signs and symptoms of toxicity. Indeed, the clinical findings of pericardial tamponade and sepsis are highly suggestive of bacterial pericarditis. A friction rub may be present but, on other occasions, the heart may be enlarged with a rapid rate without a friction rub. These findings in the presence of high fever are most suggestive for the presence of bacterial pericarditis. The patient may rapidly deteriorate, and prompt and adequate therapy is required.

Since bacterial pericarditis is often secondary to another infection elsewhere, an intensive search is always necessary

for such a primary source. Whenever possible, the medical treatment of bacterial pericarditis should be based on the identification of the primary organism, so that the most effective treatment can be selected. Any previous antibacterial treatment may interfere with this goal. Microbiological and chemical investigations of the pericardial fluid are essential. Cytological studies should be performed to exclude a malignancy.

Blood cultures are important, and from three to five sets should be taken in the first 1 or 2 days after admission. In two-fifths to four-fifths of patients, these cultures will be positive, depending on the organism involved. Specific stains for acid-fast bacteria in the sputum, gastric contents, or urine may disclose tuberculosis as the primary disease. Lumbar puncture may be necessary to prove or eliminate concomitant meningitis.

Appropriate treatment consists of prompt and adequate antibiotic therapy, together with evacuation of the pericardial fluid. The antibiotic therapy should be guided by the sensitivity of the causative organism. If possible, broad-spectrum antibiotics should be avoided. The duration of treatment depends upon the clinical response, but a total period of antibiotic therapy of at least 4 to 6 weeks is usually necessary. The curve of the fever, sedimentation rate, and white blood cell count may be helpful in evaluating the effectiveness of the treatment. A pericardial tap may be sufficient for diagnostic purposes, but a needle or a small-bore pericardiocentesis tube is inadequate for the evacuation of the pericardial fluid. This is because the pus is often loculated or thick. Subxiphoid surgical drainage with a large-bore pericardiostomy tube, or a pericardiectomy, should be performed to obtain the optimal results.

Acute Viral Pericarditis

Viral pericarditis is almost always accompanied by a myocarditis. It is the latter that usually dominates the clinical manifestations. The precise incidence of viral myopericarditis is unknown, but it is probably much higher than can be distilled from the reports in the literature. It is likely that many cases of viral myopericarditis will pass unnoticed. In approximately four-fifths of patients with the typical signs and symptoms of acute pericarditis, the aetiology cannot be established, even after extensive laboratory studies. In many instances, therefore, the viral origin of an acute pericarditis will never be proven. Such cases are better termed acute benign, or idiopathic, pericarditis. Instances of acute pericarditis have been documented with many different viruses.

The typical signs and symptoms of acute viral pericarditis are a low-grade temperature, chest pain, and a friction rub. They often develop after an infection of the upper respiratory tract. The children appear less ill than those seen with bacterial pericarditis. The white blood cell count is usually not elevated, and a relative lymphocytosis may be present. In infants, malaise, problems with feeding, tachycardia, and tachypnoea are often the presenting symptoms.

A pericardial effusion may develop rapidly, but tamponade is rare in the acute phase of viral pericarditis. Every attempt should be made to unravel the aetiology of the pericarditis. Direct proof, however, that the virus is the immediate cause of the pericarditis can only be obtained when the virus is isolated from the pericardium itself. Hence, a diagnostic pericardiocentesis must be considered. Pericardial fluid should be cultured for all types of organism,

and extensive biochemical and cytological investigations should be performed.

The therapy of acute pericarditis is symptomatic. It includes bedrest, particularly in those who have myocardial involvement, until the evidence of the infection has disappeared. Precordial pain may be relieved by salicylates, codeine, and other drugs. When there are arrhythmias, antiarrhythmic drugs may be used with care. The use of corticosteroids is best avoided, as it is thought to increase the risk of the development of chronic relapsing pericarditis. Pericardiocentesis is indicated in patients showing signs and symptoms of tamponade.

The prognosis is usually favourable. The disease is often self-limiting, with complete recovery in 3 to 4 weeks. In infants and children with diffuse myocardial involvement, nonetheless, the disease may lead to death. In the fullness of time, a recurrent chronic pericarditis, probably related to a cellular immune mechanism, or a constrictive pericarditis may develop and require surgical intervention.

Post-pericardiotomy Syndrome

Any episode of acute pericarditis may be followed by recurrent pericarditis. This includes the acute pericarditis that accompanies myocardial infarction, when the recurrence is called Dressler's syndrome. Of more relevance in children is the sequence following cardiac surgery involving opening of the pericardium, when it is called the post-pericardiotomy syndrome. The cardiac surgical procedure is followed by an acute illness, with fever, and pericardial and pleural inflammatory reactions. The symptoms develop mostly in the first week after operation, but a febrile period of 2 to 3 weeks is not uncommon. Further relapses are also uncommon, but can appear as long as months or years after the initial event. The pathogenesis of the disease is unclear. Development of anti-heart antibodies in a high percentage of the patients suggests a secondary autoimmune response, possibly in association with a viral infection. There is often an eosinophilia.³⁷

The earliest clinical manifestation is a sustained or spiked fever, usually of between 38 and 39 degrees Celsius. Sometimes the children feel ill, with symptoms of general malaise. All the features of pericarditis may be present, including the typical precordial pain. A friction rub is often present. Cardiac tamponade may require pericardiocentesis. Initially, the fluid withdrawn is serosanguineous, but at a later stage only serous fluid is obtained. The fluid is sterile. The chest radiograph and the electrocardiogram show the features of pericarditis. The echocardiogram is indispensable in demonstrating the pericardial fluid, and in

differentiating the syndrome from cardiac failure of other causes. Signs and symptoms of pleural involvement are common, especially on the left.

The disease is self-limiting over a period of 2 to 3 weeks. The most important therapeutic measure is bedrest until the fever has disappeared. Salicylates or indomethacin are useful agents in lowering the temperature and diminishing the precordial pain. In the severely ill child, a course of prednisolone, starting at 2 mg/kg per day, and reducing over 2 weeks, is very effective in normalising body temperature and reducing the pain. Colchicine has been used in adults, and has been found to be effective in the treatment of flare-ups and in the prevention of recurrences.³⁸ There have been reports of its use in children.³⁹ Diuretics may be useful in reducing the effusion, but should be used with caution. Prompt pericardiocentesis is indicated in patients who develop cardiac tamponade.

Two recent studies about the incidence and prognosis of dilated cardiomyopathy in children. They are concerned with slightly different populations, but the overall picture is similar. The conventional wisdom that a third of children recover, a third survive with impaired cardiac function, and a third die or need transplantation is in fact not far from the truth. Outcome in both studies is better in younger patients, and in those with better cardiac function at presentation.
- Reddy PS, Curtiss EI, Uretsky BF: Spectrum of hemodynamic changes in cardiac tamponade. *Am J Cardiol* 1990;66:1487–1491.
Tamponade is a haemodynamic diagnosis, so understanding the haemodynamic effects of a pericardial effusion is important if the diagnosis is to be made reliably. This is an essential analysis on the progressive haemodynamic changes brought about by a pericardial effusion leading to cardiac tamponade.

Rheumatic Fever

CHAPTER

54A

CLEONICE C. COELHO MOTA, VERA DEMARCHI AIELLO,
and ROBERT H. ANDERSON

Rheumatic fever is an acute, diffuse, and non-suppurative inflammatory disease that occurs in susceptible individuals as a late complication after an untreated pharyngotonsillitis, the infection itself sometimes being asymptomatic. It is caused by a group A β -haemolytic *Streptococcus*, specifically, *Streptococcus pyogenes*. The process is triggered by an inadequate immunological response, both humoral and cellular. There are four distinct phases characterizing the disease. The initial streptococcal pharyngotonsillitis is followed by latent period, and then by the acute and chronic phases. The chronic phase is also known as rheumatic heart disease, when the cardiac lesions remain as sequels of the acute phase. The disease has the potential to involve the heart, joints, brain, and subcutaneous and cutaneous tissues. Cardiac injury is the most important manifestation, and it is the injuries to the heart which produce its clinical, social, and economic impact.

Both rheumatic fever and chronic rheumatic heart disease continue to pose serious concerns with regard to health in many parts of the world, and present a significant challenge for those involved in providing health care. In developed countries, although its incidence has been markedly reduced since the 1950s, rheumatic fever remains a risk because of its potential for resurgence.¹ The disease has not yet been completely eradicated. As has been pointed out, prevention will be less than optimal until the pathogenesis of the disease has been totally elucidated.^{2,3} In developing countries, this preventable disease remains both socially and clinically devastating, with significant rates of morbidity and mortality. The acute episodes of rheumatic fever are still a cause of death in childhood, and the chronic disease is the most important cause of acquired cardiac disease in children, adolescents, and young adults, besides being considered the most frequent condition necessitating valvar surgery in adults. The repercussions of the disease involve patients of all ages, since the valvar sequels can be carried throughout life. The children and adolescents, who are most frequently admitted to hospital with acute episodes, are the same group of patients who, after the fourth decade of life, form the largest group when analysis is focused on invasive intervention and death. The economic impact must also be considered, not only with regard to the financial cost of clinical and surgical treatments, but also relative to the loss of productivity as the result of disability acquired at an early age.

HISTORICAL BACKGROUND

From the historical perspective, the clinical manifestations of rheumatic fever had been well described prior to the recognition of the complete syndrome. Arthritis had

been mentioned since the days of Hippocrates, but only in the 17th century did the French doctor Guillaume de Baillou distinguish acute articular rheumatism from the other forms of rheumatism. In the posthumous edition of the *Liber de Rheumatismo et Pleuritide dorsali*, published in 1642, he was the first author to use the term rheumatism to describe the acute form of arthritis. Thomas Sydenham, in England, in his book *Observationes medicae*, published in 1676, provided an accurate description of the acute migratory polyarthritis as distinct from gout. He also described, 2 years later, St Vitus's dance, another major manifestation of rheumatic fever, which we now call Sydenham's chorea. Important discoveries in cardiac pathology were made in the 18th century. Warty vegetations, and thickening of the valvar leaflets as an isolated postmortem feature, were recognised in 1709 by Giovanni Maria Lancisi, while Raymond Vieussens, in 1715, contributed a description of mitral stenosis, with calcification of the leaflets. Giovanni Battista Morgagni, in the tome *De Sedibus*, published in 1761, dealt with lesions of all cardiac valves, and described endocardial vegetations. The association of cardiac disease and rheumatism was noted by Morgagni, but deemed coincidental. It was Richard Pulteney, in the same year, who on the basis of his observation of pathology called attention to the association of cardiac involvement and acute articular rheumatism. Matthew Baillie, nonetheless, in his tome entitled *A Series of Engravings Tending to Illustrate the Morbid Anatomy of Some of the Most Important Parts of the Human Body*, gave credit for this recognition of a causal relationship between cardiac disease and rheumatism to David Pitcairn. The first full account of the pathology of rheumatic fever was then provided in 1808 by Dundas, who underscored the relationship of the cardiac features to rheumatism. In 1812, a detailed report was given in *On Rheumatism of the Heart* by William Charles Wells, who in 1813 also described the subcutaneous nodules. This author confirmed that, although Pitcairn had failed to provide a written record, he had already, by 1788, established the association between rheumatism and cardiac lesions. The introduction of the stethoscope by René Laennec, in 1816, facilitated the study of cardiac diseases, but not until 1832 did Jean-Baptiste Bouillaud provide a detailed account of rheumatic cardiac disease, correlating the clinical events with the post-mortem findings. In his treatise *Traité clinique des maladies du coeur* he introduced the term endocarditis and clarified the clinical picture, giving an accurate account of the cardiac involvement and other manifestations in patients with rheumatic fever. The eponym *maladie de Bouillaud* for rheumatic fever recognised his great contribution, distinguished by its exceptional accuracy and clinical significance. In the same year, James Hope, as had already been pointed out by Wells and Dundas, detailed and emphasised the association of acute pericarditis with

rheumatic fever. Cheadle, in 1886 described the complete syndrome, emphasising the set of clinical manifestations we currently recognise as major criterians, namely, carditis, arthritis, chorea, subcutaneous nodules, and erythema marginatum. Subsequently, the pathognomonic and distinctive microscopic nodules of rheumatic carditis were described in 1904 by Ludwig Aschoff.⁴⁻⁸

The first report of a possible connection between a bacterial infection and rheumatic fever had been suggested by Mantle in 1887, but it was not until 1930 that the causal relationship between infection by the β -haemolytic streptococcus and rheumatic fever was established.⁹⁻¹¹ From then on, data about the disease was gathered in many other fields. Todd, in 1932,¹² introduced a method for measuring one of the antibodies developed by the human body after the contact with the bacteria. Then, 1 year later, Lancefield¹³ classified the streptococcus into five distinct groups. Subsequently,¹⁴ continuous administration of sulphanilamide was shown to prevent recurrences, followed in 1950¹⁵ and 1951¹⁶ with demonstration that adequate treatment of the streptococcal pharyngitis with penicillin prevented the disease.

As early as 1944, Thomas Duckett Jones had proposed a set of clinical and laboratorial data to guide and reduce the over-diagnosis of rheumatic fever.¹⁷ The Jones criterians were subsequently modified and updated by the Committee of the American Heart Association.¹⁸⁻²² They have long been recognised as guidelines for the diagnosis of the first episode of the acute phase. The knowledge of the action of antibiotics in preventing the disease, and the systematisation of the diagnosis by means of the important Jones criterions, heralded a new era of studies.

EPIDEMIOLOGY

Rheumatic fever has a universal distribution, albeit that significant differences in the rates of incidence and prevalence depend on the interaction of characteristics of the aetiological agent and its human host, besides environmental and socioeconomic conditions. Due to the causal relationship of streptococcal pharyngotonsillitis and rheumatic fever, the epidemiology of the two diseases is closely related. Rheumatic fever is more frequent among children and adolescents between the ages 5 and 15, and has a peak of incidence around the ages of 8 to 9 years. These ages coincide with the peak of streptococcal pharyngotonsillitis in school-aged children, this infection being less common in late adolescence and in adults. Likewise, rheumatic fever is uncommon in children under 4 years of age, and exceedingly rare under the age of 2.²³⁻²⁵ The increased number of young patients can be attributed to the anticipation of the school years. Data from Brazil revealed that 2.5% of patients had their first episode under the age of 3.²⁶ In a study from India, Aschoff bodies were found in one-tenth of autopsied cases, the majority from patients between 16 and 40 years of age, indicating a recent attack of carditis.²⁷ Under special circumstances, such as focal epidemics of streptococcal infections in military populations or closed institutions, the incidence of rheumatic fever can increase in adults.^{28,29}

Rheumatic fever occurs in all populations, and shows equal frequency in both genders. The exception is Sydenham's chorea, which is more common in females, and is hardly ever seen in males after puberty.³⁰ Rheumatic fever has usually been reported as a disease of the temperate

climates, but currently it is more prevalent in warm tropical climates, especially in developing countries. Similarly, the influence of seasonal variation in the rates of incidence is now less defined, but in general follows that of streptococcal infections, which are most commonly observed in late winter and early spring.^{31,32} The disease is reputed to be more frequent in urban centres than in rural communities, but this is probably due to over-crowding.³³ Although data thus far is inconclusive, it has been suggested that there is an increased susceptibility to rheumatic fever in certain ethnic groups. The aborigines of Australia's Northern Territory, and the Polynesians, both from rural areas, show a markedly increased incidence of the disease.^{31,34} In Hawaii, wide differences in the prevalence of chronic rheumatic heart disease have been documented in the Samoan schoolchildren when compared with the Caucasian Hawaiians.³⁵ Similarly, higher frequencies of rheumatic fever and chronic rheumatic heart disease have been found in the Maori population of New Zealand,³⁶ and among black schoolchildren in South Africa.³⁷ Many factors, however, can overlap and interfere in the calculations of the incidence of rheumatic fever and the prevalence of chronic rheumatic heart disease, since different rates can be found under diverse environmental conditions for any given population. In this context, besides the role played by the bacteria and human host, other factors, such as differences in patterns of living condition and streptococcal exposure, in addition to quality of and access to health care, are important and can impact the geographical distribution of the disease, as well as the severity of its sequels.

All over the world, pharyngotonsillitis is one of the most prevalent infections caused by the β -haemolytic streptococcus. It accounts for up to one-third of the throat infections in children, and up to one-tenth in adults.^{29,38} Although the streptococcal infections are very frequent, only a few individuals develop rheumatic fever. It is calculated that, under endemic conditions, 0.3% of untreated infections, and 3% in epidemics, will lead to a first episode of rheumatic fever.³⁹ In spite of a marked decrease of rheumatic fever in the developed countries, the incidence of infections of the upper respiratory tract by the group A *Streptococcus* has not been reduced. Even considering that the strains of bacterium producing the infection are often relatively attenuated, more virulent strains can change the characteristics of the infections and their sequels. Emergence of mucoid strains was observed at the close of the 20th century in the United States of America and Western Europe, showing an apparent temporal association with the increase in frequency and severity of the systemic invasive streptococcal infections of the skin and soft tissues such as toxic shock syndrome, sepsis, myositis, and necrotizing fasciitis. The simultaneous resurgence of rheumatic fever in the United States is also highly suggestive of a relation with the appearance of more virulent group A strains.⁴⁰⁻⁴³

Recurrences of rheumatic fever, as a consequence of inadequate prophylaxis, are more frequent in developing countries, where predisposing factors to streptococcal infections still persist. The risk of subsequent attacks increases with the number of previous attacks, with the continued exposure to streptococcal infections, and falls with age. The recurrence rate is higher during the first 5 years subsequent to the acute episode, particularly in the first 2 years. Likewise, the risk of other attacks is higher in patients receiving oral secondary

prophylaxis when compared to parenteral medication. The clinical features of subsequent attacks show a tendency to mimic those seen in the initial attack.⁴⁴ Prospective follow-up to identify predictors of significant chronic rheumatic valvar disease⁴⁵ shows that almost half recurrences occur in the first 2 years of the disease (Fig. 54A-1).

In spite of a decline in both frequency and severity, rheumatic fever still remains a risk. In 1994, it was estimated by the World Health Organization that a total of 12 million individuals were affected by rheumatic fever and rheumatic heart disease worldwide.¹ In developing countries, the incidence of rheumatic fever is still very high, with a wide variation from 1.0 to 254 for each 100,000 of the population.^{1,31,35} More than 336,000 cases of rheumatic fever occur in children and adolescents aged from 5 to 14.⁴⁶ Although a downward trend has been noticed worldwide, the rates in some areas are similar to those found in developed countries at the turn of the 20 century.^{47,48} Investigations in the aboriginal communities in Northern Australia suggest a lifetime risk for having rheumatic fever to be as high as 5% to 7%.³⁴

Rheumatic fever, nonetheless, has now become rare in developed countries, where the incidence is estimated at below 1 for each 100,000 of the population.⁴⁹ The reasons for this decline of up to 100 fold over the last 50 to 60 years are not completely understood.⁵⁰ Several factors are involved, but none can explain this decline when considered in isolation.^{28,43,51,52} It has been attributed to the decreasing rheumatogenic potential of group A streptococcal strains, and to changes in susceptibility of the human host, besides the modifications in the environment. In this context, the increased nutrition and better living conditions, as a consequence of improvements in social and economic standards, have contributed to reduce the spread of the infecting agent. Other determining factors are the better availability of health care, and the advent of antimicrobial agents. The widespread use of antibiotics has accelerated the decrease of the disease, in terms of both morbidity and mortality. A fourfold acceleration of the decline was observed after the introduction of penicillin and other antibiotics.⁵³ Furthermore, the establishment of stricter clinical criteria enhanced the accuracy of the diagnosis, and consequently reduced over-diagnosis. Technological advances in laboratory diagnosis also improved the differential diagnosis from other cardiac diseases, such as congenital structural diseases, myocarditis, and mitral valvar prolapse, which in a clinical setting had often been misdiagnosed as rheumatic fever.

Figure 54A-1 The graph shows the frequency of recurrences in 258 children and adolescents followed up in the Rheumatic Fever Outpatients Clinic, Division of Paediatric Cardiology, Hospital das Clínicas, Federal University of Minas Gerais, Brazil.

Despite the apparent control, the disease had resurged in the United States of America by the mid-1980s. During the last two decades of the 20th century, outbreaks were reported in distinct geographical regions of the country among different age groups, mainly schoolchildren and young adults in military bases.^{42,52,54} The outbreaks showed an unexpected pattern, occurring among white, middle-class patients with ready access to health care and antibiotic therapy. Between 1985 and 1988, a national survey was performed in cities of 24 states of the United States, and showed evidence of an increase in the number of cases from 5 to 12 times when compared to the previous decade.⁴⁰ Isolated reports of increased frequency of rheumatic fever also came from Europe.⁵⁵⁻⁵⁷

No isolated factor can be held responsible for the epidemiological changes in both the disappearance and the reappearance of rheumatic fever, and the underlying reasons have still to be completely explained. It has been questioned whether the outbreaks represented a true risk of return of the disease, or simply were an oscillation in its declining profile of incidence.⁵¹ As was pointed out by Kaplan and Markowitz, the reasons for the virtual disappearance of rheumatic fever have not yet been sufficient to control the disease.^{3,52}

AETIOLOGY AND PATHOGENESIS

A broad range of clinical manifestations may occur after a streptococcal infection, varying in severity from mild and superficial dermal infection to necrotizing fasciitis or severe septicæmia. Non-suppurative sequels depend on a delayed immune-mediated host response, and include rheumatic fever, acute glomerulonephritis, and reactive arthritis. As we have already discussed, the association between streptococcal pharyngotonsillitis and the subsequent development of rheumatic fever was recognised in the first half of the twentieth century, but the precise pathogenesis of the disease has still not been completely elucidated. Major advances in the understanding of the pathogenic mechanisms have only recently been achieved from immunological, molecular biologic, and genetic studies. Susceptibility to rheumatic fever depends on the interaction between the streptococcus and host factors, influenced also by environmental conditions. Both humoral and cellular delayed immune responses to the streptococcal throat infection take part in the process. Their extension determines the severity of the disease in one individual. In particular, autoimmunity against the tissues of the host plays a key role in the pathogenesis and progression of the disease. Molecular mimicry between streptococcal antigens and several human tissues, such as cardiac valves and myosin, cartilage, and synovial and cerebral proteins has been proposed and proved to be the basic mechanism triggering autoimmunity. Bacteria are absent from the acute and chronic tissue lesions of rheumatic fever.

STREPTOCOCCUS AND ITS ANTIGENS

Streptococcus pyogenes, or the group A *Streptococcus*, is a Gram-positive extracellular bacterium covered by an outer layer of hyaluronic acid. Its cell wall is composed of repeating units of N-acetyl-D-glucosamine carbohydrates linked to a rhamnose polymer backbone (Fig. 54A-2).

Figure 54A-2 Schematic representation of the cell wall of the group A *Streptococcus*.

The classification of the microorganism in serogroups is based on studies that distinguished by serology the bacterial mural polysaccharides, giving groups A, B, F, and G. The concept of different bacterial strains causing disease in specific target organs emerged from decades of epidemiological studies, revealing serotypes of group A *Streptococcus* as having a strong tendency to cause pharyngotonsillitis, and others to be associated with impetigo.⁴¹ Although different serogroups may also cause throat infections, there is no evidence linking bacteria from the remaining serological groups with the development of rheumatic fever.¹

The M, T, and R proteins on the bacterial cell surface, along with lipoteichoic acid, are involved in the adhesion of the bacteria to the host epithelial cells, and in their ability to resist phagocytosis in the human host.^{1,58} (see Fig. 54A-2). Thus far, it has proved possible to identify more than 100 M serotypes, based on the antigenic variation of the N-terminal portion.⁵⁸ The M protein is particularly important in determining the virulence of the microorganism, since it promotes avid adherence to host tissues. Moreover, it is the M protein that shares structural homology with certain α -helical human molecules such as myosin, tropomyosin, laminin, vimentin, keratin, and laminin, thus forming the basis for the immune-mediated post-infectious sequelae. Laminin is an extracellular matrix protein present in the cardiac valves, being secreted by the endothelial cells that line them.

The M protein molecule itself has a variable composition (Fig. 54A-3). As explained, its N-terminal portion contains the A-repeat region that produces antigenic variation.⁴¹ The B-repeat region also varies from serotype to serotype, while the C-repeat regions contain highly conserved epitopes. Classification of the streptococcus into class I or class II

depends on whether their M protein reacts with a monoclonal antibody that targets epitopes in the C-repeat region.¹ While class I strains are predominantly negative for the production of serum opacity factor, and are recognised as rheumatogenic, class II strains produce the serum opacity factor, bind fibronectin, and are usually associated with production of glomerulonephritis.⁴⁶ Serotypes, such as M types 1, 3, 5, 6, 14, 18, and 24, have also been associated with the development of rheumatic fever. An alternative means of serotyping is to sequence the gene encoding the 5' terminal end of the M protein. A great range of genetic diversity has been shown in this fashion in isolates recovered from many different geographical locations.^{32,59,60} The identification of these so-called *emm* types present in a community at the time of an outbreak of rheumatic fever permitted recognition of the types most commonly associated to the disease, and revealed *emm* types 1, 3, 5, 6, 14, 18, 24, 17, and 29 to be rheumatogenic.⁶¹ This concept of rheumatogenicity, however, has recently been challenged, since some types frequently associated with acute rheumatic fever are infrequently found in several communities with high burdens of the disease, where new, non-M antigen typeable microorganisms have been identified.^{46,62} These new types probably result from genetic recombination between different strains of the group A *Streptococcus*. It is not surprising that a clear distinction between the rheumatogenic and non-rheumatogenic strains of the group A *Streptococcus* does not exist in areas of the world with high rates of superficial infections, since multiple genetically distinct strains circulate at the same time. This broad genetic diversity has important implications in the development of a vaccine against streptococcal infections.

Figure 54A-3 Diagram representing the A, B, C, and D repeat regions of the streptococcal M protein. At the N-terminus, the A repeat region contains the highly variable amino acid sequences that are serotype specific. The C and D regions are highly conserved among the strains of streptococci.

THE HUMAN HOST

Alleles of the Human Leucocyte Antigen Associated with Rheumatic Fever

Considering that less than 3% of the patients with acute streptococcal pharyngotonsillitis develop rheumatic fever, it is reasonable to suggest that the genetic predisposition of the individual plays an important role in the pathogenesis of the disease. In the 19th century, it was suggested that both rheumatic fever and rheumatic heart disease were hereditary,⁴⁶ possibly transmitted in autosomal recessive fashion. Further studies on the determinants of host susceptibility indicated that the immune response to the streptococcal infection is genetically controlled. More recently, molecular biologic techniques have identified an association between the disease and some alleles of the major histocompatibility complex. These class II human leucocyte antigen molecules are expressed on the surface of antigen-presenting cells, such as macrophages, dendritic cells, and B cells. Together with the bound peptide antigen, they trigger the activation of T lymphocytes. Several such alleles have been associated with rheumatic fever in different countries (Table 54A-1). While DR7 is the allele most frequently associated with rheumatic fever in Brazil, Turkey, and Latvia, the DR4 allele is found in American-Caucasian, Indian, and Saudi-Arabian patients. Recently, in Mexican and Brazilian patients with rheumatic heart disease,^{63,64} some alleles of the tumour necrosis factor- α , also located in the region of the major histocompatibility complex, were described with increased frequency. A possible explanation for the frequent association of certain

alleles with the development of rheumatic fever and rheumatic heart disease is that these molecules might cause inappropriate activation of the T cells, resulting in autoimmunity.

Interactions Between Host and Pathogens

It is well recognised that the molecular mimicry between some antigens present on the surface of group A *Streptococcus* and specific human tissues triggers the autoimmune response causing acute rheumatic fever. Structural similarities between the streptococcal M protein and myosin are the key for the development of acute carditis. On the other hand, valvar lesions are triggered by immune reactions against human proteins such as laminin, an α -helical coiled-coil molecule present in the valvar subendothelium. Both the humoral and cellular arms of the immune response take part in the host response against these self-proteins sharing some homology with the streptococcus.

Humoral Response

After the adherence of the bacteria to the host cells, the processes of colonisation and invasion supervene, inducing the production of type-specific antibodies by B-derived mononuclear cells, leading to opsonisation and phagocytosis. As pointed out recently,⁵⁸ heart-reactive antibodies were first described by Calveti in 1945. The recognition of cross-reactive streptococcal epitopes and human antigens, mainly myosin and laminin, led to a great advance in the studies directed to the knowledge of the mechanism of the disease.

Cross-reaction between antibodies to cardiac valvar tissue and the N-acetylglucosamine of the polysaccharide from group A *Streptococcus* has been clearly demonstrated.^{41,65,66} Additionally, some studies have shown that the cross-reacting antibodies bind to the endocardial surface of valves, up-regulating the local expression of adhesion molecules like vascular cell adhesion molecule-1, which facilitates infiltration of inflammatory cells inside the valvar leaflets, which are avascular, leading later to scarring⁶⁷ (Fig. 54A-4). The pathogenic mechanism responsible for the Sydenham's chorea present in some patients with acute rheumatic fever is also dependent on the cross-recognition of neuronal tissue proteins by antibodies directed to the N-acetylglucosamine of the streptococcus.⁶⁸

Cellular Response

T lymphocytes of subsets CD4 and CD8 are the main mediators of the myocardial and valvar lesions of rheumatic fever and rheumatic heart disease, participating in a delayed-type hypersensitivity reaction (see Fig. 54A-4). In the acute phase, the pathognomonic histological feature is the Aschoff body, a granulomatous lesion found in both the myocardium and in valvar leaflets, and composed of T lymphocytes, B lymphocytes, macrophages, large mononuclear cells, and polymorphonuclear leucocytes. The nodules develop as a result of cellular infiltration through the endothelium. The presence of activated macrophages inside the bodies is consistent with an immune response of the CD4+ T helper 1 type.⁶⁹

Proinflammatory cytokines, such as tumour necrosis factor- α and interleukin-1, are over-produced by peripheral

blood mononuclear cells in patients with rheumatic fever. They are also predominantly expressed by mononuclear inflammatory cells inside the chronic valvar lesions, indicating their local role even in the chronic phase of the disease. Cytokines are considered important second signals after infections, triggering effective immune responses in most individuals, but in the context of autoimmune diseases they induce a deleterious response. Differences in the pattern of cytokine production were observed between inflammatory cells derived from valvar and myocardial tissue from patients with rheumatic fever.⁷⁰ These findings reinforce the putative role of these regulatory cytokines in the myocardial healing, but not in valves, where the damage is progressive and permanent. The sparing of the right-sided cardiac valves in most cases of rheumatic fever is usually attributed to the lower pressure and shear stress to which they are usually submitted compared to the left-sided valves. Quadrivalvar rheumatic disease has been reported only rarely, and usually then in patients with congenitally malformed hearts.⁷¹ The location of the acute valvar lesions along the lines of closure of the leaflets corroborates the hypothesis that lesions occur at places that are most liable to trauma.

MORPHOLOGY OF THE ACUTE CARDIAC AND EXTRACARDIAC LESIONS

The sequence of immunological events described above culminates in the development of acute rheumatic fever, which presents as exudative and proliferative inflammatory reactions in the connective tissue of the affected organs. These lesions are more distinctive within the heart, but involve also the joints, subcutaneous tissue, brain, and vessels of the lung. Basically, they are characterised by mononuclear inflammatory cells around a focus of fibrinoid necrosis. In the heart, the pericardial, myocardial, endocardial layers are all affected, hence there is a pancarditis. The histological landmark of acute rheumatic fever is the Aschoff body (see Fig. 54-8).

Grossly, the pericarditis is characterised by the deposition of a serofibrinous exudate, giving the so-called bread-and-butter appearance. Acute valvar lesions are found as small vegetations of 1 to 2 millimetres along the lines of closure on the atrial aspect of the atrioventricular valves, and on the ventricular surface of the arterial valves (Fig. 54A-5). These small verrucous lesions may extend to the tendinous cords of the atrioventricular valves, and in rare instances may be associated with cordal rupture, causing severe valvar regurgitation and cardiac failure. Microscopically, the vegetations are composed of fibrin thrombus overlying an area of fibrinoid necrosis of the valvar connective tissue. These areas of necrosis are surrounded by a dense inflammatory infiltrate, containing mononuclear cells and occasional giant cells. Presumably, the fibrin vegetations accumulate on the ulcerated endocardium in areas of extrusion of the damaged collagen (Fig. 54A-6). Although the typical Aschoff bodies, pathognomonic of the disease and most commonly seen in the myocardium, are not usually found in valvar tissues, the acute valvar lesion transforms with time, showing inflammatory cells arranged in palisade around the central necrotic core. These lesions eventually heal, producing local fibrosis. Moreover, the adjacent tissue of the valvar leaflets is oedematous, and shows a diffuse non-specific mononuclear infiltrate. Neovascularisation is not a feature in this phase of the disease, but thin-walled blood vessels can be seen invading at the base of implantation of the leaflet.

In the case of a recurrent attack, the fibrin vegetations still appear on the same structures, but there are already valvar sequels, such as cordal fusion and thickening of the leaflets (Fig. 54A-7). The relative frequency of valvar involvement correlates to the haemodynamic closing pressures, the decreasing order being mitral, aortic, tricuspid, and pulmonary.

Although myocardial involvement in acute rheumatic fever is typically called myocarditis, direct myocytic injury as it is observed in viral myocarditis is not a striking feature. Instead, the finding of multiple Aschoff bodies is the fingerprint of the disease. These granulomatous nodules are usually located in the connective tissue around small vessels (Fig. 54A-8). They show fibrinoid necrosis surrounded by lymphocytes,⁵⁸ some plasma cells, and plump macrophages with abundant cytoplasm and a clear nucleus where a central wavy ribbon of condensed chromatin is observed. These are called Anitschkow cells, or caterpillar cells, the latter reflecting their appearance when cut longitudinally.

Figure 54A-5 The images show the characteristic lesions in the hearts from children who died in the acute phase of rheumatic fever. Panel **A** shows small vegetations on the line of closure of the mitral valve, with panels **B** and **C** showing similar lesions in the tricuspid and aortic valves, respectively. Note that, in panel **A**, there is moderate dilation of the left atrium and ventricle. The aortic valve shown in panel **C** also shows signs of chronic disease, characterised by partial fusion of the zone of apposition between the non-coronary and right coronary leaflets. Panel **D** shows a surgically excised mitral valve, with massive deposits of fibrin on the line of closure of both leaflets. The tendinous cords are delicate, indicating absence of chronic disease in this valve.

Figure 54A-6 This photomicrograph is taken from a mitral valve excised during the acute phase of rheumatic fever, and showing fibrin vegetations (arrows) overlying a densely inflamed valvar stroma. The section is stained with haematoxylin and eosin.

Figure 54A-7 This panel shows a section taken from a surgically excised mitral valve, revealing signs of co-existing chronic disease, with thickened leaflets and fused cords, and superimposed acute rheumatic lesions, with fibrin vegetations on the line of closure.

Multi-nucleated macrophages may also be present, and receive the name of Aschoff giant cells. Aschoff bodies often appear in the myocardium about 4 weeks after the acute onset of rheumatic fever, and may remain in the tissue for as long as 3 to 6 months. Although the earliest lesions

show prominent fibrinoid necrosis and inflammation, as described above, the life cycle of the nodule continues with a gradual decrease in the cellular content. The complete healing of those lesions takes the form of a fibrous scar around small myocardial vessels.

Figure 54A-8 The panels show the histological evolution of the Aschoff body in the myocardium. The exudative phase is shown in panels A to C. Panel A shows the central fibrinoid necrosis surrounded by large mononuclear cells. Panel B shows large mononuclear cells, with prominent nucleoli and also Aschoff's giant cells (*arrows*). Panel C illustrates the Anitschkow cells (*arrows*). The proliferative phase is shown in panel D, with perivascular accumulation of mononuclear cells and absent fibrinoid necrosis, while panel E shows a healed perivascular lesion characterised by fibrosis.

The role of myocarditis in the failure of the heart in acute rheumatic fever has recently been questioned,^{72,73} since levels of troponin I are typically within normal limits, which indicates absence of direct damage to cardiomyocytes. Since most patients with heart failure have valvar dysfunction, mainly isolated mitral regurgitation or combined mitral and aortic regurgitation, this in itself could explain the congestive symptoms. Even without direct damage to the contractile cells, nonetheless, the myocardium in the setting of acute rheumatic fever is oedematous and, besides the Aschoff bodies, an interstitial mononuclear inflammatory infiltrate of variable intensity is a common finding. These features could disrupt the myocardial integrity, and possibly interfere with the cardiac function. Dilation of the mitral annulus is also a contentious topic.

Some believe that valvar regurgitation precedes dilation of the chambers, while others argue that myocardial impairment comes first, since in the acute phase the leaflets are just mildly deformed by fibrin deposition. Since it is virtually impossible to be certain that a given episode of rheumatic carditis is the first, valvar regurgitation, when present in the context of an acute carditis, could always be the consequence of previous deformity of the leaflets. Another lesion considered characteristic of the acute phase is MacCallum's patch. This is an endocardial lesion on the postero-inferior left atrial wall, frequently containing Aschoff bodies when examined histologically. This thickening, however, is more likely to be a jet lesion from mitral regurgitation than a specific rheumatic lesion. Although the diagnosis of acute rheumatic fever is usually made on clinical grounds, the

endomyocardial biopsy is said to have value in diagnosis. Histological diagnosis, however, is based on the presence of Aschoff bodies. These structures were found, in one study, in less than one-third of patients with acute rheumatic fever, and only two-fifths of those with recurrent attacks.⁷⁴ This suggests that endomyocardial biopsy is not likely to add important diagnostic information.

DIAGNOSIS

Clinical Manifestations

Since the description provided by Cheadle in 1889, no modification has been incorporated into the clinical profile of rheumatic fever, characterised by its uniformity as a syndrome and by its diversity as a multi-system disease. The clinical presentation, with its variable pattern of symptoms and signs, is determined by the sites of involvement, by the time of appearance along the course of the acute attack, and whether the manifestations occur alone or in combination. Additionally, the clinical picture is also influenced by a wide range in severity of the individual manifestations.

The latent, or asymptomatic, period between the streptococcal infection and the onset of rheumatic fever lasts from 1 to 5 weeks, except for Sydenham's chorea, which may take longer to appear. The acute episodes are time limited, ranging usually from 6 to 12 weeks, but sometimes as long as 6 months in those with severe carditis. All are at risk of recurrence following a subsequent untreated infection with the group A *Streptococcus*. The duration of the acute episode is similar in both the first episode and recurrences.⁶

The diagnosis is made on a clinical basis. The supportive microbiological and serological laboratorial data is then used to characterise the underlying streptococcal infection, besides establishing the presence and resolution of the acute inflammatory process. No single symptom or sign is pathognomonic, nor are there specific laboratory tests. The diagnostic criteria formulated by Jones¹⁷ have been revised over the past years. The reviews have clarified the categorisation of major and minor manifestations, and emphasised the importance of the laboratory evidence of the preceding infection by the group A *Streptococcus*. As a consequence, over-diagnosis has been reduced with provision of more detailed information and improved specificity. In addition, exceptions to the criteria were highlighted with the aim of diminishing the risks of under-diagnosis. The division between major and minor criteria was based on the specificity of the manifestations for the diagnosis, and not on their frequency or prognostic significance.⁷⁵ The five most characteristic clinical features constitute the major manifestations, namely, carditis, arthritis, chorea, subcutaneous nodules, and erythema marginatum, independent of their severity. Classically, arthritis and carditis, isolated or in combination, are seen most frequently. Chorea is less common, and the other major manifestations are rare (Fig. 54A-9). The minor manifestations are mostly related to the underlying systemic inflammation. Although non-specific, these clinical and laboratory findings are frequent, and supportive of the diagnosis when accompanying a major manifestation. In the presence of arthritis, however, arthralgia cannot be considered as a minor manifestation. The combination of two major or one major and two minor manifestations, supported by evidence of preceding

Figure 54A-9 The graph shows the proportional distribution of 1066 children and adolescents with rheumatic fever according to the major manifestations seen in the Rheumatic Fever Outpatients Clinic, Division of Paediatric Cardiology, Hospital das Clínicas, Federal University of Minas Gerais, Brazil. EM, erythema marginatum; SN, subcutaneous nodules.

infection with the group A *Streptococcus*, indicates a high probability for the diagnosis of rheumatic fever^{1,21} (Table 54A-2).

The current guidelines are intended for the diagnosis of first attacks. Once other diagnoses are excluded, three situations—Sydenham's chorea, indolent carditis, and recurrent episodes—are exceptions to the strict adherence to the Jones criteria. Since Sydenham's chorea usually occurs as a late manifestation of the disease, the inflammatory process and the immunological response to streptococcal infection could have already subsided when this feature becomes evident, and laboratory evidence is seldom found. Similarly, patients with insidious onset of carditis can delay seeking medical attention. By the time of their clinical evaluation, the acute-phase reactants and levels of antistreptococcal antibodies may be normal. Faced with a reliable history of a previous episode of rheumatic fever, or established chronic rheumatic heart disease, the diagnosis of recurrence constitutes the third exception to

TABLE 54A-2

JONES CRITERIA, 1992 UPDATE: GUIDELINES FOR THE DIAGNOSIS OF RHEUMATIC FEVER

Major Manifestations	Minor Manifestations
Carditis	Clinical
Polyarthritis	Fever
Chorea	Arthralgia
Subcutaneous nodules	Laboratorial
Erythema marginatum	Prolonged PR interval
	Increased erythrocyte sedimentation rate
	Presence of C-reactive protein
Evidence of a preceding group A beta-haemolytic streptococcal infection: elevated or rising streptococcal antibody titre or positive throat culture or elevated or rapid antigen test for group A streptococci (AHA 92)	

Adapted from Guidelines for the diagnosis of rheumatic fever: Jones criteria, 1992 update. Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. JAMA 1992;268:2069–2073.

use of the Jones criteria. Diagnosis may then be made in the presence of one major or several minor manifestations, along with supporting evidence of recent infection by the group A *Streptococcus*. In addition to the Jones criteria, other non-specific clinical findings may also be found during the course of the acute episodes.^{1,21}

Major Manifestations

Carditis

Carditis is the most serious manifestation, because only in the heart are the lesions potential causes of sequels, such as death during the acute attack or later. The pericardial and myocardial damages carry no long-term morbidity. Carditis in first episodes is more frequent in younger children, and depending on its severity, is characterised by murmurs related to regurgitation of the mitral and aortic valves, enlargement of the heart, pericarditis, and congestive cardiac failure.

Carditis is reported to be seen in up to three-fifths of first attacks, although more recent series have shown higher rates when echocardiography is included in the evaluation.^{5,42,45,76} Carditis tends to appear early, and is usually diagnosed within the first 3 weeks of the acute episode. Different patterns of onset can be found. Clinical presentation with fever and arthritis of abrupt onset is observed in older children, with or without indistinct clinical cardiac findings. The involvement of the heart becomes more apparent later over the first 2 weeks of disease. More frequently in young children, the disease begins insidiously, with vague symptoms, slight fever, and a sallow complexion. These children can also present mild arthritic complaints, besides shortness of breath or chest pain. Cardiac findings are present at first examination, are commonly marked, and tend to progress to congestive cardiac failure. Another mode is a late appearance of carditis, concurrent with the manifestations of Sydenham's chorea. This pattern probably represents a progression of a previously unrecognised mild cardiac involvement during the early stages of the acute attack.^{6,44} Yet another pattern is that of subclinical, or silent, carditis. Mild cardiac involvement may not be clinically recognised in patients with isolated chorea or arthritis, the valvitis being demonstrated only by Doppler echocardiography.

The cardiac damage in the acute episode is characterised by pancarditis. The determinants of morbidity and mortality, nonetheless, are the degree and extent of endocarditis, represented by the lesions of the cardiac valves. Pericarditis is not common, being found in only one-tenth or less of the patients.^{77,78} As with the myocardial participation, this is part of the active pancarditis, and is not found as a sole manifestation. When present, it is invariably associated with valvar dysfunction, so other causes should be investigated if valvar dysfunction is not recognised. Pericardial involvement is diagnosed by the presence of pericardial friction rub, effusion, distant heart sounds and chest discomfort or chest pain. The rub is heard as a scratching or grating sound over the praecordium, especially along the sternal border, and is heard in both phases of the cardiac cycle, having a to-and-fro character. It is less transient in rheumatic fever than in pyogenic infections. In the early stages, the friction rub may obscure the murmur of underlying valvar dysfunction, and the murmur becomes apparent only when the rub subsides.⁷⁶ In mild cases, the pericardial

injury is sometimes an exclusive echocardiographic finding. Significant effusion is rarely found, and the rheumatic pericarditis does not result in constriction. Despite its low frequency, pericarditis has diagnostic value by providing evidence of an active disease.

Myocarditis has been diagnosed on the basis of signs such as abnormalities of first sound, protodiastolic gallop, cardiomegaly, and congestive cardiac failure. In spite of in the acute process histological and immunological evidences of the myocardial participation, nonetheless, more accurate assessment has provided new insights to the role played by both myocarditis and valvitis in the presentation of symptoms and heart failure.⁷⁹ Different from patients with other forms of myocarditis, the ejection fraction and shortening are usually normal in the first episodes. Markers of injury to the myocytes are insignificantly elevated.^{72,73,80,81} Patients with congestive cardiac failure unresponsive to clinical treatment throughout the acute phase have shown rapid recovery after valvar surgery.⁸² These observations support the notion that the valvar lesions are dominant in the clinical presentation of carditis.^{79,83-85}

Endocarditis is the diagnostic hallmark of carditis, being expressed by valvitis. The inflammatory process affects most frequently the mitral and aortic valves. Isolated aortic involvement, however, is rare. Involvement of the right-side valves is unusual. Valvar dysfunctions in the acute phase are represented by regurgitation. Obstructive lesions become established during the chronic phase, the process of cicatrisation taking time to develop. If stenotic lesions are found in the acute phase, this favours the diagnosis of recurrence.

Three murmurs are characteristic of the first acute episode, and they do not represent definitive valvar dysfunction. The apical murmur of mitral regurgitation is pansystolic, beginning with the first sound, and is heard maximally at the apex with the patient in the left lateral decubitus position. It is transmitted to the left axilla, and remains unchanged in both phases of respiration. It has a high-pitched blowing quality, with its loudness roughly proportional to the degree of valvar regurgitation. The Carey Coombs murmur is a low-pitched mid-diastolic murmur, beginning immediately after the third sound, finishing before the first sound, and usually of low intensity. The murmur is best heard at the apex, or just above it, by using the bell portion of the stethoscope applied lightly against the chest wall with the patient again lying in left lateral decubitus. This apical mid-diastolic murmur occurs when there is mitral regurgitation, is transient, and tends to disappear during the recovery from the acute episode. The mechanism is not completely understood. It has been attributed to the inflammatory process and its consequences in the mitral apparatus, besides the high velocity of flow into the dilated left ventricle. The third murmur, the basal diastolic murmur of aortic regurgitation, has a soft, high-pitched, decrescendo quality, and may be found early in the course of the disease. It is difficult to detect, and sometimes has an intermittent character. It is an early diastolic murmur, best heard with the diaphragm of the stethoscope, and is usually loudest at the third space on the left border of the sternum with the patient in the upright position, leaning forward, and after deep expiration. The severity of cardiac findings in the acute episode is variable, going from subclinical lesions to severe presentation with fulminating evolution (Table 54A-3).

TABLE 54A-3

CLASSIFICATION OF RHEUMATIC CARDITIS ACCORDING TO THE MAGNITUDE OF CLINICAL MANIFESTATIONS AND ELECTROCARDIOGRAPHIC, RADIOGRAPHIC, AND DOPPLER ECHOCARDIOGRAPHIC FINDINGS*

Type	Findings
Subclinical carditis	Absence of auscultatory evidence of carditis associated with normal radiographic and electrocardiological examinations, except for the presence of first-degree heart block. Doppler echocardiographical features show mild regurgitation of mitral and/or aortic valves with different characteristics from physiological regurgitation (see Table 54A-4).
Mild carditis	Rapid sleeping pulse, tachycardia out of proportion to fever; possible decrease in the intensity of the first sound, systolic murmur of mild mitral regurgitation, no cardiac enlargement on chest radiography, possible prolongation of the PR interval in the electrocardiographical examination, mild or mild-moderate mitral insufficiency, isolated or associated with mild aortic regurgitation and normal chamber size on echocardiography.
Moderate carditis	Clinical signs are more evident than for mild carditis with persistent tachycardia and a more intense murmur of mitral regurgitation, but without thrill, coming as an isolated lesion or associated with aortic diastolic murmur. The mitral regurgitation can be accompanied by a Carey-Coombs murmur, besides findings of incipient heart failure; a mild or mild-moderate degree of cardiac enlargement in the chest radiography due to left-sided chamber hypertrophy and, if present, the pulmonary congestion is discreet; premature beats, ST segment and T wave changes, low voltage, prolongation of QTc or PR intervals may be observed on the electrocardiogram; mild-moderate mitral regurgitation, isolated or associated with aortic valve incompetence of mild or moderate degree, mild-moderate enlargement of the left-side chambers are seen on echocardiography.
Severe carditis	In addition to the findings of moderate carditis, symptoms and signs of congestive heart failure are found; valvitis is expressed by murmurs related to more severe degrees of mitral and/or aortic regurgitation and can be associated with pericarditis and arrhythmias. There is evident cardiomegaly with prominent vascular markings on chest radiography; a more severe degree of the electrocardiographic changes of left ventricular hypertrophy is sometimes associated with right ventricular hypertrophy. Moderate-severe or severe mitral and/or aortic insufficiency are observed on echocardiography, and the left cardiac chambers show at least moderate enlargement.

*According to the protocol of the Rheumatic Fever Clinic, Department of Paediatrics, Division of Paediatric Cardiology, Hospital das Clínicas/Federal University of Minas Gerais, Brazil.

Subclinical Valvitis

Until the advent of Doppler echocardiography, the diagnosis of rheumatic valvitis had been exclusively based on the presence of auscultatory findings, supported by radiographic and electrocardiographic abnormalities. By the late 1980s, it proved possible positively to identify subclinical valvitis.^{86–89} Such silent carditis is found in patients with isolated arthritis and/or pure chorea, without auscultatory findings of valvar dysfunction, but with a pathological pattern of valvar regurgitation revealed by Doppler echocardiographic interrogation (Table 54A-4). Thickening of the valvar leaflets has also been described.^{90,91} Subsequently, regurgitant jets have been observed, with a wide range of prevalence.^{57,88,92–96} As trivial leaks of pulmonary, tricuspid, and mitral valves are commonly identified by Doppler echocardiographic investigation in normal subjects at all ages, it is essential to use strict criteria to differentiate pathological from physiological regurgitation (see Table 54A-4). Physiological insufficiency can be detected in up to nine-tenths of the normal population, being more frequent in adults than children.^{90,97–101} Aortic leaks, however, have rarely been considered physiologic. Mild degrees of mitral and/or aortic regurgitation are most commonly described in rheumatic subclinical valvitis, albeit that mild to moderate degrees have also been identified, mostly involving the aortic valve.^{90,102–104} Caution is required when interpreting the evidence of valvar incompetence. Besides the characteristics of the regurgitant jet, it is important to note that the echocardiographic findings do not define the aetiology of the process. They must be considered in the context of the disease, considering associations with other clinical and laboratory manifestations. Although the role of Doppler interrogation has long been recognised, its use without auscultatory support is still controversial.^{85,94,105–110} In the last revision of the guidelines for the diagnosis of rheumatic

fever by the American Heart Association, in 2002,²² it was concluded that the existing data was insufficient to include Doppler echocardiographic findings in the absence of clinical manifestations as a criterion for the diagnosis of carditis.

In some patients without auscultatory findings in the early stage of the disease, the murmurs can be identified later.^{90,103} Patients, therefore, require serial clinical evaluation, aimed at detecting late clinical evidence of carditis.

TABLE 54A-4

DOPPLER ECHOCARDIOGRAPHIC CRITERIONS FOR THE DIAGNOSIS OF SUBCLINICAL MITRAL AND AORTIC VALVITIS

Type	Criteria
Mitral regurgitation*	Regurgitant jet into the left atrium longer than 1 cm Posterolateral colour jet with a mosaic pattern Identification of colour jet in at least two planes beyond the valvar leaflets Holosystolic regurgitant jet by pulse or continuous Doppler Regurgitant jet with a peak velocity greater than 2.5 mm/sec
Aortic regurgitation*	Identification of colour jet in at least two planes beyond the valvar leaflets Holodiastolic regurgitant jet by pulse or continuous Doppler Regurgitant jet with a peak velocity greater than 2.5 mm/sec

*Thickening of valvar leaflets is an additional finding to support the diagnosis.^{90,91}
Data from Veasy LG: Rheumatic fever—T. Duckett Jones and the rest of the story. *Cardiol Young* 1995;5:293–301; and Ozkutlu S, Ayabakan C, Saraclar M: Can subclinical valvitis detected by echocardiography be accepted as evidence of carditis in the diagnosis of acute rheumatic fever? *Cardiol Young* 2001;11:255–260.

As mild valvar dysfunctions are most frequently seen in subclinical valvitis, favourable outcomes are expected for the great majority of patients, with anticipated spontaneous healing of the valvar lesions without sequels.^{104,110–113} More recent investigations, nonetheless, have demonstrated that the subclinical valvitis can persist for prolonged periods.^{90,102,104,110,114} The valvar lesions can remain subclinical in the chronic phase, characterizing subclinical chronic rheumatic heart disease.^{45,105,115} Considering the propensity of recurrences to mimic clinical manifestations of the first episode, the increased risk of more severe involvement of the heart must be borne in mind should there be subsequent attacks.¹¹⁴

Recurrent Carditis

Carditis is rarely present for the first time in recurrences. The term mimetic carditis was proposed, considering the heart almost always to be involved in the subsequent attacks in patients exhibiting carditis in the primary episode.^{6,52} The diagnosis of recurrent carditis in patients with an established rheumatic valvar disease is often difficult. The clinical presentation includes changes in the character of the murmur, reappearance of a previous murmur, or detection of a new one as the result of the involvement of an additional valve. In addition, detection of a pericardial friction rub or effusion, and a significant increase in the size of the heart, may also be present. Congestive failure is more common in recurrent carditis. Although the heart is invariably involved in recurrences of patients suffering carditis in the first attack, cardiac failure in the chronic phase could also reflect mechanical stress due to valvar dysfunction, being related to the extent of haemodynamic effects. The epidemiological and clinical context, as well as the evidence of a recent streptococcal infection, therefore, must be considered in the diagnosis of recurrent carditis.

Polyarthritis

Polyarthritis is the most frequent major manifestation seen in older children, adolescents, and adults, but constitutes the least specific clinical finding of rheumatic fever. Its frequency increases with age, being seen in up to three-quarters of patients as an isolated presentation, or in association with other manifestations of the disease.¹ The articular involvement usually occurs early in the illness, with duration and severity greater in adults than in children. Polyarthritis is rarely simultaneous with active chorea, the severity of the articular symptoms and signs being inversely proportional to the degree of carditis.^{6,44} Polyarthritis is non-suppurative, asymmetrical, migratory, and self-limited, and does not result in permanent deformity. The classical migratory pattern refers to the sequential involvement of joints. While the process is resolving in one joint, another becomes involved, resulting in an overlapping in time with the participation of more than one joint. There is a marked preference to involve the peripheral large joints, and mainly of the legs. Less frequently, the shoulders, hips, spine, and the small joints of the hands and feet are affected. Tenderness and severe pain, out of proportion to the findings of the physical examination, are the most prominent features, and very prompt relief of the symptoms and signs follows the use of anti-inflammatory agents. The pain occurs in both active and passive movements, is usually diffuse, can show radiation to periarticular areas, and is associated with limitation of motion. Other characteristics

of inflammation, such as heat, redness, and swelling, although present, are usually less marked. If untreated, the inflammatory findings last from 1 to 5 days in each joint, reach the higher intensity in the first 2 days, with the entire process subsiding over 2 to 4 weeks.⁴⁴

Atypical presentations of arthritis, such as monoarthritis and additive and symmetrical polyarthritis, besides simultaneous participation of several joints, and the longer duration of the inflammatory process, have been described. Involvement of only one joint is often observed if the anti-inflammatory therapy is administered before the migratory characteristic has been established. Jaccoud's arthritis is considered a rare sequel of recurrent attacks of rheumatic fever, and is a possible exception for residual articular deformity. In this situation, periarticular fibrosis of the metacarpophalangeal joint results in marked ulnar deviation and hyperextension of the proximal interphalangeal joints.^{116,117} Post-streptococcal reactive arthritis is related as an acute and non-suppurative arthritic condition following a documented group A streptococcal infection. Its characteristics are not typical of rheumatic fever, and do not meet the Jones criteria. There is a latent period, usually shorter than 10 days, and persistence of mono- or polyarthritis for several months with atypical presentation. Clinical findings include an additive and symmetrical rather a migratory pattern and involvement of small and axial joints, besides a poor response to anti-inflammatory therapy.^{118,119} An association with mitral valvar dysfunction has been registered in one-twentieth of the patients.¹²⁰ Doubts remain whether post-streptococcal reactive arthritis is a different condition from rheumatic fever, or if the two entities represent diverse expressions of the same disease.

Sydenham's Chorea

Sydenham's chorea, chorea minor, or St. Vitus's dance, affects children and adolescents, more frequently females. It is uncommon after puberty, and is rarely seen in post-puberal males.¹²¹ It has been reported in up to one-third of patients, with a peak incidence at around 8 to 9 years of age.^{5,122} The latent period after infection is longer than for arthritis and carditis, varying from 1 to 7 months. It may occur as an isolated manifestation, the so-called pure chorea, or less frequently in association with carditis or arthritis.²⁶ As a late manifestation, the disorder is rarely associated with arthritis, but may co-exist with clinical or subclinical valvitis in up to two-fifths of patients.^{1,45,123,124} Chronic rheumatic heart disease has been described in around one-quarter of patients 20 years after the presentation of isolated chorea.¹²⁵

Sydenham's chorea is usually a self-limited disorder, and diagnosis is based exclusively on clinical examination. It is a manifestation of the central nervous system characterised by muscular weakness, hypotonia, and emotional instability, besides involuntary and purposeless but conscious movements of the skeletal muscles. Although the face and the arms and legs are more often involved, any voluntary muscle may be affected. The presentation of facial grimacing is frequent, besides abrupt but not repetitive movements of the limbs, mainly the hands. The uncoordinated movements are mostly evident when the patient is awake, particularly under stress, excitement, or effort. Oculomotor problems have also been reported, which go into remission in most patients after the improvement of the choreiform movements.¹²⁶

The onset is insidious, so that chorea as the first and sole manifestation of rheumatic fever may not be recognised in the early phase, the signs being attributed to behavioural or emotional problems. The child shows attention deficit and inappropriate behaviour, and becomes irritable, restless, and clumsy. Fine muscular incoordination is noted, and voluntary movements, such as unbuttoning clothes or tying shoes laces are difficult to execute. The manifestations become progressively more evident, with disturbances in the speech and handwriting. The signs of muscular weakness and choreiform movements are mostly generalised, sometimes asymmetrical, but one-fifth of patients have hemichorea, with the manifestations limited to one side of the body. So-called chorea paralytica is an expression of generalised and severe presentation, albeit very rare.¹²² Certain manoeuvres are helpful to bring out the choreiform movements. When the patient is asked to extend the arms forward, the hands assume the shape of a spoon or dish as a result of wrist flexion and hyperextension of the fingers. The milking sign is demonstrated by alternating increase and decrease in tension when the patient grips the examiner's hand. If the arms are raised above the head, the hands are involuntarily turned outwards. Undulating movements can be observed when the tongue is protruded, resembling a bag of worms.^{5,6,44}

Recurrent chorea is not uncommon. More recently, it has been questioned whether all recurrent choreiform episodes are due to rheumatic fever.¹²⁷ The severity and the course of the illness up to its resolution are variable. In mild cases, the choreiform movements may subside in few weeks, but most frequently the recovery takes up to 6 months, albeit that in severe cases the manifestation may persist up to more than 2 years.¹ Behavioural abnormalities occur in up to one-third of patients.^{128–130} More recently, a broad spectrum of post-streptococcal movement conditions associated with emotional and behaviour disorders have been identified using the acronym PANDAS—paediatric autoimmune neuropsychiatric disorders associated with *Streptococcus*.^{131–134}

Subcutaneous Nodules

Other than being useful for diagnosis, subcutaneous nodules have a limited value due to their lower frequency. They are one of the most characteristic major criterions, almost invariably associated with severe carditis.^{78,135,136} Seen in only one-tenth of patients, their frequency seems to have been reduced over the last decades.¹³⁷ On many occasions, the subcutaneous nodules are not noted by the patients. Sometimes they are found only following careful investigation. They usually appear several weeks after the onset of the acute episode, persist from days to weeks, and rarely last longer than 1 month. They can be seen early in recurrences. The nodules are small, varying in size from millimetres to 2 centimetres, and are firm, painless, and freely movable under the skin. They are encountered in clusters, on the extensor surface of the joints and overlying bone prominences, mainly in the large joints of limbs, knuckles, scalp, and along the spine in the paravertebral areas (Figs. 54A-10 through 54A-12).

Erythema Marginatum

This is an uncommon manifestation, occurring in only one-twentieth of patients. It is a macular rash, sometimes coalescent with a serpiginous or circular form, almost coppery pink at the border, and with a lighter centre. The lesions take the form of enlarging rings, mainly located

Figure 54A-10 The image shows subcutaneous nodules near bony prominences along the spine, focusing on the thoracic and lumbar vertebrae. (Reproduced with permission from Mota CCC, Meira ZMA: Rheumatic fever. *Cardiol Young* 1999;9:239–248.)

(Reproduced with permission from Mota CCC, Meira ZMA, Graciano RN, Silva MC: Diagnostic aspects, carditis and other acute manifestations of streptococcal infection. *Cardiol Young* 1992;2:222–228.)

Figure 54A-13 The photograph shows erythema marginatum located on the trunk and proximal limbs. (Reproduced with permission from Mota CCC, Meira ZMA, Graciano RN, Silva MC: Diagnostic aspects, carditis and other acute manifestations of streptococcal infection. *Cardiol Young* 1992;2:222–228.)

on the trunk and inner surface of the proximal limbs, and are not seen on the face (see Fig. 54A-13). Although the lesion can be seen during the acute phase, it is more often seen in the early stages. Characteristically the manifestation is transient, may last minutes, more usually days, may be intermittent for months, and is not influenced by the use of anti-inflammatory therapy. The lesions are more easily seen in fair-skinned patients, may become more apparent with the application of heat, and are associated most frequently with subcutaneous nodules and carditis.

Minor Manifestations

As isolated features, the minor manifestations are limited by their lack of specificity. When associated with a major manifestation, nonetheless, they can provide support for diagnosis. As already emphasised, arthralgia is considered a minor manifestation only when other signs of inflammation, such as redness, swelling, and heat, are absent. The pain shows the same characteristics as polyarthrititis concerning the site and type of joints affected, the migratory pattern and variability in severity. Arthralgia in one or more joints may co-exist with arthritis. In that case, only the major manifestation may be used as a diagnostic criterion. Fever is usually present in the early stage of the disease, commonly of low grade, and can persist for 2 to 3 weeks.⁵ There is no characteristic pattern, and it is rare for the temperature to rise higher than 39°C. The laboratory data included among the minor manifestations, as with the clinical findings, are also non-specific.

Other Manifestations

Other symptoms and signs, although less frequent, can be observed, but are not included in the set of minor manifestations of the Jones criteria. Epistaxis is an uncommon presentation, and abdominal pain, mainly around the navel, may precede the major manifestations. Upper abdominal pain, although less common in children than adults, may be a symptom of heart failure. Rheumatic pneumonia is considered a rare event, with high rates of death, and associated with severe carditis.^{138–140} Its diagnosis remains controversial considering that similar findings may be present in severe congestive heart failure and that there is an overlapping of clinical and radiographic presentations of the two conditions. Manifestations such as anorexia, listlessness, fatigue, anaemia, weight loss, and pallor are described, but are related to systemic inflammation and to the severity of the clinical presentations, mainly carditis.

Difficulties with the Diagnosis of Rheumatic Fever

The potential for permanent damage to the cardiac valves points to the importance of an accurate and early diagnosis. As no laboratory finding is specific, the history and physical examination remain the basis for the diagnosis. The established guidelines, although very useful, cannot substitute for experience and common sense on behalf of the physician. As a systemic disease of multiple associations, with a wide spectrum of manifestations, diagnostic problems can be present, since several other conditions can fulfil the Jones criteria. On the other hand, not all patients with an acute episode meet these diagnostic requirements. Even in areas where rheumatic fever is still prevalent, its frequency and severity have decreased, resulting in less characteristic presentations. Significant cardiac involvement, particularly if associated with other major manifestations, results in a more characteristic presentation of the disease. On the other hand, characterisation of mild cardiac involvement is difficult. Subclinical or smouldering carditis may not be recognised. As a consequence, the disease is diagnosed in the chronic phase by its valvar sequels. These circumstances have potential implications in prognosis, when the risks of recurrences and worsening of the valvar lesions are considered. Both under- and over-diagnosis of carditis are frequent. Considering the number of adults who present with established rheumatic valvar disease without any preceding history of rheumatic fever, under-diagnosis is particularly common. Over-diagnosis can be equally detrimental when children with innocent murmurs or murmurs caused by congenital cardiac defects associated with sore throats or arthralgia are wrongly labelled as having rheumatic heart disease. Due to the wide group of illnesses with the same presentation, the differential diagnosis of polyarthrititis is difficult when the articular involvement is the sole manifestation of the acute phase. The difficulties increase with the presence of monoarthrititis as an atypical presentation, or as a consequence of the premature use of anti-inflammatory agents. Usually, the joint involvement is an early and self-limited manifestation along the course of the disease. Mild articular presentation may contribute to misdiagnosis, mainly when the symptoms and signs have already subsided at the clinical examination. Furthermore, the differential diagnosis between polyarthrititis and polyarthralgia is difficult if based

exclusively on clinical history. In addition, doubts also remain regarding some conditions such as subclinical valvar lesions, post-streptococcal reactive arthritis, and PANDAS. There are many disease processes that may currently fulfill the Jones criteria in their early stage, or mimic the acute rheumatic process very closely. The differential diagnosis includes rheumatoid arthritis, serum sickness, other arthropathies, infective endocarditis, Henoch-Schönlein purpura, acute leukaemia, poliomyelitis and acute appendicitis, viral myocarditis, viral pericarditis, systemic lupus erythematosus, and other collagen disorders that may affect both joints and the heart.

The diagnosis of recurrences can also, on occasion, be challenging. For a presumptive diagnosis, and with the aim of avoiding under-diagnosis, it is important to note the epidemiological context of streptococcal exposure. In patients with cardiac sequelae from a previous attack, and when carditis is the sole manifestation of the recurrence, a more precise diagnosis can only be established if pericarditis is found, or if a different valve is damaged. Another consideration is the worsening of previous valvar lesions. In patients with multi-valvar involvement, and with no other associated major manifestations, the question to address is whether the manifestations are due to a recurrence, or whether they represent a higher degree of severity in the evolution of the chronic rheumatic heart disease. The supporting evidence of a recent streptococcal infection is mandatory to confirm the diagnosis of a new attack. Even considering that the acute-phase reactants are not specific for the disease, they are useful to characterise the presence of the inflammatory process. Besides the minor manifestations, other clinical features such as fatigue, anorexia, pallor, and lack of movement contribute to the diagnostic approach when they are not part of the cardiac failure. As the clinical variables are crucial for a better comprehension of the disease, a longer period of close observation sometimes is needed to clarify the diagnosis.

LABORATORY INVESTIGATIONS

Although none of the laboratory tests is specific, they are useful in monitoring the inflammatory process, and contribute to the management of patients, besides providing the evidence of a previous streptococcal infection. There are three categories supporting the clinical diagnosis, namely, tests supporting evidence of a recent group A streptococcal infection, the acute-phase reactants, and a third group of tests, including those examinations evaluating the cardiac involvement.

Supporting Evidence of a Recent Group A Streptococcal Infection

An important requirement for the diagnosis of rheumatic fever is the evidence of the antecedent streptococcal infection, since many other diseases, unrelated to this infection, have a similar clinical profile. Demonstration of infection by the group A *Streptococcus* is necessary because clinical diagnosis of pharyngotonsillitis or scarlet fever due to this cause cannot be made with certainty at the time of the onset of rheumatic fever.^{21,29} In the circumstances of Sydenham's chorea and indolent carditis, however, this prerequisite is dispensable.²¹ The identification of the bacteria by throat cultures or rapid antigen testing of throat swabs, as well as the documentation of elevated or increasing streptococcal

antibody titres, confirms the recent streptococcal infection, but none of these tests is diagnostic of rheumatic fever.

Throat culture remains the most reliable method for identifying the β -haemolytic group A *Streptococcus* in the setting of acute pharyngotonsillitis. The blood agar culture has a sensitivity of 90% to 95% and a specificity of 100%.²⁹ In contrast with the longer time of 24 to 48 hours needed to obtain a throat culture, a more prompt result is provided by the rapid group A streptococcal antigen detection tests. Most of the available tests, when compared to the blood agar culture, show a specificity greater than 95%, but the sensitivity is variable, from 31% to 95%.^{29,141,142} Consequently, when the result is positive, the therapeutic decision can be made with confidence. Nonetheless, considering the wide variation in sensitivity, a blood agar culture is still recommended when the result is negative, particularly in settings where rheumatic fever is highly prevalent.^{111,142} In spite of the accuracy, *Streptococcus* is isolated by blood culture at the time of the onset of rheumatic fever in only one-quarter of cases.²¹ One reason is the elimination of the bacterium by the defence mechanisms of the body during the latent period, since the streptococcal infectious process usually has already subsided when the diagnosis of rheumatic fever is established. Negative results are also related to the previous use of antibiotics. On the other hand, a positive result cannot distinguish a true streptococcal infection from a streptococcal carrier state.¹⁴¹

The determination of the streptococcal antibody titres is the most specific test to confirm a previous infection. Blood titres of antibodies against extracellular products include antistreptolysin O, antideoxyribonuclease B, antihyaluronidase, and antistreptokinase. The range of normal values is variable and related to age, season of the year, and geographical location. Although the bacteria can be found in the upper respiratory tract in both the carrier state and during an acute streptococcal infection, the rising antibody response can be observed only in the case of true infection.¹ The determination of three different antibody tests shows an elevated titre for at least one antibody in up to 95% of patients.^{41,77} The antistreptolysin O assay is used most commonly, and provides reliable confirmation of a previous infection in four-fifths or more of patients. Titres tend to be higher in patients with rheumatic fever than in those with uncomplicated streptococcal infections.⁵ The titre is considered elevated if it exceeds the upper limit for a given population. This upper limit is defined as the highest value surpassed by only one-fifth of individuals. A single titre of at least 320 Todd units for children, and 240 Todd units for adults, is considered elevated.²¹ Although an increased titre is an evidence of a previous streptococcal infection, the demonstration of a rising antibody response from the acute to convalescent phase is a more reliable means to document a recent infection. For the confirmation of rising titres in samples obtained at intervals of 2 to 4 weeks, an increase in titre of two or more dilutions is considered diagnostic.⁵ Timing of the determination should also be considered when interpreting the results. The titre usually becomes elevated 2 weeks after the streptococcal infection, peaks at 3 to 4 weeks, and starts to decline after 2 to 3 months.^{1,137} As a result, the titres are likely to be normal in the early phase of the disease, as well as in patients with chorea or with indolent carditis, when the titres have usually already returned to normal levels. Borderline or low titres are detected in around one-fifth of patients during the first 2 months after the onset

of rheumatic fever, and in about two-fifths of those affected by isolated Sydenham's chorea.²¹ Considering the availability, if the titre is not elevated and the diagnosis of rheumatic fever is strongly suggested, another antibody test may be requested to confirm the previous streptococcal infection.¹³⁷ The anti-DNAase B titres remain elevated for a longer period of time than do the antistreptolysin O titres, even after uncomplicated streptococcal infection.¹⁴¹ The streptozyme test is a rapid commercially available slide agglutination test used to detect antibodies to several streptococcal antigens. It has been less well standardised, raising questions about its reliability.^{137,141}

Acute-phase Reactants

The acute-phase reactants have been used to identify the presence and degree of the inflammatory process, and to follow the course of the disease activity, as well as its resolution. The most commonly used acute-phase reactants are the erythrocyte sedimentation rate and C-reactive protein. Both these laboratory markers of acute inflammation are sensitive but non-specific, since abnormal results may be produced by many other conditions. Both tests are abnormal in patients with carditis and polyarthritis, whereas they are frequently normal in patients with late presentations of the disease, such as isolated chorea, or only slightly elevated in indolent carditis. In general, the levels normalise after the anti-inflammatory therapy, and the use of corticosteroids results in a quicker return when compared to salicylates.¹¹¹ The increase in the erythrocyte sedimentation rate is proportional to the intensity of the inflammatory reaction, but it is unrelated to the site of the clinical manifestation of rheumatic fever.^{44,143} The erythrocyte sedimentation rate may be increased in patients with anaemia and suppressed in those with congestive heart failure, neoplasms, and tissue necrosis.

As the C-reactive protein is not usually present in the blood, slightly positive results are significant. It can be an over-sensitive indication of the acute inflammatory process, and is not influenced by anaemia or by heart failure. A C-reactive protein test becomes negative earlier than the decrease of erythrocyte sedimentation rate. Other markers of the inflammatory activity are currently less often used. The serum mucoprotein, and the α_2 -globulin fraction in the electrophoretic study, are abnormal along the course of the acute phase, usually show higher levels related to severity of the disease, and are not influenced by medication. The complexity of the quantitative process in the diverse analytic phases is a limitation for the use of the serum mucoprotein. Leucocytosis may occur, but is not sufficiently constant to be of diagnostic value.

Examinations to Evaluate Cardiac Involvement

The third group includes the tests evaluating cardiac involvement. Although the electrocardiogram and chest radiography constitute useful methods, they are characterised by low specificity and sensitivity. Normal results do not exclude the diagnosis of carditis. The chest radiograph is useful in the determination of the presence and degree of the cardiac enlargement in supporting the clinical diagnosis, as is the presence of prominent vascular markings or pulmonary oedema, which characterises the severity of

carditis. Variations in cardiac size are also valuable when charting evolution of the disease. Marked cardiomegaly with a rapid increase of the cardiac size, or the configuration of water flask in the erect position, suggest the diagnosis of pericardial effusion even in the absence of a friction rub.¹³⁷ In severe cases, this is dubbed rheumatic pneumonia, a rare entity related to multiple radiological patterns, with uni- or bilateral involvement, consolidation, patchy areas of infiltration in the lungs fields, diffuse bilateral and migratory infiltrates, pleural effusion, and confluent nodular lesions.¹³⁹

Electrocardiographic abnormalities are also non-specific, usually temporary, and mainly represented by sinus tachycardia, disturbances in conduction, diffuse ST and T changes, low voltage of the QRS complex and changes in the T wave. There is no correlation with severity, nor do the changes have prognostic significance. Normal tracings do not exclude cardiac involvement, and the diagnosis of carditis should not solely be based on electrocardiographic abnormalities. Arrhythmias are occasionally found, albeit frequently self-limited and benign. In those suffering recurrences, atrial fibrillation can be seen when the left atrium is significantly enlarged.⁷⁸ The prolonged PR interval relative to heart rate and age is included as one of the minor manifestations in the Jones criterions. This disturbance may be found with similar frequency in patients with or without carditis, and is also reported in normal children.⁵ Advanced conduction delay, including second- and third-degree atrioventricular blocks, is rarely seen. As with the prolonged PR interval, such changes appear as temporary events during the acute episode.^{144,145} A prolonged QTc interval has been reported as a more frequent finding in rheumatic fever than first-degree atrioventricular block.^{90,146} More recently, the increase in QT dispersion, and its association with cardiac involvement in children with the first episode of rheumatic fever, has been reported. At follow-up, the reduction on the QT dispersion was concomitant with the clinical improvement.¹⁴⁷

The continuing evolution of technology has allowed the incorporation of non-invasive techniques such as Doppler echocardiography. This now constitutes one of the most important tools for investigating the functional and morphological aspects of patients with rheumatic fever, besides providing support for the management at the first evaluation and follow-up. The technique has added important information regarding the structure of the valvar and subvalvar apparatus, resulting in a better understanding of the mechanisms of valvar dysfunction. Additionally, the technique is useful when evaluating involvement of the pericardium and its repercussions. The evaluation of the degree of severity, and the impact of valvar lesions, by Doppler echocardiography is an integrative process based on multiple parameters, and is dependent of the site and the type of dysfunction.^{1,148,149} The accurate assessment of the extension of valvar lesions provides an earlier diagnosis in cases of mild cardiac involvement, identifying subclinical valvar lesions in both the acute and chronic phases (Figs. 54A-14 and 54A-15). A set of Doppler echocardiographic characteristics has been established for the diagnosis of subclinical valvitis, based on patterns of regurgitant jets different from those found in physiological regurgitation (see Table 54A-4). The morphological features of initial involvement include valvar

Figure 54A-14 Colour flow mapping in a 9-year-old girl with Sydenham's chorea and subclinical valvitis shows mild aortic regurgitation. AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

Figure 54A-16 Colour flow mapping in this 14-year-old boy with moderate mitral and aortic regurgitation shows thickening of mitral leaflets, dilation of left-sided chambers, and moderate mitral valvar regurgitation. LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 54A-15 Colour flow mapping in this 7-year-old boy with Sydenham's chorea and subclinical valvitis, with mild thickening of the mitral valvar leaflets, shows mild mitral regurgitation. LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 54A-17 The cross sectional echocardiogram in this 9-year-old girl with mild to moderate mitral regurgitation shows moderate thickening of the aortic leaflet of the mitral valve (arrow). AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

thickening, with focal nodular changes at the tips and bodies of the leaflets, mainly in the mitral valve, and with associated annular dilation (Figs. 54A-16 and 54A-17). Leaflet prolapse is not a frequent finding in first acute episode. The aortic leaflet of the mitral valve is most often involved, showing an elongated and redundant arrangement with wide excursion.^{85,150–152}

Rupture of the tendinous cords is a rare event. If seen, it usually involves the aortic leaflet, with resulting severe mitral insufficiency.^{151,153,154} In severe cases, monitoring the progress of valvar damage makes it possible to determine the need for intervention during the acute episode, as well as choosing the procedure.^{155,156} Doppler echocardiography also contributes to avoidance of over-diagnosis, permitting exclusion of other conditions which, in a clinical setting, could have been misdiagnosed as rheumatic fever.^{85,89}

Other modalities for the assessment of cardiac damage include endomyocardial biopsy and radionuclide imaging. As already discussed, the low diagnostic sensitivity of endomyocardial biopsy limits the technique to clinical investigation.^{74,111,121} For radionuclide imaging, gallium-67

has shown better diagnostic results when compared to anti-myosin scintigraphy, but experience with both methods for imaging myocardial inflammation is limited.¹⁰⁸

MANAGEMENT

Management of the acute episode includes eradication of tonsillar and pharyngeal group A *Streptococcus*, and treatment of the presenting manifestations. No intervention can be made in the immunological process, however, once it has been triggered. Anti-inflammatory agents can be symptomatically beneficial, but have no curative properties. Considering that the available treatment is supportive, the most effective therapeutic approach is directed towards prophylaxis.¹⁵⁷

Eradication of the Group A Streptococcal Infection

It is important to eradicate the infecting agent even in the presence of a negative throat culture. Although antimicrobial therapy does not influence the course or severity of the

TABLE 54A-5

PRIMARY PREVENTION OF RHEUMATIC FEVER: TREATMENT FOR GROUP A STREPTOCOCCAL PHARYNGOTONSILLITIS AND ERADICATION OF STREPTOCOCCI^{1,141,177}

Agent*	Dose	Route	Duration
Benzathine penicillin	600,000 U for patients <60 lb (27 kg) 1,200,000 U for patients ≥60 lb (27 kg)	Intramuscular	Once
or			
Phenoxymethylpenicillin	250 mg (400,000 U)/dose, for patients <60 lb (27 kg) 500 mg (800,000 U)/dose for patients ≥60 lb (27 kg) Two to three times daily	Oral	10 full days
or			
Amoxicillin	Children: 25–50 mg/kg per day divided into 3 doses Adolescents and adults: total dose of 750–1500 mg/day divided into three doses	Oral	10 full days
For individuals allergic to penicillin:			
Erythromycin estolate	20–40 mg/kg per day divided into 2–4 doses (maximum 1g/day)	Oral	10 full days
or			
Ethylsuccinate	40 mg/kg per day divided into 2–4 doses (maximum 1g/day)	Oral	10 full days

*For other acceptable alternatives, see text. The following agents are not acceptable: sulfonamides, including trimethoprim-sulfamethoxazole, tetracyclines, and chloramphenicol. Modified from Guidelines for the diagnosis of rheumatic fever: Jones criteria, 1992 update. Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. JAMA 1992;268:2069–2073.

disease, it is necessary to avoid the continuous exposure to streptococcal antigens. As soon as the diagnosis is established, patients with any manifestations of the acute rheumatic process, including the late ones such as chorea, should undergo antibiotic therapy to eradicate the streptococcus. The efficacy of eradication is dependent on the choice of the drug, and the length of time in which effective levels are maintained in the blood. In all patients, eradication should be followed by long-term secondary prophylaxis to prevent recurrences. Eradication is similar to treatment recommended for acute streptococcal pharyngotonsillitis (Table 54A-5).

Medical Management of Clinical Manifestations

Apart from a therapeutic course of penicillin needed to eradicate the group A *Streptococcus*, the medical treatment of the clinical manifestations remains supportive, and is based on anti-inflammatory drugs and bedrest. The choice of suppressive medication, duration of bedrest, and subsequent restriction of physical activity is best decided on an individual basis, depending on the severity and clinical response. Corticosteroids and salicylates, the mainstay of therapy, are effective in suppressing the acute signs of inflammation. Corticosteroids have shown a prompt action than salicylates, and can be lifesaving in severe presentations of carditis. There is no evidence that the anti-inflammatory therapy affects the frequency or severity of the valvar lesions, or prevents the cardiac sequels in the chronic phase. When comparing salicylates and corticosteroids, no treatment has been shown definitely to be superior. Meta-analysis showed no statistically significant difference in preventing development of pathological murmurs 1 year after treatment.¹⁵⁸ Likewise, no differences were found concerning the risk of cardiac disease when comparing several corticosteroid agents and intravenous immunoglobulin with aspirin, placebo, or no treatment.^{159–161} It is advisable to defer the starting of anti-inflammatory or suppressive treatment until a definitive diagnosis has been established. It is unwise to

start a therapeutic trial of either salicylates or steroids prematurely, since this may suppress the inflammatory process sufficiently to make a firm diagnosis almost impossible. It is doubtful if the anti-inflammatory drugs have any effect on either erythema marginatum or subcutaneous nodules.

Bedrest

The recommended duration and strictness of bedrest is variable depending on the manifestations and severity of the clinical presentation. At all stages of treatment, the necessities of patients to participate in recreational activities must be taken into consideration by providing alternatives according to their age and clinical condition. The recommendation of prolonged bedrest is based primarily on reducing cardiac work in those with carditis, and avoiding as much as possible the use of the involved joints in those with arthritis. Strict bedrest should be limited to patients with a more significant involvement of the heart, and to those with arthritis of the legs. Patients with polyarthritis, and without carditis, can be allowed out of bed as soon as the fever and local symptoms have subsided, and laboratory evidence of inflammation has begun to regress, usually after a period of 1 to 2 weeks. If there is no evidence of cardiac involvement in progress, this period is followed by gradual release for activities during the next 2 weeks. In those with carditis, the duration of bedrest depends on the severity of the cardiac lesions and the speed of regression of the acute episode. Patients with carditis, either isolated or associated with polyarthritis, but without cardiomegaly or congestive heart failure, should be made to rest for about a month. The rest need not be strict, and it should be followed by supervised activities for the following weeks. Patients with cardiomegaly, but without definite congestive failure, should be made to rest, with strict enforcement over the first 3 to 4 weeks, before a gradual release. In the presence of carditis and congestive heart failure, patients should be kept on absolute rest until the failure is completely controlled, and they should maintain modified bedrest with slow and gradual restoration of activities, provided there is no rebound.

TABLE 54A-6

TREATMENT OF MAJOR MANIFESTATIONS OF CARDITIS

Clinical Manifestation	Treatment Schedule*
Severe carditis	Prednisone [†] 2 mg/kg/day once daily
Moderate carditis	Prednisone 1–2 mg/kg/day once daily or Aspirin [‡] 75–100 mg/day divided into 4 doses
Mild carditis	Aspirin 75–100 mg/day divided into 4 doses
Polyarthritides	Aspirin 75–100 mg/day divided into 4 doses or Naproxen 10–20 mg/kg/day
Chorea	Haloperidol [§] 2–6 mg/day or Valproic acid 20–30 mg/kg/day

*See text for complementary information.

[†]Maximum dose is 80 mg/day.[‡]Serum level should not exceed 30 mg/dL.[§]Maximum dose is 6 mg/day.**Carditis**

Anti-inflammatory drugs have been extensively employed in the treatment of carditis, showing a prompt effect in terms of cardiac symptoms (Table 54A-6). Salicylates have been used for those with less severe forms of carditis, when there is no necessity for powerful suppression of inflammation.^{1,111,137} Corticosteroids have been recommended for patients with at least moderately severe carditis, especially for those with congestive heart failure. Prednisone is usually preferred as it produces less retention of sodium and loss of potassium. The initial dose of prednisone is given for 2 to 3 weeks depending on the severity of the carditis. After this period, a gradual tapering is required. The dose should be slowly withdrawn, decreasing by one-fifth each week, which means a total duration of the treatment of about 8 to 12 weeks, coinciding with the duration of the acute episode. Rebounds are sometimes associated with rapid withdrawal of corticosteroids. Some authors have recommended an overlapping therapy with the aim to prevent rebounds, with the introduction of salicylates as the dose of corticosteroids is reduced.^{137,162} The advantage of the use of high doses of methylprednisolone as an alternative treatment remains controversial. It has most frequently been administered as a life-saving therapy for those with severe carditis.^{163,164} The use of intravenous gamma-globulin has been reported in patients with carditis, but more investigations are required to evaluate this therapy.^{161,165} The lack of clinical improvement due to mechanical factors can be observed in patients with severe valvar lesions, mainly in those with recurrences, and sometimes the treatment is surgical.²⁶

Supportive measures include the treatment of congestive heart failure and arrhythmias. Congestive heart failure in rheumatic carditis is often controlled with bedrest and corticosteroids alone. In patients with severe forms of presentation, the use of digoxin, diuretics, and inhibitors of angiotensin-converting enzyme should be considered.¹

Arthritis

Salicylates are the first-line treatment for patients with established arthritis but without carditis. These agents usually have a dramatic effect on the articular inflammatory process, with a prompt improvement, commonly within 24 to

48 hours. In this context, premature treatment can interfere in the characterisation of the migratory pattern of the arthritis, thus making the diagnosis difficult. The differential diagnosis with other diseases must be considered when the articular symptoms are not responsive to salicylates.²¹ An effective and safer dose of aspirin for children usually produces a level of salicylate in the blood of not more than 20 mg, which is well below the toxic range (see Table 54A-6). The full dose is given for the first 2 weeks and subsequently is gradually reduced to up to 60 mg/kg over the next 2 to 3 weeks. A smaller or a larger dose can be used, depending on the clinical response to treatment, and may be maximised for those failing to respond to lower doses. A higher dose, such as 100 mg/kg, is required by few patients. If more massive doses of salicylates are given, toxicity can occur. Rapid breathing is one of the early signs of toxicity. Nausea, vomiting, tinnitus, lassitude and occasionally delirium, convulsion, and coma can occur. Naproxen is an alternative therapy for patients who are allergic to or intolerant of aspirin.^{1,166,167}

Sydenham's Chorea

Isolated chorea is treated symptomatically. The patients should be kept in a quiet environment to protect them from external stimulation and stress. Precautions must be taken to prevent accidents and, according to their condition, appropriate sedation can be helpful. Besides barbiturates and chlorpromazine, diazepam has been used in management. Haloperidol and valproic acid are frequently employed, and have been shown to be effective in controlling symptoms,^{168,169} albeit requiring longer periods when compared to the time required to control carditis and arthritis²⁶ after the use of anti-inflammatory drugs (see Table 54A-6).

Anti-inflammatory agents are usually not indicated, because chorea often occurs after the resolution of the systemic inflammatory process. The use of corticosteroids and immunoglobulin in patients with isolated Sydenham's chorea is controversial.^{170–174} The need for the eradication of the streptococcus, followed by regular secondary prophylaxis, is as important in chorea as in any other rheumatic manifestation. Due to the more recent observations regarding the neuropsychiatric disorders and persistent disabilities in some patients, a more aggressive treatment has been recommended, along with the need for closer vigilance in the period of follow-up.^{128,129,130,175,176}

Rebounds

Clinical or laboratory evidence of rebounds is infrequent. They can be seen after cessation of the anti-inflammatory treatment, and usually occur within 2 to 3 weeks. Some patients show only laboratory abnormalities. Those with clinical rebounds usually show arthralgia, fever, and occasionally arthritis, but severe cardiac manifestations may also occur. Rebounds occur more often after corticosteroid therapy than salicylates. Laboratory rebounds, and most of the clinical rebounds, do not require any treatment. They usually subside spontaneously within a few days. Only the very severe clinical rebounds need a full reinstitution of the earlier treatment.^{1,162}

PREVENTION

Prevention of both primary episodes and recurrences is related to the control of the group A streptococcal infections. Primary prevention implicates controlling the initial attack of rheumatic fever by means of the identification and

eradication of the group A *Streptococcus* from the tonsillar and pharyngeal tissue during the acute infection, besides promoting means to reduce the exposure of patients to the bacteria. Secondary prevention, by means of the continuous use of antibiotics, is related to the control of recurrences in patients who have already been affected by rheumatic fever, independent from the clinical manifestation or presence of sequels. These patients are particularly susceptible to developing subsequent attacks of the disease when faced with an acute infection by the group A *Streptococcus*, symptomatic or not.

Public education is an important aspect of prevention when the low cost of the prophylactic therapy is compared with the consequences of the disease. In this respect, in Brazil we have followed the concept of vertical programming. Thus, our programme for prophylaxis of rheumatic fever is based on progressive involvement from local through city administrations to the level of a nation-wide programme. In the case of rheumatic fever, the majority of available national resources has been allocated towards diseases specific projects. This is vertical programming, to be contrasted with more broad-based improvements in the health of the population, such as general measures for prevention, and development of primary care services and the health workforce, which represent horizontal programming.

Primary Prevention

Besides preventing rheumatic fever, an accurate diagnosis of a streptococcal pharyngotonsillitis, and the prompt introduction of antibiotic therapy, can shorten the evolution of the infection, with improvement of symptoms. Additionally, adequate management reduces the rate of transmission to close contacts, since after 24 hours of the onset of the treatment, patients are considered noncontagious.^{141,177}

Table 54A-7 summarises the clinical features and epidemiological data which may be helpful in identifying the streptococcal pharyngotonsillitis. These characteristics are useful for diagnosis, but none can predict or exclude the streptococcal aetiology with certainty, because the same clinical picture may be produced by other agents which cause exudative pharyngotonsillitis. Hoarseness,

conjunctivitis, cough, nasal congestion, and a runny nose are symptoms and signs more usually associated with viral infections.^{29,61,177} Considering the difficulties for a precise clinical diagnosis, the laboratory confirmation of group A streptococcal infection should ideally be performed before starting antibiotics. Throat swabs, or the rapid antigen detection test whenever possible, should be obtained with the aim of avoiding excessive use of antibiotics, and consequently the emergence of resistant organisms. The serological examination for streptococcal antibodies to extracellular antigens constitutes a useful method to identify the preceding infection with the group A *Streptococcus* and support the diagnosis of rheumatic fever. The test, however, has limitations in diagnosis, since the results can be interpreted only in retrospect.^{1,29,30}

Difficulties exist in providing effective primary prevention, since a clinical diagnosis of the streptococcal infection often poses a problem because of the difficulty in ruling out other bacterial and viral causes. Approximately two-fifths of acute throat infections are of bacterial aetiology, and the streptococcus is responsible for about half of these events.^{29,178,179} Another difficulty includes the presence of the unrecognised forms of infection, considering that the streptococcal pharyngotonsillitis may not always manifest as a severe infection. A clinically mild sore throat is not uncommon, and sometimes is asymptomatic, but may still lead to rheumatic fever. At least one-third of patients with rheumatic fever have no history of an antecedent streptococcal infection, a limiting condition for primary prophylaxis.¹⁸⁰ In addition, the efficacy of primary prevention is restricted in areas with high rates of exposure. In this context, unfavourable living conditions, such as over-crowding with closer interpersonal contact, constitute a propitious condition for the propagation of the bacteria. Persistence of the streptococcus following the infection as a result of an inappropriate regime for eradication is a cause of failure to prevent rheumatic fever. Streptococcal pharyngotonsillitis, independent of treatment, can present as a self-limited condition. Use of bactericidal drugs, with administration of sufficient doses to ensure therapeutic levels in the serum for 10 days, therefore, is an important requirement to achieve maximal rates of eradication and to prevent rheumatic fever. No single regime achieves the complete eradication in treated patients.^{111,141,181} Routine culturing after an adequate treatment with good compliance, nonetheless, is not indicated, except in specific epidemiological situations, such as increased risk of streptococcal infections or presence of streptococcal non-suppurative sequels.^{1,29,121,177} Tonsillectomy is not recommended for the primary prevention of rheumatic fever, as no controlled studies have shown its effectiveness in reducing the frequency of the disease.⁴⁸

Recommended regimes for primary prophylaxis are shown in Table 54A-5. Factors to be considered for the selection of therapy include an antimicrobial agent of confirmed clinical and bacteriological efficacy, narrow antimicrobial spectrum, good compliance with therapy, low incidence of side effects, and low cost. The treatment of an acute episode of pharyngotonsillitis before the ninth day of infection is effective in preventing the attack of rheumatic fever.¹⁸² The group A β -haemolytic *Streptococcus* remains remarkably sensitive to penicillin.⁵² This antibiotic is considered the drug of choice for treatment, with proven effectiveness in primary prophylaxis. Serious side reactions and major

TABLE 54A-7	
CLINICAL CHARACTERISTICS OF ACUTE PHARYNGOTONSILLITIS CAUSED BY GROUP A β-HAEMOLYTIC STREPTOCOCCI	
Most common in age group of 5–15 years	
Sudden onset of acute pharyngeal pain and malaise	
Headache	
Fever of 102°–104°F (39°–40°C)	
Pharyngeal erythema and exudate, soft palatal petechias	
Enlarged tender cervical lymph nodes	
Scabby erosions on the edges of nostrils	
Presence of constitutional signs and symptoms	
Acute otitis media	
Vomiting	
Suppurative sinusitis	

sensitive reactions to penicillin are unusual.^{1,30,32,183,184} Drugs other than penicillin offer no advantage for treatment of streptococcal infection, when account is taken of their cost-effectiveness. Intramuscular benzathine penicillin, also known as benzathine penicillin G, is often used, especially for those patients who are unlikely to complete the conventional 10-day course of oral treatment. The oral antibiotic of choice is phenoxymethyl penicillin, or penicillin V. Amoxicillin and ampicillin have been used but have no microbiological advantage over penicillin.¹⁷⁷ The disadvantage, as occurs with phenoxymethyl penicillin, is that oral antibiotics may be taken irregularly or for a shorter period, leading to an inadequate level in the blood, or may be used for insufficient time to achieve maximal rates of eradication of the bacteria. Patients must continue to take the penicillin regularly for the entire period, even though they will probably be completely asymptomatic after the first few days. Another acceptable alternative for a 10-day course of therapy is a first-generation cephalosporin. Besides the disadvantage of the broader spectrum of activity and higher cost, when compared to penicillin, care must be observed, as those who are allergic to penicillin may also be allergic to cephalosporins. Shorter courses of oral penicillin have been reported for the treatment of group A streptococcal pharyngotonsillitis. Although these regimes may be clinically effective in non-epidemic settings, they are not adequate for prevention of rheumatic fever when the treatment of the infection due to rheumatogenic strains is considered.³⁰ Erythromycin is the first alternative choice for patients allergic to penicillin. It should also be given in divided doses for 10 days, and the dose should not exceed 1 g daily. When a macrolide antibiotic is considered, account should be taken of the rates of resistance in the community. For the rare situation of patients allergic to both penicillin and erythromycin, clindamycin is an option.²⁹

Newer macrolides such as azithromycin and clarithromycin are reported as being effective. Azithromycin has a similar antibacterial spectrum to that of erythromycin against the group A *Streptococcus*, has fewer gastrointestinal side effects, and produces high tonsillar tissue concentration. The drawback of these alternatives is cost and their broader spectrum, with the risk of emergence of resistant pathogens.¹¹¹ Regarding the shorter courses of azithromycin and some cephalosporins, there is insufficient evidence to recommend these regimes for routine treatment. They should not replace penicillin as the agent of choice.^{1,29,32,185} Certain antimicrobials are not recommended for the treatment of streptococcal infections, due to high rates of resistance and consequent failure in eradicating the streptococcus. Tetracycline should not be used because of the high prevalence of resistant strains to this antibiotic. The sulphonamide drugs, although effective as continuous prophylaxis for the prevention of recurrent attacks of rheumatic fever, should not be used for the treatment of streptococcal infection owing to the frequent failure to eradicate the bacteria.²⁹

Carriers

Throat carriers can be transient, convalescent, or chronic. Chronic carriers may not show any clinical or serological evidence of infection and, in time, may reveal the organisms in the throat only intermittently. They are known as spotty carriers. The treatment of carriers has questionable value, especially in the absence of clinical or epidemiological evidence of active infection. According to the American

Academy of Pediatrics,¹⁷⁷ antimicrobial treatment for throat carriers is an exception, and is indicated only in specific circumstances such as a family history of rheumatic fever, an outbreak of rheumatic fever, or an outbreak of streptococcal pharyngotonsillitis in semiclosed or closed communities.

Secondary Prevention

Secondary prophylaxis should be started soon after the diagnosis of an acute episode of rheumatic fever, or when well-documented rheumatic heart disease is established. The institution of continuous prophylactic regimens to prevent recurrences is mandatory for all patients, independent of the clinical manifestation or presence of sequels, and is based on two premises. First, as it occurs in the primary episodes, there is a causal relationship between the group A streptococcal pharyngotonsillitis and the subsequent attacks. Second, an increased number of recurrences is usually associated with a poor prognosis. Although none of the regimes is able to modify the course or severity of the valvar sequels, prevention of colonisation or streptococcal infections is markedly effective in reducing recurrences and, consequently, the appearance of new valvar lesions or worsening of the preexisting ones. In patients whose diagnosis of rheumatic fever has not completely been elucidated, the need for secondary prophylaxis depends on the judgement of individual risks. Its maintenance should be evaluated during the follow-up.

The regimes for secondary prevention are shown in Table 54A-8. Benzathine penicillin is the first choice, and

TABLE 54A-8

SECONDARY PREVENTION OF RHEUMATIC FEVER: PROPHYLAXIS OF RECURRENT ATTACKS*

Agent	Dose	Route
Benzathine penicillin (benzathine penicillin G)	600,000 units for patients <27 kg (60 lb) 1,200,000 units for patients ≥27 kg (60 lb), single dose, every 3 or 4 weeks [†]	Intramuscular
or		
Phenoxymethyl penicillin (penicillin V)	250 mg twice daily	Oral
For individuals allergic to penicillin:		
Sulphadiazine (sulfadiazine)	0.5 g for patients <27 kg (60 lb) 1.0 g once daily for patients ≥27 kg (60 lb), once daily	Oral
For individuals allergic to penicillin and sulphadiazine:		
Erythromycin	250 mg twice daily	Oral

Geneva:WHO, 2004; and Dajani A, Taubert K, Ferrieri P, et al: Treatment of acute Streptococcal pharyngitis and prevention of Rheumatic fever: a statement for health professionals. Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young, the American Heart Association. Pediatrics 1995; 96 (4 pt 1): 758-764.

constitutes the most effective strategy to prevent recurrences of acute episodes. Regarding the mode of administration, the monthly use of the repository presentation of penicillin has long been considered an effective form of prophylaxis, and is still currently advocated.¹⁸⁶ Nonetheless, in populations with high prevalence of rheumatic fever, shorter intervals are recommended, supported by observations of higher rates of recurrences related to monthly prophylactic regimens when compared to 3-week intervals.^{26,187–189} In addition, pharmacokinetic studies have demonstrated inadequate levels of penicillin in the serum to cover the last week of the month.^{190–194} Prevention with regimes at 2-week intervals has shown high levels of penicillin and lower rates of recurrences, but there is the inconvenience of the frequent use of medication, and the adherence to treatment.^{26,190,195} The choice of either a 3- or 4-week interval, therefore, must be tailored to the epidemiological context, mainly the frequency of rheumatic fever in the community and individual risks of exposure to the group A *Streptococcus*. In areas where the incidence and prevalence of rheumatic fever are particularly high, the administration of benzathine penicillin every 3 weeks is justified, and is also recommended in special circumstances and for certain individuals deemed to be at high risk.^{1,141} For effective prevention, it is necessary to ensure that protective levels will be reached and maintained in the serum during the interval between the doses, besides considering adverse factors such as lack of compliance with continuous medication, bioavailability, and absorption of the drug. In this setting, adequate levels are less predictable when using oral medication. Oral sulphadiazine is recommended for patients allergic to penicillin, and for those allergic to both drugs, erythromycin is the recommended alternative. Sulphadiazine, although effective in preventing colonisation of the upper respiratory tract with streptococcal strains, is not indicated for primary prevention.

Regarding the duration of secondary prophylaxis, life-long prevention is particularly important in those with established rheumatic heart disease, since patients with cardiac lesions are at higher risk of recurrences. It is known, however, that the risk of subsequent attacks declines with age and the length of time since the last attack. Considering the difficulties of maintaining lifelong treatment, exceptions may be made, especially in older patients. These are determined on an individual basis. In coming to a decision, the physician should carefully take into account a number of factors, such as age, socioeconomic and educational status, the rates of recurrence in the community, the individual risks of acquiring a streptococcal infection, the presence of a recent attack of rheumatic fever, the number of previous attacks, the presence of rheumatic heart disease, and the potential risks of a recurrence in the severity of an established valvar lesion. Adults at an increased risk, such as parents of young children, school teachers, medical and paramedical personnel, and military cadets and servicemen, necessarily need prophylaxis over a longer period of time. In countries with poor socioeconomic development, the environmental factors weigh heavily against effective programmes for secondary prophylaxis. The greatest risk of rheumatic recurrences is in the disadvantaged, which includes children and adolescents, those with established rheumatic heart disease, those who have had multiple

TABLE 54A-9

DURATION OF SECONDARY PROPHYLAXIS*

Category of Patient	Duration
Patients without carditis	For 5 years after the last acute episode or until age 21 years, whichever is longer
Patients with carditis but without sequels	For 10 years after the last acute episode or until age 25 years, whichever is longer
Patients with carditis and residual valvar lesion	At least until age 40 years or life-long

Data from Dajani A, Taubert K, Ferrieri P, et al: Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: A statement for health professionals. Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young, the American Heart Association. *Pediatrics* 1995;96 (4 Pt 1):758–764; and World Health Organization: Rheumatic Fever and Rheumatic Heart Disease. Report of a WHO Expert Consultation. Geneva, 29 October–1 November 2001. WHO technical report series No. 923. Geneva: WHO, 2004.

attacks in the past, and those suffering crowding at home. Prophylaxis should be continued for prolonged periods in individuals who have had valvar surgery for rheumatic heart disease, even after valvar replacement with prosthetic valves, since they continue to be at risk (Table 54A-9).

One of the main concerns is the adherence of patients to the prophylactic regimens. As a consequence of the use of a medication involving painful administration, or daily oral therapy for long periods of time, sometimes compliance with prophylactic regimens can constitute a challenge, mainly in adolescents. Another reason to discontinue prophylaxis would be incomplete information about the disease and the need of prevention, besides the fear of allergic reactions. Anaphylaxis, however, is a rare event, and the great majority of cases of hypersensitivity are represented by mild reactions, mainly skin rashes. The risk of a serious complication is lower in children than in adults, and long-term prevention does not appear to increase the risk of an allergic reaction.^{28,196,197} To improve compliance with the prophylactic regimen, it is important to plan the follow-up with patients and families. Information must be given about the importance of the continuous medication, and why it is necessary to prevent subsequent streptococcal infections.

For the prevention of infective endocarditis, regular evaluation of the oral health is important to avoid the increased risk of bacteraemia associated with dental or gingival diseases. Special attention must be given to patients with valvar lesions and, particularly, in case of prosthetic valves, which are associated with higher predisposition to endocarditis. Additionally, a prosthetic valve is one of the underlying conditions associated with the highest risk of adverse outcome from endocarditis.¹⁹⁸ Patients with previous episodes of endocarditis are at a higher risk of subsequent episodes.¹⁹⁹ Endocarditis prophylaxis should be recommended for patients with rheumatic valvar lesions, depending on the risks of bacteremia, cardiac condition, and the characteristics of the interventional procedure. The updated recommendations for endocarditis prophylaxis have been more restrictive regarding the cardiac conditions warranting prophylaxis.^{198,200–202} As the usual dosages used to prevent recurrences of rheumatic fever are lower than those recommended for the prevention of endocarditis, the long-term therapy does not protect from endocarditis.

Additional prevention is necessary. For those on secondary prophylaxis with oral penicillin, it is advisable to administer another class of antibiotic to prevent endocarditis. These patients are likely to harbour viridans streptococci, which are relatively resistant to penicillin and amoxicillin.¹⁹⁸

Strategies for Immunisation Using Vaccines Against Rheumatic Fever

The efforts to produce a vaccine against infection date from the first decades of the 20th century. The M protein, the principal virulence factor of that bacterium, was initially used as an inducer of protection. The early vaccines, however, despite producing type-specific immune responses, were ineffective in preventing primary or recurrent attacks of rheumatic fever because individuals who have suffered infection with streptococci of a given serotype are rarely reinfected with a microorganism of the same M type.¹ The great diversity in M types and *emm* genotypes of *Streptococcus pyogenes* which cause rheumatic fever in different populations, combined with the rapid turnover of its serotypes in endemic regions, make it difficult to obtain an efficacious vaccine.⁴⁶

The key point in production, however, is to avoid the risk of triggering or aggravating rheumatic fever and rheumatic heart disease in the recipients, since antibodies against some M protein sites, the so-called autoimmune epitopes, may cross-react with α -helical human proteins, such as tropomyosin, myosin, and vimentin. One of the recent strategies in the development of vaccines is to use the highly conserved C region of the streptococcal M protein, common to most strains of the bacterium.^{203,204} Another attempt to achieve a safe vaccine is the search for protective epitopes of the C-terminal portion of the M protein,²⁰⁵ aiming at identifying amino-acid residues that could elicit a B-cell response dependent on T-cell signalling, thus providing a protective immune response against *S. pyogenes*.

In a recent communication, use of a recombinant vaccine containing N-terminal M protein fragments from six serotypes of group A *Streptococcus* showed, after a 1-year follow-up period, that the vaccine was well tolerated, did not induce cross-reactivity with human tissues, and increased the antibody levels to M antigens and also the bactericidal serum activity.²⁰⁶ These preliminary conclusions, however, should not be extrapolated to children, especially those residing in regions of the world with high prevalence of rheumatic fever. Clinical trials directed to this population will be needed. Moreover, there are some other problems in the development of the vaccine that must be overcome, such as the duration of the immunological protection against the bacterial infection, especially in endemic areas from developing countries, routes of administration, and potential side-effects. Still other issues, such as cost and stability of the vaccine under field conditions, must also be addressed, if primary prevention of rheumatic fever is to become effective in a variety of socioeconomic and epidemiological conditions.¹

Randomised trials describing cardiac outcomes in patients treated with several corticosteroid agents, aspirin, intravenous immunoglobulin, and placebo were analysed in a Cochrane review. The results of the comparative analysis did not demonstrate evidences of one therapy to be more effective in reducing the risk of valvar sequelae in the long term.

Chronic Rheumatic Heart Disease

CHAPTER

54B

CLEONICE C. COELHO MOTA, VERA DEMARCHI AIELLO, and ROBERT H. ANDERSON

Chronic rheumatic heart disease, representing the permanent lesions of the cardiac valves, is the most serious consequence of rheumatic fever. It accounts for a significant number of repeated hospitalisations and deaths. Recurrences of rheumatic fever play an important role in the worsening of the valvar lesions, but the damage, as a result of the process of cicatrisation, can be progressive even in the absence of subsequent acute episodes. The clinical presentation, the mortality, as well as the frequency and speed of development of an established valvar disease after the acute phase, vary considerably geographically, influenced primarily by the socioeconomic and medical backgrounds of the populations involved. In developed countries, severe rheumatic valvar disease is now uncommon in children and adolescents, and treatment for the advanced form of the disease is usually limited to adults. In contrast, in many developing countries, chronic rheumatic heart disease remains the most important cause of acquired cardiac disease among patients aged between 5 and 30.¹ On a global scale, it has been estimated that around 2 to 4 million patients aged from 5 to 14 are affected with rheumatic heart disease. It is also anticipated that each year an additional 282,000 new patients present with the ravages of chronic disease.² The prevalence of chronic disease was mostly based on surveys of schoolchildren, with rates ranging from 0.2 to 77.8 for each 1000 of the population in developing communities.³⁻⁷ The highest rates are registered in the Pacific region and in the Republic of Congo.⁸ Among 550 Brazilian students, aged from 10 to 20 years and chosen randomly, the prevalence was calculated at 1.8 cases for each 1000 students.⁹ Although progress in diagnosis and management over recent decades has provided a better quality of life, the disease causes significant disabilities and premature deaths in young individuals, with considerable personal and collective costs. The disability-adjusted life years lost to chronic rheumatic heart disease ranged from 27.4 to 173.4 per 100,000 population, giving an estimated 6.6 million life years lost each year throughout the world. The disease is responsible for up to two-thirds of the admissions to hospital due to cardiac problems in some countries. The rates of death because of chronic rheumatic heart disease show a wide variation, from 0.5 to 8.2 for each 100,000 population, according to the area of investigation. For the year 2000, the number of deaths worldwide was estimated at 332,000.⁴

The healing process of rheumatic carditis results in varying degrees of fibrosis and valvar damage. In some instances, fusion and thickening of the pericardium may also occur, but this rarely affects the ultimate cardiac performance. Resolution of the chronic valvar disease has been associated with the degree of the valvar involvement during the acute inflammatory process. Those suffering only mild valvar

lesions in the acute phase, with minor degrees of thickening of the valves and tendinous cords, and some fibrosis of the valvar endocardium, are unlikely to suffer abnormal haemodynamic effects in the chronic phase. If recurrences are prevented, mitral insufficiency in patients without cardiomegaly, pericarditis, or cardiac failure is expected to heal without scarring in about four-fifths of cases.¹⁰ On the other hand, more severe valvar damage can occur in the initial acute episode, and the early onset of significant lesions has an important impact on the development and severity of the permanent valvar damage. Considering the clinical and echocardiographic evaluation of cardiac involvement from the acute to the chronic phase, regression of valvar lesions was found mostly in those initially suffering mild carditis, with less regression in those known to have had moderate carditis, and no improvement observed in cases of severe carditis.¹¹ Poor outcomes for rheumatic heart disease have also shown a causal relation with recurrences.¹²⁻¹⁷ Repeated episodes of rheumatic fever usually lead to significant valvar disease in childhood and adolescence, often associated with pulmonary hypertension. The socioeconomic condition is known to be a contributing factor for the high rates of rheumatic fever, recurrences, and rheumatic heart disease.^{8,18} In this setting, a low level of maternal schooling also emerged as a variable interacting with recurrences, as well as featuring as an independent risk factor in predicting severe chronic valvar disease in patients without recurrences.¹⁵ It is also likely that episodes of subclinical carditis can result in chronic rheumatic valvar disease. The fact that many adults present with rheumatic heart disease without an earlier history of an acute episode supports this view, although the exact incidence of subclinical attacks is difficult to evaluate. The true incidence of carditis, nonetheless, is probably much higher than previously thought. Failure to recognise the primary episode of rheumatic fever, and inadequate secondary prevention, were identified as the major contributors to the increase in the frequency of recurrences and chronic rheumatic heart disease.¹⁹ More recent studies using echocardiography have consistently documented that subclinical carditis does occur, and have shown a wide variation in prevalence.²⁰ Similarly, pathological valvar regurgitation detected only by Doppler echocardiography has been reported during the chronic phase in patients not previously suspected to have rheumatic valvar disease after physical examination.^{7,15,21,22} Patients with chronic subclinical rheumatic valvar disease, as well as those with subclinical valvitis, are susceptible to infective endocarditis, which, should it occur, significantly alters the cardiac state.

In all age groups, the mitral valve is most commonly affected, followed by a combination of mitral and aortic

Figure 54B-1 The distribution of children and adolescents with rheumatic heart disease according to the valvar lesions ($N = 585$) as seen in the Rheumatic Fever Outpatients Clinic, Division of Paediatric Cardiology, Hospital das Clínicas, Federal University of Minas Gerais, Brazil. AR, aortic regurgitation; MR, mitral regurgitation; MS, mitral stenosis; TR, tricuspid regurgitation.

valves, then isolated aortic valvar disease, usually incompetence, and combined mitral, aortic, and tricuspid disease.^{23–26} Chronic rheumatic involvement of the pulmonary valve is rare. Analysis of the patients seen in the Rheumatic Fever Outpatients Clinic in Belo Horizonte, Brazil, has revealed isolated mitral regurgitation in almost half of the patients with chronic disease, and the combination of mitral and aortic regurgitation as the second most frequent lesion. Valvar insufficiency was present in almost three-quarters, insufficiency and obstruction in just over one-quarter, and isolated valvar obstruction in only 0.7% (Fig. 54B-1).

Mitral insufficiency is the most frequent valvar lesion involved in paediatric surgical series. In developing countries, mitral stenosis is also a common lesion, and percutaneous balloon valvoplasty, or closed mitral commissurotomy, are procedures frequently carried out in children and adolescents in these regions. Mitral or aortic regurgitation may be sufficiently severe to cause life-threatening haemodynamic effects. These complications may require major cardiac surgery, either electively, or even occasionally as an emergency.²⁷ The progress in diagnostic methods, catheter interventions, surgical expertise and techniques, and the development of improved valvar prostheses has encouraged the increased use of non-surgical and surgical techniques for the treatment of rheumatic valvar disease in children, adolescents and young adults.

PATHOGENESIS OF CHRONIC LESIONS

Recurrent attacks of acute rheumatic fever lead to rheumatic heart disease, characterised by sequels in the cardiac valves and myocardium. Rheumatic heart disease is estimated to occur in around three-fifths of all patients having acute rheumatic fever. The chronic lesions are the consequence of valvar scarring, and of healing of the pancarditis, including fibrosis of the myocardium and occasionally adhesive pericarditis. In the valves, the organisation of superficial fibrin vegetations from the acute phase results in thickening of the leaflets, fusion of the ends of the zones of apposition, and shortening of tendinous cords. Subsequent damage occurs due to local disturbances of haemodynamics and flow of blood leading to deposition and organisation of thrombus. Once neovascularisation

of the valvar leaflets has occurred, inflammatory cells can reach the valvar stroma, not only through the endocardial surface, but also from the endothelium of the newly formed vessels. The predominance of cells producing the regulatory interleukins 4 and 10 in the myocardium, as compared to the valvar tissue, explains at least in part the milder or absent inflammation in the myocardium during the chronic phase of the disease, whereas in valvar tissue inflammation is a permanent finding.²⁸

Myocardial remodelling secondary to pressure or volume overload due to valvar dysfunction depends on the severity and duration of the haemodynamic disturbance. If the valvar lesions stand for long periods, as is likely to occur in patients from countries with limited resources for public health, progressive cardiac hypertrophy, chamber dilation, and interstitial myocardial fibrosis may occur, leading to severe cardiac failure that can become irreversible even after later valvar replacement or valvoplasty. In this context, cardiac transplantation is an option to treat these end-stage patients. In a multi-centric study in Brazil, chronic valvar rheumatic heart disease accounted for 3.5% of all cardiac transplants performed over a period of 16 years.²⁹

Lesions of the left-sided valves also lead to chronic pulmonary congestion and passive pulmonary hypertension, and consequently to right ventricular hypertrophy and functional tricuspid regurgitation. Atrial fibrillation, a complication present in about half of patients with chronic mitral stenosis as seen in adults, is attributed to the increase of left atrial volume.³⁰ The disturbed flow of blood in this condition may lead to formation of mural thrombus, and to the risk of systemic thromboembolism. Myocardial dysfunction definitely influences the severity, clinical progress, and prognosis of rheumatic valvar disease.

The potential risk for infective endocarditis in patients with chronic rheumatic disease derives from disruption by the irregular valvar endocardial surface of the normal pattern of laminar flow across the valvar orifice. As stated previously, this progresses to deposition of fibrin. Initially these deposits are sterile and may heal. In the face of significant bacteremia, the microorganisms become enmeshed within the vegetations, leading to infectious endocarditis.

Morphology of Chronic Lesions

The evolution from the initial attack of acute fever to appearance of severe chronic lesions requiring surgical intervention is known to have geographical variation, being shorter in patients from countries with conditions of poor health care because of the greater risk of repeated acute episodes. Although fibrin vegetations and inflammation usually heal, leading to fibrosis of the leaflet, additional damage may be caused by organisation of minute thrombuses deposited on the valvar surface, and also by local haemodynamic disturbances. Moreover, inflammation persists in valvar tissues, perpetuating the process. As discussed already, the mitral valve alone is involved in most children and adults with chronic rheumatic heart disease, but both the mitral and aortic valves are involved in about one-quarter of individuals.³¹ Milder lesions can afflict the tricuspid valve, but are rarely seen in the pulmonary valve.

Chronic Rheumatic Mitral Valvar Disease

In the adult patient, isolated mitral stenosis, or stenosis in association with regurgitation, is the most frequent valvar sequel. As with the acute lesions, stenosis is not usually the first presentation of mitral dysfunction, with regurgitation usually seen first. In gross terms, the leaflets are diffusely thickened, and at the early stage of regurgitation, the mural leaflet is retracted, typically showing only one scallop instead of the usual three (Fig. 54B-2). With progression of the disease, the two ends of the zone of apposition between the leaflets fuse together, producing so-called commissural fusion. Varying degrees of shortening and fusion of the cords is also observed, leading, in the most severe cases, to obliteration of the interchordal spaces. In the normal valve, of course, these spaces are wide, and may be considered as part of the valvar orifice (Fig. 54B-3). The morphological feature of obliteration of the interchordal spaces further aggravates the stenosis, and must be given attention during any attempted surgical repair. In severe cases, the valvar apparatus is funnel-like, with the leaflets seemingly inserted directly to the tips of the papillary muscles. Should there be a recurrent acute attack, fibrin vegetations will be found on the already distorted leaflets and cords (see Fig. 54A-7).

Deposition of calcium is a late complication of the chronic involvement, usually appearing in adulthood, but it may be present in children with accelerated evolution of the disease. The deposits are seen as large yellow masses on the atrial surface of the leaflets, but especially at the ends of the zone of apposition (Fig. 54B-4). In the setting of severe stenosis, the valvar orifice appears slit-like, and is likened to a fish-mouth or button-hole (Fig. 54B-5). As emphasised, the subvalvar apparatus is also stenotic. The left atrium is usually greatly enlarged, carrying the possibility of formation of thrombus and atrial fibrillation. Thrombi may be attached to the valve itself (Fig. 54B-6), or be formed inside the tubular left atrial appendage. Rarely, a large free-floating ball thrombus may be found inside the left atrium, with the risk of a fatal systemic embolisation or occlusion of the valvar orifice.

Infective endocarditis is a potential complication of valves afflicted by chronic rheumatic lesions (Fig. 54B-7) because of the disturbed pattern of flow of blood and also the irregular endocardial surface. While large vegetations may be misdiagnosed echocardiographically as thrombi, small ones may be missed, and the diagnosis confirmed only at histological examination.

The differential diagnosis of rheumatic mitral fibrous scarring includes valvar lesions produced by systemic lupus

erythematosus, antiphospholipid syndrome, rheumatoid arthritis, post-thoracic irradiation, and carcinoid valvar disease, and those associated with the use of certain appetite suppressants, such as fenfluramine or phentermine. The clinical history and laboratorial findings, nonetheless, usually point to the proper diagnosis.³¹

Chronic Rheumatic Aortic Valvar Disease

As we have discussed, the aortic valve is the second most commonly involved valve, usually in association with involvement of the mitral valve. Isolated aortic lesions are uncommon. In one recent study,³² solitary involvement

Figure 54B-6 The atrial aspect of a stenotic mitral valve with superimposed thrombosis.

Figure 54B-7 This surgically excised mitral valve shows a chronic rheumatic lesion and a superimposed vegetation of infective endocarditis.

of the aortic valve was found in less than 3% of the cases. Rheumatic aortic stenosis is particularly rare in children and adolescents. When seen as an isolated lesion in patients of this age, it is considered to be associated with a congenital lesion.³³

Macroscopically, the leaflets are diffusely thickened and retracted. Fusion along the zones of apposition between the leaflets begins at their peripheral attachments at the level of the sinotubular junction (Fig. 54B-8). As with the mitral valve, calcification is rare in children, but may involve the free edges of the leaflets, which is different from the finding in degenerative aortic stenosis.

Chronic Rheumatic Tricuspid and Pulmonary Valvar Disease

Functional tricuspid valvar regurgitation is a common finding in patients with significant mitral valvar disease, resulting from right ventricular and annular dilation caused by long-standing pulmonary hypertension. When seen, thickening of the leaflets and shortening of cords are the macroscopical features of the chronic lesion, besides focal fusion of the zones of apposition between the leaflets. Calcific deposits are rare. Chronic organic pulmonary valve involvement is very rare. If found, it almost always involves

Figure 54B-8 The arterial view of an aortic valve with thickened leaflets and fusion of the ends of the zones of apposition.

rheumatic lesions in the other three valves.²⁴ Rheumatic fever, nonetheless, can also be found in patients with congenitally malformed hearts, including tetralogy of Fallot, septal defects, and aortic coarctation, with the chronic lesions then being superimposed on the congenital anomalies.^{34,35}

HISTOLOGIC FEATURES OF CHRONIC RHEUMATIC VALVAR AND MYOCARDIAL LESIONS

Histologically, valves with chronic rheumatic involvement show dense and diffuse fibrosis, which effaces the typical architecture. It is also possible to recognise newly formed vessels, some with thick walls, along with variable degrees of inflammatory infiltrates made up of lymphocytes and macrophages (Fig. 54B-9). As previously described, the main type of inflammatory cell present is the T lymphocyte of CD4 phenotype,³⁶ expressing predominantly interferon γ , tumour necrosis factor- α and interleukin 10. Calcium deposits, if seen, are usually surrounded by aggregates of mononuclear cells, including plasma cells. Occasional endocardial ulcerations are covered with thrombus. Aschoff bodies are no longer present at this phase of the disease, unless an acute attack of rheumatic carditis has occurred

within the last few weeks. Myocardial fibrous scars result from the organisation of the nodules of the acute phase, and are perivascular in location (see Fig. 54A-8). Additional damage is a consequence of altered haemodynamics, and usually involves variable degrees of myocardial hypertrophy.

Secondary Changes in the Airways and Pulmonary Vasculature

Chronic pulmonary congestion due to left valvar and myocardial dysfunction may be so severe as to result in passive pulmonary hypertension. The alveolar septums become thickened, initially by capillary dilation and later by fibrosis, and alveolar lumens may contain numerous haemosiderin-laden macrophages, the so-called heart failure cells. The interlobular septums show oedema and dilated lymphatic vessels. Venous changes may include intimal and adventitial fibrosis, along with hypertrophy of the medial layer. Long-standing congestion results in extension of the lesions to the arterial territory, with medial hypertrophy, intimal fibrosis, and adventitial enlargement of intra- and pre-acinar arteries.³⁷

VALVAR LESIONS

Mitral Regurgitation

Mitral regurgitation, as an isolated lesion or in combination with other valvar defects, is probably, at all ages, the most common valvar dysfunction resulting from the acute rheumatic process. In developing countries, severe forms have necessitated early surgical intervention in young patients.^{38,39} In a recent large series of young patients aged under 18 years,²³ isolated mitral regurgitation, as the single most frequent lesion produced by chronic rheumatic heart disease, was found in one-third of the cohort. Analysis of repair of the mitral valve revealed that over one-quarter of operations were performed in patients aged less than 15 years of age.²⁴ In South Africa, pure mitral regurgitation was the most common lesion in young patients treated by surgery due to rheumatic mitral valve disease, accounting for almost three-fifths of patients aged 20 years or younger, and for almost four-fifths of those who needed surgery in the first 10 years of life.³⁸ As we have emphasised, it is

Figure 54B-9 Photomicrographs of cardiac valves with chronic rheumatic involvement. Panel A shows diffuse fibrosis and new vessels, while panel B shows an inflammatory focus made up of mononuclear cells adjacent to a thick-walled vessel. Haematoxylin and eosin stain.

the severity of the acute lesion, and the number of subsequent episodes, that determine the course of the disease. Unlike mitral stenosis, when there is a variable latent period between the establishment of the valvar lesion and the acute episode, mitral regurgitation is frequently present from the onset of the active process. Initial regurgitation has been noted to disappear over periods ranging from 2 months to 9 years, while new lesions such as mitral stenosis, or stenosis combined with regurgitation, appeared over a period of up to 12 years.²⁶ Patients with mitral regurgitation are far more likely to have suffered a more severe acute episode than those with mitral stenosis.⁴⁰ Significant insufficiency may progress rapidly, leading on to congestive heart failure. In contrast, a systolic murmur of mild valvar incompetence may well persist throughout the lifetime of the patient without any symptoms or further complications. In general, mild-to-moderate mitral regurgitation is better tolerated than similar degrees of mitral stenosis. Unlike mitral stenosis, isolated mitral regurgitation affects men more often than women.

Physiology

Mitral valvar regurgitation may be found early in the course of the acute episode, and pathological, haemodynamic, and functional changes are important determinants in the worsening of valvar incompetence. The valvar leaflets become thickened and retracted, with shortening and fusion of the tendinous cords also contributing to restricted valvar closure, which may be aggravated by dilation of the annulus and left atrium. The increased volume overload and output of the left atrium as a result of the regurgitation leads to an increased diastolic volume of the left ventricle, with dilation and hypertrophy of both chambers proportional to the severity of the valvar dysfunction. Hypertrophy of the muscle normalises left ventricular mural stress, and is appropriate for both the degree of volume load and the degree of dilation.⁴¹ In those with moderate valvar incompetence, regurgitant flow from the left ventricle to atrium during systole is approximately half of the total ventricular stroke output. As the left ventricular end-diastolic volume is increased, in spite of the regurgitation into the left atrium, an adequate forward flow is maintained into the aorta during ventricular systole. The size of the left atrium is an important determinant of the rise in pressure in this chamber and in the pulmonary veins. In the setting of chronic disease, as the left atrium has time to dilate, the rise in pressure is relatively low. This factor, coupled with the lower energy cost of ventricular work, probably explains why moderate-to-severe mitral regurgitation is tolerated in many patients for a number of years. In contrast, in acute valvar incompetence with a normally sized left atrium, the left atrial pressure rises suddenly to a marked degree.

Severe mitral regurgitation is much better tolerated than an equal degree of aortic regurgitation. In chronic mitral regurgitation, the increased end-diastolic volume brings in the Frank-Starling mechanism, allowing a larger stroke output and increased left ventricular compliance. The increase in end-diastolic length of the myocytes, without a corresponding elevation in end-diastolic pressure, prevents a marked rise in pulmonary venous pressure.⁴² Left ventricular end-diastolic pressure rises relatively minimally because of the compensatory change in left ventricular compliance, and the relations between left ventricular pressure and time remain normal. Ventricular function, therefore,

is usually normal in children with mitral regurgitation. The favourable loading conditions often maintain the ejection fraction in the low normal range, and can make the left ventricular dysfunction imperceptible up to the later phases of the disease.⁴³ At this stage, the mean left atrial and pulmonary venous pressures rise, leading to a decreased pulmonary compliance and, subsequently, to pulmonary vasoconstriction. The mean pulmonary venous pressure is the major determinant of the resulting pulmonary arterial hypertension. Even with moderate-to-severe mitral regurgitation, though pulmonary arterial hypertension does occur, it does not reach the levels found in tight mitral stenosis. The forward stroke volume is maintained until late in the disease, when the regurgitant volume becomes so large that most of the stroke output empties into the left atrium. The forward stroke volume and cardiac output then decrease. A direct relationship exists between the regurgitant volume, the reduction in the forward stroke output, the elevation of the left atrial pressure, and the degree of clinical disability.⁴⁴

Clinical Features

The severity, and to a lesser extent the chronicity, of the regurgitant valve are the main factors in determining the symptoms. Those patients with mild lesions are completely asymptomatic. In patients with even moderate mitral regurgitation, symptoms may be relatively unimpressive. In contrast, in those with severe incompetence, there is effort dyspnoea, easy fatigability, poor weight gain, palpitations on effort, paroxysmal nocturnal dyspnoea, and finally congestive heart failure. Paroxysmal or chronic atrial fibrillation and infective endocarditis are more common than in mitral stenosis. The susceptibility to thromboembolism, on the other hand, is smaller.^{45,46} The jugular venous pressure is normal when there is no congestive heart failure, while normal blood pressure is associated with a slightly widened pulse pressure, giving a brisk pulse. The apical impulse is usually normal in those with mild lesions, with no major precordial pulsations. In significant mitral regurgitation, a hyperdynamic forcible left ventricular heaving apex is palpable, being displaced downwards and laterally. In general, the first heart sound is normal in intensity or somewhat soft. The second heart sound is usually normal, but can be markedly split in those with severe lesions because of the shortening of left ventricular systole. The presence of a loud third heart sound excludes the co-existence of significant mitral stenosis. The most important clinical feature is the characteristic apical systolic murmur. The murmur is pan- or holosystolic, starting with the first sound, which is often muffled. Indeed, it may well extend to the sound of closure of the aortic valve. It is heard best at the apex, radiates to the left axilla and left sternal edge, is unaffected by respiration, and has a blowing quality with no accentuation in mid- or late-systole. There is no definite correlation between the severity of the lesion and the length or intensity of the apical systolic murmur. Some patients with significant mitral regurgitation have a musical seagull murmur. The late systolic murmur of mild mitral regurgitation is often indistinguishable from that of the late systolic murmur found in patients with prolapsing leaflets of the mitral valve.⁴⁷ Occasionally, especially in the presence of acute valvitis, the murmur may be short, occurring in early mid- or late-systole. With severe valvar incompetence, a mid-diastolic blowing murmur is audible at the

apex, caused by increased diastolic flow through the mitral valve and the turbulence created at the end of the rapid ventricular phase. This murmur, while it may be rumbling, does not extend to late diastole. It is usually shorter than the murmur heard in mitral stenosis. A low-pitched third heart sound, which is often palpable and is caused by the considerable early diastolic filling of the ventricle, is heard in those with significant mitral regurgitation. When there is associated pulmonary hypertension, its signs are present. These include a right ventricular parasternal lift, a loud palpable pulmonary sound, and murmurs of pulmonary and/or tricuspid incompetence. The clinical signs of mitral regurgitation are much less clear-cut than those of mitral stenosis.

The electrocardiogram may be normal when the regurgitation is mild. Even with moderate valvar incompetence, the features may be inconclusive. The P wave is broad, bifid or notched, and usually best seen in lead II or V_1 . A more reliable sign of left atrial enlargement is a terminal negative deflection of the P wave in lead V_1 of more than 0.04 seconds in duration and more than 1 mm in depth. Left ventricular hypertrophy occurs when mitral incompetence is more than moderate. There may be changes in the ST and T waves over the lateral chest leads when the valvar lesion is severe. In the presence of associated pulmonary hypertension, right ventricular hypertrophy, and right atrial enlargement are not uncommon (Fig. 54B-10). Although uncommon in children and adolescents, atrial fibrillation occurs in patients with severe disease, and in those with long-standing chronic mitral regurgitation. The chest radiograph may be normal in patients with mild lesions. With well-established mitral regurgitation, the left atrium and the left ventricle are enlarged, their sizes being proportional to the degree of valvar dysfunction. There is

Figure 54B-10 The electrocardiogram from an 8-year-old child with isolated and severe mitral regurgitation complicated by pulmonary hypertension. There is evidence of biventricular hypertrophy and enlargement of both atria.

pulmonary venous engorgement, especially in the upper lobes (Fig. 54B-11). With the onset of pulmonary hypertension, the pulmonary trunk becomes prominent, and there is dilation of the right ventricle and atrium. Septal lines appear with the onset of cardiac failure.

The Doppler echocardiogram can be very useful, permitting highly sensitive and specific diagnosis of mitral regurgitation. In the M-mode echocardiogram, the EF slope of diastolic closure is not specific, nor does it indicate the severity of the valvar incompetence. There is an increase in the movements of the left ventricular septum and inferior wall because of the large stroke volume. In spite of difficulties in assessing left ventricular function because of the loading conditions in patients with chronic mitral regurgitation, the ejection fraction has been identified as a predictor of survival after surgical correction.⁴⁸ Thickening of the leaflets may be seen. Although the rheumatic leaflets may prolapse, the echocardiogram is useful in differentiating rheumatic disease from other causes of valvar prolapse, such as functional mitral regurgitation caused by severe cardiac dilation in primary cardiac muscle disease. The cross sectional echocardiogram in the long-axis view reveals a large, dilated, well-contracting left ventricle, and a dilated pulsatile left atrium. It also provides important information about the morphology of the valvar apparatus. The leaflets of the rheumatic valve are thickened and rigid, and the mural leaflet is frequently noted to be immobile. Cordal rupture, vegetations of infective endocarditis, and either presence or absence of left atrial thrombosis can all be recognised. Besides the morphological data, the severity of valvar incompetence can be assessed by mapping of the regurgitant jet and the width of the vena contracta, in addition to two quantitative methods used for evaluation of the regurgitant volume and calculation of the effective regurgitant orifice area^{49–52} (Figs. 54B-12 to 54B-14). In this setting, it is important to avoid over-diagnosis, since trivial incompetence can be seen even in normal subjects. Although rarely needed in children and adolescents, transoesophageal echocardiography is useful in patients in whom evaluation and quantification of the severity of mitral regurgitation has proved difficult when using the transthoracic windows. The valvar apparatus can now be accurately assessed by the three-dimensional technique. Exercise testing may be helpful in evaluating symptoms and establishing changes in exercise tolerance, particularly when it is difficult to obtain a reliable history.⁴³

Cardiac catheterisation and angiography are rarely indicated nowadays in patients with isolated mitral regurgitation. If performed, the mean left atrial or pulmonary capillary pressure is usually elevated, but in a small number of cases, aneurysmal dilation of the left atrium can produce a normal left atrial pressure despite significant regurgitation.⁵³ With significant valvar incompetence, the left atrial pressure is elevated, with a large V wave and a sharp Y descent.⁵⁴ A diastolic pressure gradient across the mitral valve can be found even in the absence of significant mitral stenosis. The left ventricular systolic pressures are usually normal, and end-diastolic pressure is normal unless there is left ventricular failure. Calculation of the valvar area by the Gorlin formula is less reliable in the setting of valvar incompetence. The regurgitant volume is measured as the difference between angiographically determined total left ventricular volume and the forward stroke volume using

Figure 54B-11 Pre- and post-operative radiographs from an 11-year-old child with severe isolated mitral regurgitation. **A**, The frontal view shows cardiomegaly, marked enlargement of the left atrium with a prominent appendage, and venous congestion of the upper lobes of the lungs. **B**, The barium swallow profiled in right oblique projection confirms the dilatation of the left atrium, with posterior displacement of the oesophagus. **C**, After replacement of the mitral valve, there is regression of all the abnormal features.

Figure 54B-12 The echocardiogram, in apical four-chamber projection, is from a 16-year-old girl with severe mitral and aortic regurgitation, moderate tricuspid regurgitation, and pulmonary hypertension. The image shows the left-sided chambers greatly enlarged. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Figure 54B-13 Colour flow mapping in the apical four-chamber view from a 14-year-old boy with moderate to severe mitral regurgitation. LA, left atrium; LV, left ventricle; MV, mitral valve.

Figure 54B-14 This 6-year-old patient has moderate mitral regurgitation. The Coanda effect is seen in the apical four-chamber view, with the jet stream adhered to the lateral wall of the left atrium. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

the Fick method, the fiberoptic technique, or the indicator dilution technique.^{55–57} It can also be achieved by calculating the angiographically measured difference between the right and the left ventricular stroke volumes.⁵⁸ Selective left ventricular angiography in the 30-degree right anterior oblique projection profiles the left ventricle, left atrium, and mitral valve (Fig. 54B-15). From a practical point of view, a qualitative estimation of severity from the amount of regurgitation into the left atrium of material injected into the left ventricle has been found useful. The degree of opacification of the left atrium depends on the quantity of blood in this chamber and on its rate of emptying, as well as on the severity of regurgitation. The width of the jet of mitral regurgitation is a good guide to the size of the regurgitant orifice. The left ventricular size, mural thickness and function, besides the degree of movements of the

Figure 54B-15 A left ventricular angiogram is profiled in 30-degree right anterior oblique orientation, from the same patient as shown in Figure 54B-11. There is severe regurgitation with a wide jet across the mitral valve, producing dense opacification of the entire left atrium. The aorta appears relatively hypoplastic as a result of the low cardiac output.

leaflets, can also be assessed. In patients with a decreased left ventricular ejection fraction, there will be an increased end-diastolic volume.

Mitral Stenosis

Mitral stenosis is a common chronic rheumatic valvar lesion, becoming established earlier than aortic stenosis. As with the other lesions, there is marked geographic variation. Mitral stenosis, in particular, appears precociously in patients from countries with high rates of the disease, probably due to repeated episodes of acute rheumatic fever associated with poor socioeconomic conditions. This is corroborated by some data from India,²⁶ showing a change in the pattern of valvar dysfunction according to the phase of the disease. While, in the initial acute attack, mitral regurgitation is frequently the only type of dysfunction present, subsequent episodes are accompanied by different combinations of valvar lesions. In most developing countries, mitral stenosis develops rapidly after the acute event, producing symptomatic young patients, and necessitating early surgical or catheter intervention.^{38,59–62} In South Africa, one-fifth of patients with pure mitral stenosis had been treated surgically before the age of 20 years.³⁸ Similarly, of those treated by balloon valvoplasty in Saudi Arabia, over one-sixth were aged 20 or less.⁶³ Another series, from the United States,⁶⁴ although much smaller, revealed a tendency to milder mitral lesions, and more patients with isolated aortic regurgitation, reflecting the less severe outcome for patients in North America.

Physiology

Mitral stenosis in patients with rheumatic fever is caused by thickening and calcification of the leaflets, along with fusion of the ends of the zone of apposition between the leaflets and obliteration of the intercaval spaces. The resulting narrowing of the valvar orifice produces a barrier in diastolic left ventricular filling from the left atrium, and a gradient is established between the left atrial and left ventricular end-diastolic pressures. The rise in the left atrial pressure is reflected by the elevated pulmonary capillary or pulmonary wedge pressure. With critical mitral stenosis, there is severe left atrial and pulmonary venous hypertension. The pulmonary arterial pressure rises correspondingly to maintain an adequate pulmonary flow. Pulmonary arteriolar constriction, a result of a combination of vasospasm and pulmonary arteriolar disease, results in an elevated pulmonary vascular resistance. In the face of such persistent and significant pulmonary hypertension, there is right ventricular failure. In patients with mild-to-moderate elevation of left atrial pressure, exercise or sudden tachyarrhythmias may diminish the diastolic filling period, resulting in an abrupt elevation of the left atrial pressure. Pulmonary oedema may then occur. Pulmonary hypertension is initially passive. With alteration of pulmonary exchange of gases, and associated hypoxia and arteriolar vasoconstriction, obliterative pulmonary hypertension develops. Since the pulmonary venous pressure in critical mitral stenosis may exceed the oncotic plasma pressure of 30 mm Hg, the increased pulmonary vascular resistance is, to a large extent, a protective mechanism. Thickening of the capillary walls, interstitial tissues, and alveolar membranes produces a barrier at the interface between the capillaries and the alveolar sacs. In isolated mitral stenosis, the relationships

between pulmonary pressure and flow are not constant. In some patients, the pulmonary circulation is maintained with only modest elevation of pulmonary arterial pressure, while in others pulmonary vascular disease becomes established, with severe hypertension pushing pulmonary pressures above the systemic level. Most patients with mild-to-moderate mitral stenosis, nonetheless, are able to maintain an adequate cardiac output with moderate exercise. In the presence of critical mitral stenosis, the cardiac output is low at rest. Exercise does not increase the cardiac output, which may even fall in the presence of significant pulmonary hypertension. The increased pulmonary pressure also causes tricuspid regurgitation. In patients who have had repeated episodes of rheumatic carditis, the severity and frequency of congestive heart failure is out of proportion to the severity of the valvar disease alone.

Clinical Features

The symptoms, physical signs, and amount of clinical disability parallel the severity of mitral stenosis. Those with minimal stenosis may be completely asymptomatic. Exercise and atrial fibrillation are among the precipitating causes of the initial presentation of symptoms, even in patients with mild-to-moderate mitral stenosis.⁴ Critical or significant mitral stenosis is present when the area of the valvar orifice is reduced to about one-quarter of the expected normal for the age. The common symptoms in critical stenosis are effort dyspnoea, orthopnoea, paroxysmal nocturnal dyspnoea, and episodes of pulmonary oedema. These symptoms may be aggravated by recurrence of carditis, intercurrent infections, and uncontrolled tachycardia or atrial fibrillation. Congestive cardiac failure usually occurs with severe stenosis and more than moderate pulmonary hypertension. The onset of atrial fibrillation usually indicates a relatively advanced stage of disease, and often accounts for worsening in its course. Atrial fibrillation and systemic embolisation, however, are uncommon in children and adolescents.^{40,65} The systemic venous pressure is elevated in the presence of cardiac failure and pulmonary hypertension. This elevation is proportional to the severity of stenosis, and it becomes marked with the onset of cardiac failure or atrial fibrillation. The cardiac impulse is usually right ventricular, characteristically described as tapping in nature. When pulmonary hypertension is present, a parasternal lift is found, and pulmonary arterial pulsations, as well as closure of the pulmonary valve, are palpable. There are classic auscultatory findings in mitral stenosis. The first heart sound is accentuated because of an abrupt closure of the leaflets, which are held open until the beginning of ventricular systole. There is a loud, sharp, and high-pitched opening snap caused by a sudden tensing of the leaflets at the limit of their excursion of opening in diastole. A long, rumbling, low-pitched mid-diastolic murmur is heard at the apex, often with presystolic accentuation. In the absence of associated mitral regurgitation, the duration of the diastolic murmur is directly proportional to the severity of the stenosis. The duration of the murmur may be altered by the presence of a fast ventricular rate or congestive heart failure. The murmur is best heard in the lateral position, using the bell of the stethoscope. It is augmented by exercise. Should the patient develop atrial fibrillation, then there is usually loss of the presystolic accentuation. The presence of a pulmonary ejection click and an accentuated pulmonary component of the second

Figure 54B-16 Electrocardiogram from an 11-year-old child with tight mitral stenosis and severe pulmonary hypertension. There is evidence of right-axis deviation, right ventricular hypertrophy, and enlargement of both atrial chambers.

sound, along with murmurs of pulmonary and tricuspid regurgitation, indicate severe pulmonary hypertension.

The electrocardiogram shows evidence of left atrial enlargement. Broad, notched P waves are seen in the limb leads, or a biphasic P wave in leads V_1 and V_2 , with a marked negative component. Right atrial enlargement, right-axis deviation, and right ventricular hypertrophy of varying degrees reflect the severity of the pulmonary hypertension (Fig. 54B-16). The chest radiograph shows varying degrees of left atrial enlargement, which displaces the oesophagus backwards, with elevation of the left main bronchus and widening of the carina. The enlarged left atrial appendage may be visible on the left cardiac border (Fig. 54B-17). In the presence of pulmonary hypertension, the pulmonary trunk and the right chambers are enlarged. The aorta is usually normal or small. The degree of left atrial enlargement is usually less in isolated mitral stenosis than in mitral incompetence. With mild pulmonary venous hypertension, there is initially distention only of the pulmonary veins from the lower lobes, which may be difficult to identify clearly. Once there is significant pulmonary venous hypertension, there is interstitial oedema in the lower zone, and vasoconstriction in the veins supplying them. The flow of blood is then increased in the veins to the upper lobes, which are dilated, producing differential pulmonary venous circulation. Kerley's A and B lines are seen because of interstitial oedema and small interlobar effusions. Acute pulmonary oedema is recognised by the typical perihilar opacity, with radiations to the periphery. Exercise testing may be helpful in cases with discrepancy between haemodynamic data and symptoms.⁴³

Echocardiography has, over the last years, become the most useful tool for both diagnosis and follow-up of patients with mitral stenosis (Figs. 54B-18 and 54B-19). M-mode interrogation still provides information. The valvar leaflets move inferiorly during diastole, rather than posteriorly as in the normal situation. The EF slope is decreased, as is the rate of diastolic closure of the aortic leaflet,

Figure 54B-17 Chest radiograph, shown in postero-anterior and right anterior oblique views, the latter with a barium swallow, from a 12-year-old child with severe mitral stenosis and pulmonary hypertension. The frontal view (A) shows cardiomegaly, with an enlarged left atrium, seen as a double density, a dilated pulmonary trunk and venous congestion in the upper lobes of the lungs. The oblique view (B) demonstrates the backward displacement of the barium-filled oesophagus caused by left atrial enlargement.

Figure 54B-18 M-mode echocardiogram from a 14-year-old child with severe mitral stenosis shows a decreased EF slope of the aortic leaflet of the mitral valve, and abnormal movement of the mural leaflet. Both leaflets are thickened and move forward parallel to each other during diastole.

generally in relation to the severity of the mitral stenosis. The mural leaflet is frequently tethered to the aortic leaflet, and both can move in parallel fashion during diastole. The amplitude of opening of the aortic leaflet is decreased. The left atrial dimension is increased, but the left ventricular and aortic dimensions are usually normal. There may be evidence of right ventricular dilation, paradoxical septal motion, and deviation of the septum into the left ventricle with the onset of pulmonary hypertension, especially in the presence of tricuspid incompetence. Cross sectional interrogation, combined with Doppler, permit assessment of the severity of the obstruction, the morphology of the valvar apparatus, and the suitability for valvotomy, by providing information concerning the ends of the zone of apposition, and the extent of thickening, tethering, reduced mobility and shrinkage of the leaflets, besides subvalvar fusion. Calcification is uncommon in children and adolescents. An accurate assessment of the anatomy of the valvar orifice, and the thickness of the leaflets, besides planimetry

of the orifice area, is obtained using the short-axis view. The relative size and relations of the ventricles and atriums are better seen in the apical four-chamber view. Left ventricular contraction is usually normal, but there may be a reduced rate of filling. Measurements of mean diastolic gradient across the stenotic valve are highly flow and rate dependent, and can be determined from the continuous wave Doppler signal using the modified Bernoulli equation. The Doppler estimation of the valvar area can be obtained from either the diastolic pressure half-time or the continuity methods.⁶⁶

As measurements and other necessary data can now be provided with a high degree of accuracy by echocardiography, cardiac catheterisation and angiography are seldom necessary, and should only be considered if diagnostic questions remain unanswered. If performed, the cardinal abnormality at catheterisation is the diastolic gradient across the mitral valve, measured by simultaneous recording of pressures in the left ventricle and either in the pulmonary capillary wedge or directly in the left atrium. Simultaneous measurements are more useful than measuring pulmonary capillary wedge pressures alone (Fig. 54B-20). The severity of obstruction shown by the degree of the diastolic gradient correlates well with calculated areas of the mitral valve. In sinus rhythm, the late diastolic post-A gradient is the most important measurement. In the presence of atrial fibrillation, however, the A wave disappears. The C wave then becomes prominent, and an X descent is not usually clearly seen. It is useful to calculate the gradient in six or seven consecutive cycles, and to take an average. The level of pulmonary hypertension can be measured from the peak and the mean pulmonary arterial pressure, besides the calculated index of pulmonary vascular resistance. In those who have apparently mild mitral stenosis, as shown by a small gradient, but with significant symptoms, measurement of the gradient is useful subsequent to exercise. If angiography is performed, the mitral valve is best profiled by selective left ventricular angiography in the 30-degree right anterior oblique position. In mitral stenosis with a mobile valve, a clear non-opacified

Figure 54B-19 The echograms are from a 17-year-old boy with severe mitral stenosis and moderate regurgitation. The parasternal short-axis view (A) shows thickening and tethering of the mitral valve leaflets. Colour flow mapping from the apical four-chamber view (B) shows an eccentric high-velocity flow jet. Continuous wave Doppler examination of the stenotic mitral valve (C) reveals a valvar area of 0.8 cm². LA, left atrium; MV, mitral valve; RA, right atrium; RV, right ventricle.

Figure 54B-20 Simultaneously recorded pulmonary capillary wedge and left ventricular pressures reveal a gradient across the mitral valve in a 10-year-old child with severe mitral stenosis. The wedge pressure is markedly elevated, with a high end-diastolic gradient between the pulmonary wedge (PW) and left ventricular end-diastolic pressure (LVEDp).

crescent is clearly visualised (Fig. 54B-21). This view is also the best for assessing the degree of mitral regurgitation and the function of the left ventricle. The degree of any associated aortic regurgitation can be assessed by aortic root angiography in the left anterior oblique view.

Aortic Regurgitation

Aortic regurgitation is commonest consequence of rheumatic aortic valvitis, albeit occurring most frequently in combination with mitral valvar disease. Isolated aortic regurgitation was found in only one-twentieth of a large series of patients in India.⁶⁷ Likewise, in Brazil it was seen in only 2.7% of patients under 19 years as the unique valvar dysfunction, but in almost half when associated with other valvar lesions.¹¹ It is commoner in men. Unlike mitral disease, the disappearance of the aortic murmur is relatively uncommon. Aortic regurgitation may range in severity from minimal dysfunction with a faint murmur to severe free aortic regurgitation. The usual natural history is a long asymptomatic period in which mild-to-moderate regurgitation is well tolerated during the compensated phase. In adults, a rate of less than 6% per year is estimated for the progression to symptoms and/or systolic dysfunction. Asymptomatic patients with left ventricular dysfunction develop cardiac symptoms at a rate greater than 25% per year, and the rate of death for symptomatic patients surpasses 20% annually.^{43,68} Patients who have recurrent rheumatic episodes may have a more rapid progress. In

Figure 54B-21 A left ventricular cineangiogram profiled in 30-degree right anterior oblique projection in a patient with tight mitral stenosis. The left ventricular function is normal. A clear crescent is produced by the non-opacified blood from the left atrium crossing a mobile but stenotic valve.

developing countries, as with mitral valvar disease, severe aortic incompetence may become established within 1 to 2 years of the initial episode. Those with associated mitral valvar disease, especially mitral incompetence, have a more rapid downhill course.

Physiology

The volume overload on the left ventricle results in a series of compensatory mechanisms to maintain an adequate forward stroke output, including a large end-diastolic volume, increase in chamber compliance, and both eccentric and concentric hypertrophy of the ventricle.^{4,43} The degree of left ventricular dilation is proportional to the severity of the regurgitant volume. There are additional factors such as the size of the regurgitant opening, the phasic nature of the regurgitation, the duration of diastole, the peripheral resistance, the reaction of the left ventricle in diastole, and myocardial perfusion.⁶⁹ In chronic aortic regurgitation, since the left ventricle is able to dilate over a period of time, the increase in diastolic compliance permits the left ventricle to accommodate a large regurgitant fraction without a corresponding increase in end-diastolic pressure. The ventricular stress is kept within the normal range through associated ventricular hypertrophy and reduced aortic impedance.⁴² Peripheral vasodilation is almost always present with significant aortic lesions. The rapid dissipation of blood into the dilated peripheral vascular bed augments the central aortic regurgitation, resulting in a low diastolic pressure. The lowering of the diastolic pressure has two ill effects. These are reduction of coronary arterial flow and inadequate nutrition of the peripheral tissues. The peak systolic pressure rises as a compensatory mechanism, resulting in a higher mean arterial pressure. The elevated systolic pressure adds a pressure

overload to the already existing volume overload of the left ventricle. Both the preload and the afterload are altered, and there are volume and pressure overloads.⁴⁶ The wide peripheral arterial pulse pressure in severe incompetence is the result of a combination of the peripheral vasodilation and central aortic regurgitation. The peripheral pulse curve shows a rapid rise to a high peak, with a sharp descending limb and a relatively unimportant dicrotic notch, with a low diastolic pressure and a high systolic peak pressure. The central aortic pressure, however, differs from the peripheral arterial pulse in that there is a sharp early peak followed by a second peak of varying amplitude. With the onset of left ventricular failure, the end-diastolic pressure rises, with an appropriate rise in the left atrial and pulmonary venous pressures, and subsequently of the pulmonary arterial pressures. Severe pulmonary hypertension is not common in chronic aortic incompetence. In contrast, when the aortic regurgitation is acute, there is a sudden rise in the ventricular diastolic pressure, and a sharp rise in pulmonary venous pressure because the left ventricle is relatively unprepared. A sharp and high rise of the end-diastolic pressure may further markedly decrease the flow of blood in the coronary arteries. All these factors added to the systolic dysfunction of the left ventricle result in a low cardiac output with pulmonary oedema and severe congestive heart failure.

Clinical Features

Patients with mild aortic regurgitation are asymptomatic. In some, apart from the murmur, even the peripheral signs may be absent. Those with moderate lesions may remain relatively asymptomatic despite cardiac dilation, as the ventricle is able to increase the cardiac output appropriately on exercise.⁷⁰ There may be palpitations on effort or on rest when the aortic regurgitation is severe. Effort dyspnoea occurs early and progresses. With the onset of left ventricular failure, orthopnoea and pulmonary oedema occur. Children and adolescents with severe disease may have nocturnal sweating, tachycardia, and nightmares. Angina is found in those with more severe disease. The blood pressure shows elevated systolic and low diastolic pressures, with a wide pulse pressure. The width of the pulse pressure, and the low diastolic pressure, is roughly proportional to the severity of the lesion. In those with moderate valve dysfunction, however, the width of the pulse pressure does not always correlate with the severity. With severe regurgitation, a water-hammer pulse is present. Other peripheral signs of a wide pulse pressure are increased and marked carotid pulsations; so-called Corrigan's sign; pistol-shot sounds over the femoral pulses; Duroziez's sign of a systolic and diastolic murmur becoming audible when critical pressure is applied to a large artery; visible capillary pulsations in the nail beds; known as Quincke's sign; and the sign of the nodding head. The last, also known as de Musset's sign, is one of the few signs named in honour of a patient. Cardiac enlargement is related to the severity of regurgitation. The apex beat is hyperdynamic and forcible, and there may be expandable pulsations over the entire precordium, with prominence of the left chest. The diagnostic sign of aortic regurgitation is the diastolic high-pitched blowing decrescendo murmur more prominent at the mid left sternal border or the right sternal border. It is best heard with the diaphragm of the stethoscope, with the patient leaning forwards in full expiration. The length and loudness of the murmur are poorly correlated with the severity of the

lesion. An aortic systolic ejection flow murmur radiating to the neck, occasionally preceded by an ejection click, is present with severe regurgitation, and the apical mid- and late-diastolic murmur named for Austin Flint often occurs. This is indistinguishable from that of mitral stenosis, but it is usually not accompanied by a thrill. This murmur results from fluttering of the aortic leaflet of the mitral valve, along with antegrade flow of blood through a closing mitral orifice. Premature closure of the mitral valve may occur in severe regurgitation, producing a decreased intensity of the first heart sound. A fourth heart sound is uncommon, and a third sound indicates ventricular failure. With the onset of left ventricular failure, orthopnoea and pulmonary oedema occur. In the presence of severe congestive failure, particularly in acute aortic regurgitation, the peripheral signs are diminished, and murmurs may not be easily audible. Acute aortic regurgitation presents with acute pulmonary oedema and gross congestive heart failure.

The electrocardiogram may be normal, with mild lesions. When there is more severe regurgitation, left ventricular hypertrophy is present, with deep Q waves over the left chest leads. In advanced disease, left atrial P waves and changes in the ST-T segments are present. The chest radiograph shows considerable enlargement of the left ventricle with moderate or severe valvar lesions. The left atrium is usually normal or slightly increased. The ascending aorta and arch are prominent. With advanced disease, enlargement of the left atrium and pulmonary venous congestion are found.

Echocardiography is useful in assessing the dimension, mass, and function of the left ventricle, and quantifies the severity of aortic regurgitation (Figs. 54B-22 and 54B-23). A dilated left ventricular cavity with a normal left atrium, along with increased movement of the ventricular septum and the left ventricular inferior wall, are frequently seen. Wide fluttering of the aortic leaflet of the mitral valve usually occurs in patients who have an Austin Flint murmur. In severe aortic regurgitation, premature closure and delayed opening of the mitral valve are seen. Additionally, semiquantitative assessment and indirect measurements of the severity and width of the aortic regurgitation can be obtained by Doppler interrogation.^{66,71}

Figure 54B-22 This apical four-chamber view is from a 14-year-old boy with severe mitral and aortic regurgitation. It shows massive dilation of the left chambers and thickening of the mitral valvar leaflets. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle;.

Figure 54B-23 The continuous Doppler recording from a 14-year-old boy shows severe aortic regurgitation.

Cardiac catheterisation and angiography are rarely indicated nowadays in young patients. Should they be performed, the aortic tracings in the face of severe regurgitation reveal a wide pulse pressure and a low diastolic pressure. The left ventricular end-diastolic pressure may be slightly elevated or high, and the pulmonary capillary wedge pressure usually reflects the left ventricular end-diastolic pressure unless there is associated mitral valvar disease. Pulmonary arterial hypertension is uncommon, unless there is chronic long-standing disease, additional mitral valvar disease, or acute aortic incompetence. The cardiac output is relatively normal or slightly decreased. Left ventriculography is useful in assessing the size and the function of the left ventricle, besides the presence or absence of additional mitral incompetence. The left ventricular end-diastolic volume has a close correlation with the regurgitant volume. In the absence of myocardial failure, it is a good index of the severity of the regurgitation.⁶⁹ Regurgitation fractions of more than 50%, and an ejection fraction of less than 40%, indicate severe left ventricular dysfunction. Selective aortography in the right and the left anterior oblique projections provides details of the size of the aortic root and the aortic valve, and the degree of regurgitation. In moderate aortic incompetence, the entire left ventricle is opacified for several beats. In those with severe regurgitation, the ventricle is opacified for more than 10 beats.

Aortic Stenosis

Aortic stenosis is a rare rheumatic sequel in childhood. Since this lesion develops slowly and gradually, it often presents at a much later age, usually over decades. Consequently, aortic stenosis occurring as an isolated lesion in children is usually considered to be congenital in origin.⁷² In the developing countries, rheumatic aortic stenosis, like rheumatic mitral stenosis, can occur in young patients.^{11,73,74}

Physiology

As a consequence of a prolonged latent period for the development of the obstruction, the left ventricle hypertrophies progressively in response to the systolic pressure overload, while a normal systolic mural stress, a normal chamber volume, and an adequate ejection fraction are

preserved.^{75,76} The increased ratio of volume to mass and mural thickness, besides the reduced compliance, lead to an increasing end-diastolic pressure without dilation, which commonly reflects diastolic rather than systolic dysfunction. The degree of diastolic dysfunction is related to the extent of left ventricle hypertrophy.^{77,78} At a more advanced stage, when the hypertrophy and the proportion of the increase of the mural thickness to the pressure are inadequate, the high afterload impairs the systolic function, and consequently the cardiac output. An important contribution to ventricular filling is represented by a forceful atrial contraction. In cases of atrial fibrillation, clinical deterioration can occur with the loss of atrial contraction.

Clinical Features

The mild lesions usually cause no symptoms. In moderate aortic stenosis, there may be effort intolerance of some degree, along with palpitations and angina on extreme effort. With severe stenosis, dyspnoea is present. Palpitations and angina, on effort or at rest, and syncope can occur. Since rheumatic aortic stenosis is most usually seen in association with other lesions, it tends to be the clinical findings of those lesions that dominate the clinical picture. The peripheral pulse volume is low, with an anacrotic and slow-rising pulse. The apical impulse is left ventricular in type, with a sustained thrust and minimal cardiomegaly. Presystolic pulsation from left atrial contraction may be palpable. A systolic thrill of varying intensity and duration is felt in the aortic area, often radiating to the suprasternal notch and into both carotid arteries. The characteristic murmur is rough, coarse, and long, being ejection and systolic in type. It is best heard in the aortic area or in the third left intercostal space. It radiates to the neck. An ejection click may be audible. In case of severe valvar dysfunction it may be inaudible, the long ejection systolic murmur may have a late systolic accentuation, and a loud fourth heart sound may be heard.

The electrocardiogram shows left ventricular hypertrophy of varying degree. With severe disease, there are changes in the ST-T waves. The chest radiography may appear normal in the early stage of the disease. Left ventricular enlargement is apparent with severe disease, and post-stenotic dilation of the aorta can be seen. Pulmonary venous congestion indicates the presence of ventricular failure. Echocardiographic studies show hypertrophy of the left ventricle, with increased thickness of the free wall and septum and good contraction. The ratio of the left ventricular cavity to the ventricular mural thickness can be related to the severity of the aortic stenosis and gradient.⁷⁹ Movements of the leaflets are limited, and multiple echoes may be obtained from the thickened leaflets. Unlike congenital aortic stenosis, it is unusual to find an eccentric position of the leaflets. The estimation of the valvar area by the pressure half-time or continuity methods, and Doppler measurement of the gradient, serve to quantify the severity of the obstruction.⁶⁶ The systolic gradient may be overestimated in the presence of associated aortic regurgitation. Magnetic resonance imaging may also be useful to assess the severity of the lesion, left ventricular systolic function, mural thickness, volume, and mass.⁸⁰ Cardiac catheterisation and angiography are rarely necessary. If performed, the data can document the degree of obstruction by showing the gradient across the valve, permitting calculation of the valvar area, assessment of left ventricular function, and exclusion

of other lesions. The left ventricular pressure, besides being elevated, may show an A wave impression on the upstroke. In severe disease, the left ventricular end-diastolic pressures are elevated. Pulmonary hypertension is uncommon, and pulmonary capillary pressures are usually normal or only minimally elevated. Left ventricular angiography shows a relatively normal or small cavity, with vigorous contraction. Selective angiography in the aortic root can demonstrate the presence of three valvar leaflets, and document presence or absence of associated aortic regurgitation.

Tricuspid Valvar Lesions

Primary tricuspid involvement is a rare lesion in rheumatic heart disease. Neither tricuspid incompetence nor stenosis occurs as an isolated dysfunction. Valvar regurgitation is frequently a functional lesion, with right ventricular overload and dilation occurring as a result of severe pulmonary hypertension, though occasionally it can be organic. Functional tricuspid regurgitation generally co-exists with severe left-sided valvar disease and progressing pulmonary hypertension. Such pulmonary hypertension was present in almost half of children and adolescents, and four-fifths of patients older than 18 years in one series,²³ with functional tricuspid regurgitation found in almost two-fifths and four-fifths, respectively. When found, tricuspid stenosis is most frequently associated with mitral stenosis, followed by mitral stenosis and regurgitation, although it does also occur in combination with mitral and aortic valvar disease. Albeit with very few cases present in childhood, one-quarter of patients seen in Saudi Arabia required operations on the tricuspid valve, with half of the valves showing evidence of organic disease.⁸¹

Physiology

When the tricuspid valve is competent, the annulus usually shortens during systole. In cases of pulmonary arterial hypertension and enlargement of the right ventricular cavity as result of important left-sided disease, the tricuspid annulus dilates and fails to shorten. The leaflets, which remain normal in appearance, fail to coapt.^{40,82} With valvar incompetence, there is right atrial volume load, and the increase in the mean right atrial pressure is transmitted to both superior and inferior caval veins. The larger volume in the right atrium increases the size of this chamber. During diastole, the right ventricle is subjected to a higher filling pressure. With consequent dilation to accommodate the extra volume, this intensifies the leak. As with other types of valvar incompetence, the tricuspid regurgitation also shows a tendency to progress, albeit that the ventricular overload on the right side of the heart has a slower deleterious effect than on the left.⁴⁰ When present, the tricuspid stenosis adds an additional increment to the right atrial and systemic venous pressures. The large A wave in tricuspid stenosis is caused by increased atrial contraction, and the slow Y descent reflects impairment of the right ventricular filling with inspiration.

Clinical Features

The symptoms of patients with functional tricuspid regurgitation are usually dominated by the associated mitral and/or aortic disease. Occasionally, in some patients, the onset of the valvar incompetence tends to decrease the degree of dyspnoea and orthopnoea. Hepatic enlargement, which is usually present, can produce discomfort or pain

in the right upper quadrant of the abdomen. The jugular venous pressure is always elevated, sometimes markedly so, with a dominant V wave and a rapid Y descent. A large C wave may also be seen in the absence of atrial fibrillation. Since the jugular venous pressure represents right atrial pressure, the height of the V wave and the Y descent are good indicators of the severity of the tricuspid regurgitation. The liver is enlarged, tender, and pulsatile in systole. The murmur is pansystolic, blowing in nature, best audible in the fourth left intercostal space, and characteristically increases on inspiration, the so-called Rivero Carvallo sign. With mild lesions, the murmur may be audible only during inspiration. In moderately severe dysfunction, it is present throughout the respiratory cycle, yet increases with inspiration. With severe incompetence, the right ventricle is already maximally overloaded, and inspiration cannot alter the flow of blood across the tricuspid valve. The murmur may then be loud and audible over a large area of the pericardium, including the axilla, and may produce diagnostic difficulties in excluding associated mitral regurgitation. A right ventricular third heart sound may be audible. Mid-diastolic flow murmurs in the tricuspid area are less frequent than in the setting of mitral regurgitation, since the cardiac output is usually low. The combination of low cardiac output and renal congestion can result in a decreased glomerular filtration rate and marked retention of fluid. With severe valvar incompetence, a hypodynamic high-amplitude right ventricular parasternal lift, with retraction along the right sternal border, produces a seesaw rocking motion of the entire precordium.⁸³ With tricuspid obstruction, a sudden increase in pulmonary flow is less likely, and dyspnoea or orthopnoea may be less prominent. The symptoms are commonly related to those of the associated valvar lesions. With significant tricuspid stenosis, there is a sharp A wave in the jugular venous pressure, and a slow Y descent is found in those patients in sinus rhythm. When atrial fibrillation is present, the prominent A wave, as well as the presystolic murmur, will then disappear. In the presence of severe mitral stenosis and low cardiac output, especially in those patients with atrial fibrillation, the signs of tricuspid stenosis may be masked unless they are looked for carefully. The murmur of tricuspid stenosis usually has a higher pitch than that of mitral stenosis, which it closely resembles. When there is atrial fibrillation, the murmur occurs earlier in diastole. A tricuspid opening snap is often present, but it may be difficult to differentiate it from that of an associated mitral stenosis.

The electrocardiogram in tricuspid regurgitation usually demonstrates right ventricular hypertrophy, right atrial enlargement with a tall spiked P wave in the presence of sinus rhythm, as well as the effects of the left-sided lesions. Although less common in children than in adults, atrial fibrillation may be present. The chest radiograph usually shows considerable generalised cardiomegaly, with right atrial and caval venous engorgement in addition to the signs of underlying mitral and/or aortic valvar disease. Echocardiography shows dilated right ventricular cavities, with paradoxical motion of the ventricular septum and exaggerated movement of the tricuspid valve. Doppler echocardiography permits estimation of the severity of the valvar lesion, right ventricular systolic pressures, and the diastolic gradient, besides aiding the evaluation of the associated lesions (Fig. 54B-24). Cardiac catheterisation,

Figure 54B-24 Colour flow mapping from the apical four-chamber view of a 16-year-old boy with mitral valvar dysfunction, aortic regurgitation, and functional tricuspid regurgitation. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

if performed, shows an elevated right atrial mean pressure, with a dominant V wave and a sharp rapid Y descent. The right ventricular end-diastolic pressure is usually elevated. Right ventricular angiography in the 30-degree right anterior oblique projection profiles the tricuspid valve. A dilated right ventricle with regurgitation of the contrast medium into the right atrium is usually found, but the valvar leaflets are not usually easy to visualise.

The electrocardiogram of patients with tricuspid stenosis and sinus rhythm shows severe right atrial enlargement with tall, peaked P waves, in addition to the changes produced by the associated lesions. Similarly, the radiological abnormalities are basically those of the associated lesions but, in addition, show an enlarged right atrium and a distended superior caval vein. The echocardiogram shows a thickened tricuspid valve, with a marked decrease in its rate of diastolic closure. More importantly, it documents the presence or absence of associated mitral stenosis. At cardiac catheterisation, rarely needed nowadays, a diastolic gradient can be demonstrated across the tricuspid valve. The right atrial pressure is increased. Those patients with sinus rhythm show a giant A wave and a slow Y descent. It is preferable to record simultaneous right atrial and right ventricular pressures using a double lumen catheter rather than make a withdrawal from the right ventricle to the right atrium. A selective right atrial angiogram in the 30-degree right anterior oblique projection demonstrates the doming effect of the tricuspid valve into the right ventricle, with the narrow jet of dye passing through the stenosed orifice.

MANAGEMENT

Patients with chronic rheumatic heart disease usually require long-term follow-up. This is based on serial clinical examinations, supplemented by periodic laboratorial evaluations, including electrocardiography, chest radiography, and echocardiography. Medical treatment essentially consists of adequate prevention of recurrences and infective endocarditis, and treatment of congestive cardiac failure and arrhythmias, especially atrial fibrillation. The patients require close observation to detect progression of the disease, besides control of medical therapy, supervision of physical activities, and recognition of complications.

In this setting, complications which should also be considered in the therapeutic approach include embolism, intercurrent infections, and electrolyte imbalance as a consequence of long-term treatment with diuretics.

The ultimate decision of clinical management or invasive therapy is made on an individual basis. The operative risks, and potential post-operative complications, should be balanced against the benefits of an invasive treatment and the risks produced by the valvar lesion in the absence of an invasive approach. The timing and indication for the invasive approach are mostly determined by the severity of the clinical condition, degree of valvar dysfunction, and overall cardiac function. Progression of symptoms, recurrent or persistent congestive cardiac failure, progressive or severe pulmonary hypertension, increasing cardiomegaly on the chest radiograph, progressive evidence of left-sided hypertrophy on the electrocardiogram, atrial fibrillation, and thromboembolism are all indicative of severe disease, and make the patient a potential candidate for invasive treatment.^{4,43,84} Preservation of ventricular function and adequate pulmonary pressures are the most important factors determining the efficiency of surgical or catheter intervention.

The advances in non-invasive methods, mainly Doppler echocardiography, have had an important role in the selection of patients, along with the choice of the most appropriate invasive intervention. The echocardiographic data has also been used as a prognostic predictor of surgical results, while intra-operative transoesophageal echocardiography has advanced reconstructive surgery, as well as providing a guide during percutaneous balloon valvoplasty.^{85–87} The introduction of three-dimensional echocardiography, and pulsed tissue Doppler imaging, have provided new insights into the geometry and spatial relations of the valvar apparatus and myocardial function.

The options now available for invasive treatment include surgery, and percutaneous balloon valvoplasty for stenotic lesions. The percutaneous option became an alternative to surgery in the early 1980s. The excellence of the obtained results led to its increasing use worldwide, with specific indications as discussed below.^{88,89} On the other hand, surgical repair retains the advantage of permitting an individual approach to the particular morphological abnormality, and is currently the procedure of choice for valvar insufficiency. Percutaneous valvar implantation is now the new horizon in transcatheter therapeutics, but is rarely used as an alternative to the other approaches, and then only in highly selected cases.⁹⁰

Percutaneous Intervention for the Chronic Valvar Lesions

Approach to Mitral Stenosis

There are currently two techniques, one employing balloons and the other using a metallic device. Valvoplasty with the Inoue balloon is the most popular technique, and has equivalent results to the double balloon technique, which is effective but more demanding.⁹¹ The metallic device has been used for mitral commissurotomy in a large series of patients and has the potential advantage of reutilisation, reducing the cost of the procedure.⁹² Percutaneous transvenous mitral valvoplasty proved successful in 94% of patients, with a rate of restenosis of 16% over a mean follow-up of 34.4 months.⁹³ Restenosis was presumed to

be the consequence of turbulent flow, since the patients were receiving appropriate prophylaxis to prevent recurrent attacks of rheumatic fever.

Echocardiography is used to evaluate the valvar anatomy prior to the procedure, aiming to validate the indications for percutaneous treatment, and also to define the prognosis. Scores have been devised to predict the results of percutaneous valvoplasty. Wilkins score is most commonly used, which takes into account the pattern of mobility of the leaflets, the intensity of valvar and subvalvar thickening, and the extent of calcific deposits.⁹⁴ Other scores use a more general assessment of the valvar anatomy, taking also in consideration the uneven distribution of the anatomic abnormalities.^{95,96} No system, however, has been shown to be superior.⁹¹ Contra-indications to the percutaneous approach include left atrial thrombosis, moderate or severe associated mitral regurgitation, massive calcification of the ends of the zone of apposition between the leaflets, contra-indications for transeptal catheterisation, and the need for surgery on another valve or artery.⁹¹

Symptomatic patients with moderate to severe mitral stenosis, this representing an area of the valvar orifice of less than 1.5 cm², or an indexed area of less than 0.6 cm²/m² of body surface, who are in the second to fourth functional classes of the categorisation established by the New York Heart Association, and with favourable valvar morphology, are all candidates for percutaneous balloon valvoplasty. Children and adolescents with favourable anatomy and mild symptoms can also benefit from the balloon procedure, because it can postpone surgery, avoiding the inherent risks of the surgical procedure, including bypass, as well as avoid scarring of the chest wall and adhesive pericarditis. At the other end of the spectrum of disease, balloon valvotomy has become the procedure of choice for patients with stenotic lesions who are in poor clinical condition and hence present a high surgical risk.^{43,52}

The desired end-point of the procedure is to produce a valvar orifice with an area greater than 1 cm²/m² of body surface, opening completely at least one end of the zone of apposition between the leaflets, accompanied by the appearance of, or increment in, mitral regurgitation greater than the first grade in the angiographic classification proposed by Sellers.⁹⁷ The results of valvoplasty can be evaluated echocardiographically. Follow-up studies in the immediate, short, and intermediate term show that patients with a score in the Wilkins system equal to or lower than 8 have significantly greater survival and freedom from combined events than patients with scores greater than 8. Some additional features, such as severe mitral regurgitation, high pulmonary arterial pressure after the procedure, and functional classification greater than 4, among others, were identified as predictors of poor outcome.⁹⁸ The main complications of the percutaneous approach are haemopericardium, massive mitral regurgitation, and embolism. Severe regurgitation is usually the consequence of tearing the leaflets other than along their zone of apposition, or more rarely rupture of the papillary muscles or tendinous cords. Surgery as an emergency procedure may be required to treat these complications.

Therapeutic Approach to Aortic Stenosis

As we have discussed extensively, significant aortic stenosis is rare in young patients as a sequel of rheumatic carditis. The need for invasive intervention, therefore, usually

occurs in adulthood. A few reports have emerged of percutaneous valvotomy for rheumatic aortic stenosis, usually in critically ill patients, or as a bridge to open heart surgery.⁹⁹ According to the guidelines for the management of patients with valvar disease provided by the American Heart Association,⁴³ because of the high rate of complications and restenosis following percutaneous valvoplasty, replacement of the aortic valve is the only effective treatment for degenerative calcific aortic stenosis as seen in the adult. On the other hand, the same publication recommends that younger patients with congenital or rheumatic aortic stenosis could be candidates for the balloon procedure.

Surgery

Surgical intervention adds a considerable burden to the already high cost of management of patients with chronic rheumatic heart disease. The rate of requirement for such surgical intervention in rheumatic valvar dysfunction reflects also the developmental state of the country, with few needs in nations where patients have better access to medical treatment and antibiotic prophylaxis.⁶⁴

Although guidelines for invasive management of patients with valvar disease have been developed and periodically reviewed, they are mostly applicable to adults. In young patients with rheumatic heart disease, several questions remain unsettled. Discussion continues regarding the timing and indications for surgical intervention, since the ideal valvar prostheses are still not currently available. On the other hand, the increased understanding of the mechanics of valvar function, and the advances in surgical techniques, have markedly improved the outcome for children and adolescents. Irreversible myocardial damage, and pulmonary hypertension, need to be prevented because they increase considerably the immediate surgical risk as well as outcomes in the long term.

The potential surgical strategies include open-heart valvar repair or valvar replacement. When the valve is suitable, then repair is the operation of choice. The effort of preserving the native valve is well worthwhile, delaying valvar replacement and its complications in childhood and adolescence. Relative contra-indications to repair or replacement include end-stage lesions with severe ventricular dysfunction, significant fixed pulmonary hypertension, and extensive tissue destruction as a consequence of endocarditis.⁴

Symptomatic children and adolescents with severe mitral regurgitation who are in the third or fourth classes of the categorisation of the New York Heart Association, yet have normal left ventricular function, require surgery. A decline in left ventricular function, even if mild or moderate, has also been taken as an indication for operation in symptomatic or asymptomatic patients with severe rheumatic mitral regurgitation.^{40,100,101} Although still controversial, the aim of surgery in asymptomatic patients with severe mitral regurgitation is to prevent deterioration of the contractile state and improve long-term results. According to the American Heart Association and the European Society of Cardiology, surgery should not be undertaken when ejection fraction remains within the lower normal limits,^{43,52} and intervention is advised, therefore, when the left ventricular ejection fraction is less than 0.60 and the end-systolic dimension is equal to or greater than 45 mm, adjusted to body surface area. In patients with severe ventricular

dysfunction, the possibility of repair should be evaluated before recommending cardiac transplantation. Although there is still divergence of opinion, operation should be contemplated in those patients with severe mitral regurgitation who are in the second class of the categorisation of the New York Heart Association with preserved ventricular function and significant cardiomegaly. In these circumstances, there is a high probability of successful repair at low risk.^{40, 43,52,102} In children and adolescents who are not candidates for percutaneous valvotomy, the indications for surgical treatment of mitral stenosis include those who are symptomatic, in the third or fourth classes of the New York classification, and have moderate or severe obstruction, defined as an area of the valvar orifice less than 1.5 cm², or an indexed area less than 0.6 cm²/m² of body surface, taking into account also the mean mitral valvar gradient and the systolic pulmonary arterial pressure.^{4,43,51,52}

In patients with aortic regurgitation, surgery should be considered only in case of severe dysfunction. Hence, intervention is required for symptomatic patients, irrespective of ventricular function. The onset of symptoms such as syncope or near-syncope, dyspnoea, and angina, either on effort or at rest, has important significance in patients with severe valvar regurgitation. When symptoms are mild and their characterisation unclear, clinical judgement is required. Considering the risks of the disease without intervention, and the combined risk of operation and late potential complications of valvar surgery in children and adolescents, but bearing in mind its benefits, a detailed evaluation is necessary to establish the cause and nature of symptoms in the light of haemodynamic and functional parameters. For those who are asymptomatic, with an ejection fraction at rest below the normal lower limit in serial studies, in other words less than 0.50, findings of progressive and severe left ventricular dilation, with an end-systolic dimension greater than 50 mm or 26 mm/m² of body surface, should also be considered.^{43,52}

Repair of Atrioventricular Valves

Considerable advances have been made in the last decades in the repair as opposed to the replacement of the diseased valves. One of the controversies raised by detailed analysis of the post-surgical evolution is that the late results of repair can be adversely affected by new episodes of rheumatic fever, especially in children and young adults, with ongoing progression of the disease.³⁹ Thus, the long-term follow-up of repair of the mitral valve in patients with rheumatic disease has not been good when compared to the same procedure used for valvopathies of other aetiologies.^{103,104} There remains, nonetheless, a strong incentive towards repair rather than replacement because of the drawbacks of the latter procedure.

Surgery is rarely required during the acute episode of rheumatic fever. If undertaken, it is usually to treat severe mitral insufficiency, typically resulting from the rupture of tendinous cords or prolapse of the aortic leaflet. For chronic lesions, techniques of repair must be tailored to the morphological findings. Débridement of thickened leaflets usually improves their mobility and pliability, while so-called commissurotomy, in reality opening the fused ends of the zone of apposition and sliding plasties of the papillary muscles, increases the area of the valvar orifice. Insufficient valves may require annuloplasty with either prosthetic rings or the De Vega technique, the latter usually

applied for regurgitant tricuspid valves. Procedures on the tendinous cords include transposition and shortening. Retracted leaflets can be extended by insertion of patches of autologous or bovine pericardium.¹⁰⁵ Data from a tertiary centre in Brazil demonstrated a significantly greater rate of reoperation at 125 months after repair of the mitral valve in patients aged 16 years and less when compared to those older than 16 years. This probably reflects progression of the rheumatic disease in the younger patients.³⁹

Repair of the Aortic Valve

There is limited experience with aortic valvar repair for chronic rheumatic dysfunction. The advantages of repair compared to replacement, nonetheless, include better haemodynamics, the possibility of growth of the aortic root, freedom from anticoagulation, and avoidance in young patients of the complications related to insertion of a prosthetic valve.⁶⁰ Compared to repair of the mitral valve, reconstructive techniques are much more demanding for the aortic valve, and are associated with greater rates of failure.⁶⁰ Opening of the fused zones of apposition, extension of the leaflets with pericardium, and thinning of the leaflets, are among the techniques that may be applicable in the individual patient. Good results have been reported using fresh autologous pericardium to extend the leaflets.¹⁰⁶ Another series from India, with ages ranging from 6 to 53 years, reported survival free from reoperation of 85.4% at 160 months.⁶⁰ Even triple valvar repair is an option to avoid implantation of prostheses.¹⁰⁷

Valvar Replacement

When repair is not possible because of severely distorted morphology, replacement may be the only available option. Late complications after insertion of prosthetic valves include the need for a new valve as the child overgrows the initial prosthesis, or because of the limited durability of tissue valves, besides the morbidity associated with long-term anticoagulation and the risk of infective endocarditis.^{108,109} Mechanical prostheses are generally preferred for children because of their durability compared to the accelerated calcification and dysfunction of bioprostheses^{109,110} (Fig. 54B-25). Despite that advantage, mechanical prostheses are known to be thrombogenic, and anticoagulation is thus mandatory. In the setting of poverty, long-term anticoagulation is difficult to manage, and the least thrombogenic prostheses should be implanted.⁴ Lower reoperation rates, and fewer complications, have been reported in those who received mechanical prostheses.¹¹¹ Insertion of porcine bioprostheses, albeit in adults, achieved an actuarial estimate of freedom from failure equal to 63.7% and 7.7% at 10 and 20 years after surgery, respectively, with a mean duration to failure of over 12 years.¹¹²

According to the technical report from the World Health Organization, the expected incidence of infective endocarditis on valvar prostheses (Fig. 54B-26) varies from 0.2 to 1.2% per year.⁴ Another concern in those with rheumatic heart disease is the best choice whenever there is the need for simultaneous replacement of the mitral and aortic valves. While some groups recommend repair of the mitral valve and replacement of the aortic valve,¹¹³ others prefer double valvar replacement as the standard procedure.¹¹⁴ The main problem is the need for reoperation on the mitral valve due to the progression of rheumatic lesions in this group of patients. In one series,¹¹⁵ no potential advantages were identified for preserving rather

Figure 54B-25 The biological prosthesis inserted in mitral position shows massive calcification (diffuse yellowish colour).

Figure 54B-26 Another biological prosthesis inserted in mitral position shows an extensive vegetation of infective endocarditis.

than replacing the mitral valve when the aortic valve was replaced. According to this group, repair of the mitral valve should be considered only in selected patients in whom the durability of the procedure is expected to be excellent.

On the horizon of the interventional approach to valvar disease is percutaneous valvar replacement. Although this procedure is currently limited to a very few centres dealing with highly selected patients, it is a promising alternative to surgery for patients with rheumatic heart disease. The early results with percutaneous replacement of arterial valves have been better than attempts at repairing atrio-ventricular valves.¹¹⁶ At the present stage, several questions remain to be answered, mainly regarding the best time for intervention, the technique of implantation, and the best material to be used.⁹¹

This extensive review of valvular heart disease in Africa considers the differences in magnitude and pattern when compared with developed countries. The main focuses are the discussion of epidemiological aspects and the huge burden imposed by rheumatic fever and its sequels on limited health care resources. The current concepts on pathogenesis are also discussed, besides considerations regarding controversial issues in the diagnostic and therapeutic approaches.
- Akhtar RP, Abid AR, Zafar H, et al: Prosthetic valve replacement in adolescents with rheumatic heart disease. *Asian Cardiovasc Thorac Ann* 2007;15:476–481.
The long-term survival and anticoagulant-related complications following valve replacement are described in patients with rheumatic heart disease and aged less than 18. Thrombosis and stroke were the causes of death in six patients. Survival at 1 and 10 years was 87.5% and 82.9%, respectively. As regards complications, 4.5% of patients had thrombosis, the same percentage as found for haemorrhage.
- Talwar S, Rajesh R, Subramanian A, et al: Mitral valve repair in children with rheumatic heart disease. *J Thorac Cardiovasc Surg* 2005;129:875–879.
Based on a cohort of 278 children with rheumatic heart disease, the authors report the experience with repair of the mitral valve. Pre-operative left ventricular dysfunction was associated with greater mortality. The authors report an early mortality of 2.2%, with seven late deaths. Actuarial, reoperation-free, and event-free survivals at 15 years were 95.2, 85.9, and 46.7, respectively.

Infective Endocarditis

ROHAYATI TAIB and DANIEL J. PENNY

Infective endocarditis is a microbial infection of the endocardium. It is a serious and life-threatening disease which is uncommon in childhood. Endocardial infections were formerly known as bacterial endocarditis, but the term infective endocarditis is used in order to encompass both bacterial and fungal causes. The term may also be used to describe infections of the arterial duct, surgically created shunts such as a classical or modified Blalock-Taussig anastomosis, and infection at the site of aortic coarctation, although infective endarteritis would be a more accurate term for this group.

EPIDEMIOLOGY

Prevalence and Incidence

Infective endocarditis is less prevalent in children than in adults, although its incidence in children may be increasing.^{1,2} This is in part due to the increased incidence of infective endocarditis in patients with congenitally malformed hearts who are now surviving longer. The epidemiology of infective endocarditis in developed countries has changed. There has been an increase in the survival of children with congenitally malformed hearts, along with a decline in prevalence of rheumatic heart disease, so that in most countries congenital cardiac disease is now the most common substrate for infective endocarditis.

Subsequent to surgical correction of complex congenital cardiovascular malformations, patients have a long-term risk of infective endocarditis, although in up to one-tenth of cases seen in children, no structural cardiac disease or identifiable risk factors exist.³ The condition in such cases commonly involves infections of the aortic or mitral valves in the setting of bacteraemia due to *Staphylococcus aureus*.^{4,5}

The incidence of neonatal endocarditis is also increasing.^{6,7} The rate of death in this age group is high, and often the diagnosis is made after death. Early repair of congenital malformations of the heart in neonates and infants has increased the prevalence of perioperative infective endocarditis in this age group.⁵ The increased use of indwelling intravenous lines and implantable devices, along with the evolution of more advanced neonatal and paediatric intensive care, has increased the risk of endocarditis related to catheters.^{2,7} Indwelling catheters may also predispose to the development of endocarditis in children with cancer.⁸

These changing patterns of infective endocarditis have not occurred in many poor or underdeveloped parts of the world. Rheumatic fever in these countries is still common, and access to congenital cardiac surgery is limited.⁹ Rheumatic disease of the mitral and aortic valves, therefore, remains the most common basis for infective endocarditis

globally. Abuse of intravenous drugs and degenerative diseases of the heart, which are important causes of endocarditis in adults, are not common predisposing factors in children.

Mortality

Infective endocarditis was universally fatal prior to the introduction of antibiotics. When sulphonamides were introduced, a small proportion of patients were successfully treated. A larger proportion of patients was cured with the introduction of penicillin, when about two-thirds survived the infection, with further increases in survival in more recent decades.¹⁰ This reduction in mortality and morbidity has been due to advances in antimicrobial therapy, early detection of endocarditis, aggressive management of its complications, and improvements in surgical techniques.¹⁰ Despite these improvements, between one-tenth and one-quarter of those suffering endocarditis may still die.^{11,12}

PATHOGENESIS

Intact endothelium is resistant to colonisation by microorganisms. Injury or erosion to the endothelial surface, which can occur from haemodynamic or mechanical stress, is a potent inducer of thrombogenesis. The initial deposition of platelets and fibrin over the damaged endothelium is referred to as a nonbacterial thrombotic endocarditis. This is the crucial lesion, which provides a surface for bacteria to stick to the endothelium, leading to the development of infective endocarditis.¹³ When microorganisms enter the bloodstream, colonisation on the altered endothelial surface will ultimately convert the nonbacterial thrombotic endocarditis to infective endocarditis. Trauma to the oral mucosa, particularly the gums, the genitourinary tract, and the gastrointestinal tract are especially associated with increased risk of bacteraemia.

The propensity to adhere to the nonbacterial thrombotic endocarditis depends on the type of microorganism. Gram-positive organisms, such as enterococci or viridans streptococci, have the propensity to adhere to valvar surfaces, whereas gram-negative bacilli, such as *Klebsiella*, do not adhere well.¹⁴ Gram-positive microorganisms, therefore, are the predominant organisms in endocarditis. Other bacterial factors, including dextran produced by the *Streptococcus viridans*, have been identified as promoting adherence to heart valves.¹⁵ Furthermore, the interactions of gram-positive organisms with platelets, and their capacity to resist the antimicrobial properties of platelets, are pivotal to the development and persistence of endocardial infections.¹⁶

Figure 55-1 There is an endocarditic lesion on the leaflet of the truncal valve in this heart from a patient with common arterial trunk.

The defenses of the host play a major role in the onset of infective endocarditis. In children with cardiac disease, the shear forces associated with a stream of blood with high velocity can damage the endothelium. In damaged valves, the local pattern of flow is altered as a result of changes in the geometry of the valve. Indwelling intravenous catheters positioned in the right side of the heart may traumatise the endocardium, commonly that on the valves, exposing the subendothelial collagen.¹⁷ These factors promote the development of non-bacterial thrombotic endocarditis, allowing adherence of microorganisms during bacteraemia, and the onset of infective endocarditis. Microorganisms, in turn, promote the further deposition of platelets and fibrin, thus enlarging the vegetation (Fig. 55-1). Organisms within the vegetation are protected from the defense mechanisms of the host, which allows them to proliferate rapidly.^{18,19}

INFECTIVE ENDOCARDITIS IN THE CONGENITALLY MALFORMED HEART

Congenital cardiac disease is now the major underlying condition predisposing to infective endocarditis during childhood in developed countries. The incidence of infective endocarditis in this group is increasing⁵ as more children with congenital cardiac disease survive surgical interventions. Many such patients will have undergone previous cardiac surgery. At highest risk are those who have had repair or palliation of cyanotic disease.²⁰

Site of Infection

It has long been known that endocarditis commonly occurs when blood is driven from a source of high pressure, for example, the left ventricle or aorta, through a narrow orifice, for example, aortic coarctation, a small ventricular septal defect or arterial duct, or a regurgitant aortic or mitral valve, at high velocity into a low pressure sink, for example, the atrium, pulmonary trunk, or right ventricle.²¹ It has been suggested that the high velocity of the stream of blood immediately beyond the orifice leads to a marked drop in the hydrostatic pressure laterally, so

Figure 55-2 This cross sectional echocardiogram was obtained from a patient with endocarditis in the setting of a small ventricular septal defect. The vegetation is on the right ventricular side of the defect, as the jet of high velocity passes from the left to the right ventricle.

that, consequently, the perfusion of the endothelial intima at this level is reduced. This is then the characteristic site of the infective process. This so-called Venturi effect accounts for the finding that it is the left atrial side of the mitral valve that is affected in mitral incompetence, while in a ventricular septal defect, infection is usually centred on the right ventricular surface of the septum (Fig. 55-2). Small defects are nearly always involved, as large defects dissipate any differences in pressure. Similarly, in an arterial duct, it is commonly the pulmonary arterial end that is infected, while in aortic incompetence, it is the ventricular surface of the leaflet that is involved.

Infective Endocarditis in Unoperated Congenital Heart Disease

The lesions which are most commonly affected by infective endocarditis are small ventricular septal defects, aortic stenosis or incompetence, tetralogy of Fallot, and persistently patent arterial ducts.²² Conversely, there have been only a few reports of endocarditis possibly related to isolated defects of the atrial septum, although patients with the so-called ostium primum defect, in reality an atrioventricular septal defect with separate valvar orifices for the right and left ventricles, may be affected.^{23,24}

In children aged between 5 and 14 years with a ventricular septal defect, the estimated risk is 1 in 500 patient-years, or two infections per 100 patients over a period of 10 years.²⁵ The risk is increased considerably when there is associated aortic incompetence, or in the setting of defects producing a shunt from the left ventricle to right atrium. When infective endocarditis occurs in those with tetralogy of Fallot and pulmonary atresia, it is usually the aortic valve that is affected. This is also the case in tetralogy with pulmonary stenosis, although the pulmonary valve can also be affected. Prolapse of the mitral valve remains an important

underlying cause in children in whom no cardiac anomaly was suspected prior to the development of infective endocarditis. This is also the case in older patients with aortic valves having two leaflets. Infective endocarditis in patients with hypertrophic cardiomyopathy is virtually confined to those with obstruction to the outflow tract, and is more common in those with both obstruction and atrial dilation,²⁶ although this rarely occurs in childhood.

Infective Endocarditis after Surgery for Congenital Cardiac Disease

When defects such as a ventricular septal defect or the persistently patent arterial duct are completely repaired without residual sequelae, the risk of endocarditis is reduced to that for the normal population by 6 months after surgery.⁵ For some patients, however, the risks of infective endocarditis may be increased by cardiac surgical procedures, particularly after palliative surgery involving insertion of conduits or creation of shunts to relieve obstruction to the flow of blood to the lungs, and after replacement of the aortic valve with a prosthesis. The risk for infective endocarditis is particularly high in the immediate postoperative period, especially where prosthetic valves or conduits have been used during the repair, or when haemodynamic problems persist.²⁷

MICROBIOLOGY

Gram-positive organisms are most commonly responsible for infective endocarditis in children, particularly, streptococci, staphylococci, and enterococci.²⁸

Streptococcus

Streptococcus of the Viridans or α -Haemolytic Group

These organisms, which exhibit so-called α -haemolysis on blood agar plates, were responsible for more than nine-tenths of cases before the widespread use of antibiotics.²⁹

Oral Streptococcus Group

The species that most commonly cause endocarditis are *Streptococcus sanguis*, *Streptococcus oralis*, also known as *mitis*, *Streptococcus salivarius*, *Streptococcus mutans*, and *Gemella morbillorum*, formerly called *Streptococcus morbillorum*. These organisms form part of the normal flora of the mouth and the upper respiratory tract and are almost always susceptible to penicillin G.

Streptococcus milleri Group (*Streptococcus anginosus*, *Streptococcus intermedius*, and *Streptococcus constellatus*)

Infection with these organisms has the tendency to form abscesses, which disseminate through the bloodstream, for example, visceral abscesses and osteomyelitis.

Abiotrophia defectiva and Infective Endocarditis Produced by Granulicatella Species

These agents were formerly known as nutritionally variant streptococci. The strains have nutritional deficiencies that hinder their growth in standard culture media. They often exhibit tolerance to penicillin.

Staphylococcus

Coagulase-positive species, such as *Staphylococcus aureus*, or species which are coagulase negative, such as *Staphylococcus epidermidis* and others, can cause infections in both native

and prosthetic valves, indwelling vascular catheters, and prosthetic materials. They are predominantly very resistant to penicillin G and to ampicillin, due to the production of enzymes called β -lactamases

Staphylococcus Aureus

This is one of the most common organisms responsible for infective endocarditis in children. It has virulent properties, and is associated with acute bacterial endocarditis. The organism has the ability to affect normal valves, especially in patients with impaired immunity. Advances in invasive medical treatments, and in particular the increased use of intravascular devices, have resulted in an increased incidence of this form of endocarditis.³⁰

Enterococcus

Enterococcus is responsible for endocarditis less frequently in children than in adults, accounting for about one-twentieth of isolates from blood cultures. Faecal organisms are normal commensals in the gut, genitourinary tract, and sometimes the mouth.³¹ In older patients, endocarditis may follow procedures within the genitourinary tract, such as urethral catheterisation, abortion, normal delivery, and even insertion of an intra-uterine contraceptive device.

Other Bacterial Organisms

Infection from *Streptococcus pyogenes* was formerly associated with an acute fulminating infection following erysipelas. Infection by this organism is now uncommon, presumably related to the early use of antibiotics in this condition. Similarly, infection with *Streptococcus pneumoniae* was a recognised complication of pneumococcal meningitis or lobar pneumonia, although it is rare following the introduction of antibiotics. Patients with right isomerism and asplenia are still at risk from this infection.

Gram-negative organisms very rarely cause infective endocarditis in children. *Neisseria gonorrhoeae* can cause a fulminating endocarditis, but it is not a major problem in children in the current era. *Pseudomonas aeruginosa* can cause infection in patients on intensive care units, particularly those with indwelling catheters.

Less frequently, endocarditis can be caused by fastidious gram-negative organisms of the so-called HACEK group, specifically, *Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Haemophilus paraphrophilus*, *Haemophilus influenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*, and *Kingella denitrificans*.³²

Fungal Endocarditis

Fungal endocarditis is rare, but its incidence appears to have increased significantly in recent years due to advances in medical technology. Risk factors include the requirement for prolonged intravenous catheterisation or use of antibiotics, dialysis, hyperalimentation, and immunosuppression, as well as surgical procedures which require implantation of prosthetic devices such as heart valves and pacemakers.³³ The organisms are usually candidal species although aspergillus has been reported. Up to three-quarters of those suffering fungal endocarditis still die. The typical large and friable vegetations contribute to the higher

rates of complication. Delay in diagnosis is common and may contribute to the high rates of death.³⁴

CLINICAL FEATURES

In paediatric practice, it is still useful clinically to distinguish between acute and subacute presentation. Often no precipitating event or primary focus of infection is found in children. When one is found, dental extractions, orthodontic procedures, or other dental manipulations are the most common.³⁵ Cardiac catheterisation rarely causes endocarditis, although staphylococcal infection may occur especially at the site of entry of the catheter. The increased use of indwelling intravascular catheters and implantable devices has resulted in many catheter-related infections, bacteraemias, and device-related infections. Endocarditis may follow cardiac surgery, particularly when an artificial material such as external conduit or prosthetic valve is used.

The defense mechanisms of the host, along with the virulence of the infecting organisms, determine the clinical manifestations. Other important factors include the type of valve infected, whether native or prosthetic, whether the infection was acquired in the community or in hospital, and if previous antimicrobial therapy was used. The indiscriminate use of antibiotics in children with congenitally malformed hearts is ill advised unless a genuine cause of illness or pyrexia is found. These factors increase the variability with which infective endocarditis can present. In some patients, infective endocarditis may mimic a wide spectrum of disorders, ranging from other infections to malignancies or diseases of connective tissue. The clinician requires vigilance in keeping infective endocarditis in mind, particularly when a patient with known cardiac disease has an unusual febrile illness, as any delay in diagnosis may lead to a higher rate of complications.

Non-specific Features

Fever

Fever is the most common symptom in patients with endocarditis, particularly in those outside the neonatal period. The fever is initially continuous, but may become recurrent and low grade with asymptomatic intervals, particularly if short courses of antibiotics were given. A low-grade fever is the predominant symptom in the classical presentation of subacute bacterial endocarditis, which is typically caused by the viridans group of streptococci. Infection with *Staphylococcus aureus* often causes very high fever. The fever is usually accompanied by a variety of somatic complaints, including fatigue, weakness, arthralgias, myalgias, anorexia, weight loss, rigors, and diaphoresis.

Arthralgias and Arthritis

These features are typical of subacute infective endocarditis, so that it may mimic rheumatologic diseases. Sometimes there is arthritis of a single joint, but more commonly there is generalised arthralgia.^{36,37}

Cardiac Features

Congestive Cardiac Failure and Valvitis

Increasing breathlessness and tachycardia may reflect cardiac failure and/or anaemia. Cardiac failure may result from both mechanical and myocardial factors. Valvar

involvement may result in destruction of the aortic or mitral valves causing severe regurgitation. Embolism to the coronary circulation may produce myocardial infarction, while occasionally a diffuse myocarditis may also contribute to myocardial dysfunction.

Embolisation

Embolisation of infected or thrombotic material from cardiac vegetations may lead to ischaemia, infarction, or mycotic aneurysms. The site of embolism determines the clinical findings. In patients with endocarditis involving the right side of the heart, embolisation may be misdiagnosed as pneumonia in a patient who presents with chest pain and breathlessness. Typically, the chest radiograph demonstrates multiple, scattered, fluffy infiltrates, which disappear and then reappear on serial films.³⁸ Vegetations on the mitral valve appear to be particularly associated with a high risk of embolisation. When such embolisation occurs, any organ can be affected. Splenic infarcts present with features typical of an acute abdominal problem.

Neurological Complications

Neurological complications or manifestations are common, being found in more than one-third of patients.³⁹ These may result from embolisation to the central nervous system, which may result in a stroke or diffuse cerebral vasculitis, which results in a confusional state, headache or psychiatric disturbance. Rarely, mycotic aneurysms within the central nervous system can occur. Their rupture can be catastrophic (Fig. 55-3).

Renal Abnormalities

Renal involvement is most common in patients with staphylococcal infections, resulting in haematuria, glomerulonephritis, or renal infarction, which may occur in up to half of such patients.^{40,41}

Physical Findings

Patients appear ill, with a fever. Splenomegaly is present in two-thirds. It is often painless unless the spleen is greatly enlarged. There may be hepatomegaly and other signs of heart failure. Anaemia is common. The auscultatory signs of valvar regurgitation should be carefully sought. The child may have a cardiac anomaly with preexisting murmur. Frequent examinations are necessary if infective endocarditis is suspected, since a change in murmur is one of the classical features of the disease. The classical extracardiac manifestations of infective endocarditis, such as petechial haemorrhages, Roth's spots, Janeway lesions, Osler's nodes, and splenomegaly, are all rare in children.

INFECTIVE ENDOCARDITIS IN THE NEWBORN

Infective endocarditis affecting the newborn commonly occurs in those born prematurely, particularly after a period of prolonged hospitalisation.⁴² The incidence appears to be rising, in part due to the increased survival of such premature infants with indwelling catheters,⁴³ but also due to increased recognition of endocarditis by the application of cross sectional echocardiography. Infections

Figure 55-3 Magnetic resonance imaging of the brain in a patient with infective endocarditis involving the aortic valve. The upper panels show transverse images, while the lower panels show frontal images. There are multiple abscesses (arrows) involving the inferior part of the left frontal lobe and the superior part of the right parietal lobe.

usually involve the right-sided cardiac structures in babies who have structurally normal hearts. Less than one-third of cases of neonatal endocarditis occurs in the presence of congenital cardiac disease.⁴⁴ The most common infecting organisms are *Staphylococcus aureus*, coagulase-negative staphylococci, and *Candida* species.

The signs are usually non-specific, particularly in the preterm neonate. Many infants have feeding difficulties, respiratory distress, and tachycardia. Fever is seldom a major feature. Neonates may present with septicaemia, hypotension, congestive cardiac failure, or a changing murmur. Neurological signs and symptoms such as seizures, hemiparesis, and apnoea occur in many infants. Septic emboli are common, and cause foci of infection outside the heart, such as osteomyelitis, meningitis, and pneumonia.

LABORATORY DIAGNOSIS

Cultures of Blood

Cultures of blood are of paramount importance in order to isolate the infecting organism. The identity of the organism may suggest the source of bacteraemia, for example, isolation of *Streptococcus viridans* points to an oral source. Based on the organism's sensitivity to antibiotics, initial antibiotic therapy may be corrected, which has been shown to reduce mortality.⁴⁵ Blood should be cultured from all patients with fever of unexplained origin and a pathological murmur, a history of cardiac disease, or previous endocarditis. The last indication is because a previous episode of endocarditis is a risk factor for a further episode.⁴⁶ Bacteraemia in patients with infective endocarditis is usually continuous. It is not necessary, therefore, to obtain the cultures at any particular phase of the fever cycle. One set of cultures, while better than none, is not sufficient, as it does not demonstrate

the continuous nature of the bacteraemia, nor does it maximise the chances of isolating the organism and differentiating between contamination and true bacteraemia.⁴⁷ In most units, two or three cultures through separate venipunctures on the first day is considered to be adequate. In the critical situation of acute infective endocarditis, where prompt treatment is crucial, cultures can be obtained within 5 minutes of each other prior to the administration of empiric antibiotic therapy. Pathogens will be grown in cultures in well over seven-tenths of untreated patients, but only from three-fifths of those in whom antibiotics were used before the sample was taken.⁴⁸ Further cultures are necessary when results are negative and the clinical suspicion of endocarditis is high, particularly if antibiotics had been given prior to sampling.

False-positive results can be due to contamination by skin flora, or from samples obtained from contaminated intravascular catheters. Such false-positive results can be averted by optimal preparation of the skin before venipuncture. Whenever possible, samples from indwelling catheters should not be used.⁴⁹ Adequate volumes of blood should be obtained. The volume of blood taken should be as large as reasonably possible for the size of the child. Both aerobic and anaerobic cultures should be obtained, though anaerobic cultures are not necessary for all sets.

Other Tests

It is important to determine the sensitivity of the organism to antibiotics and to measure the so-called minimum inhibitory concentration to optimise the choice of antibiotics. Anaemia is common, particularly in those with chronic disease. The number of white cells in the blood is

Figure 55-4 Cross sectional echocardiogram from a patient in whom there is a large vegetation within the right atrium, which is prolapsing across the tricuspid valve into the right ventricle.

typically elevated, with a preponderance of polymorphonucleocytes. More than nine-tenths of patients will have at least microscopic haematuria. Haematuria with red blood cell casts, proteinuria, and renal insufficiency may indicate the presence of glomerulonephritis. Elevated levels of acute phase reactants, specifically the rate of erythrocytic sedimentation and levels of C-reactive protein, are common.

In patients who undergo surgery for endocarditis, resected cardiac tissue may be helpful in the identification of so-called fastidious organisms,⁵⁰ although it has also been shown that the rate of contamination of such specimens may be high.⁵¹ Amplification of specific bacterial sequences

of deoxyribonucleic acid using polymerase chain reaction has also been used for the analysis of blood and tissue samples,^{52,53} although this technique is not routine in most laboratories. Cultures of cells may be of use in the identification of intracellular organisms, such as *Bartonella* or *Coxiella*,⁵⁴ while serological methods may play a role in the identification of infections with these organisms and others.⁵⁴

IMAGING STUDIES

Echocardiography

Echocardiography is the primary modality for the detection of vegetations and cardiac complications from endocarditis. It can demonstrate the site of infection and extent of damage. Serial assessments can follow the course of infection. Cardiac and valvar function can be monitored and the response to therapy assessed.⁵⁵

Typical echocardiographic findings include the presence of vegetations (Fig. 55-4), abscesses, and new valvar insufficiency. Vegetations are usually seen on the upstream side of the valve, that is, on the atrial side of the atrioventricular valves, on the ventricular side of the arterial valves, and at the points of impingement of high-velocity jets on the valve or cardiac wall. In those with prosthetic valves, vegetations can arise from the prosthetic ring and/or along the edge of the site of a jet with high velocity. The size of the vegetation is likely to predict the likelihood of embolisation, particularly when it is on the mitral valve.^{56,57}

Because of superior echocardiographic windows, the sensitivity of transthoracic echocardiography is higher in children than in adults for the detection of vegetations. Transoesophageal echocardiography is more invasive, has a higher cost, and is unnecessary in most cases, especially in younger children. Excellent agreement has been shown between transthoracic and transoesophageal echocardiography, such that, when positive findings at the transoesophageal study are used as the gold standard, the sensitivity of

Figure 55-5 A, This cross sectional echocardiogram was taken from a parasternal window in a patient with a para-aortic abscess. B, The communication between the cavity of the abscess and the aortic root is demonstrated by colour flow mapping.

Figure 55-6 Cross sectional echocardiogram demonstrating a vegetation in a patient after surgical palliation involving banding of the pulmonary trunk. The small vegetation, which was difficult to identify, is fixed to the distal side of the band.

transthoracic echocardiography for the detection of vegetations is 93%.⁵⁸ A transoesophageal study, therefore, should be reserved for patients in whom transthoracic windows are limited. Transoesophageal echocardiography is particularly useful in the assessment of endocarditis involving the left ventricular outflow tract. In patients with involvement of the aortic valve, a changing dimension of the aortic root on transthoracic examination may indicate the development of an abscess of the aortic root, or involvement of the sinus of Valsalva. A transoesophageal study should be

considered in all such patients due to the dangerous consequences of these complications (Fig. 55-5).

Limitations of Echocardiography

The significance of echocardiographic findings should be considered in the setting of the overall clinical picture. Thus, the absence of vegetations on an echocardiogram does not rule out infective endocarditis. Conversely, other types of echogenic masses may resemble a vegetation, for example, a sterile thrombus, sterile prosthetic material, or a normal anatomical variation such as a Eustachian valve.⁵⁹ Vegetations are more likely to be identified by transthoracic echocardiography in patients with normal anatomy or isolated valvar pathology than in patients with complex cyanotic disease, as interference of echocardiographic imaging by arterial grafts, conduits, and valves reduces the sensitivity of echocardiography in this group (Fig. 55-6). In such patients transoesophageal studies may be useful (Fig. 55-7).

Magnetic Resonance Imaging and Computerised Tomography

The role of these newer investigative techniques has yet to be established. Anecdotal reports have demonstrated the ability of both modalities to detect complications of infective endocarditis, particularly in the evaluation of intracranial complications, but to the best of our knowledge, there have been no large scale studies. Magnetic resonance imaging may also be of use in the detection of infective endarteritis involving the aortic arch (Fig. 55-8). The length of time currently needed to acquire images, the inability to evaluate motion, and the presence of motion artifact are major limitations of both techniques.⁶⁰

DIAGNOSTIC CRITERIONS

The presentation of infective endocarditis in the majority of patients is non-specific, and does not follow the classical clinical presentation. Much attention was focused, therefore, on the development of a diagnostic criterion for infective endocarditis. The rules known as the Duke criteria⁶¹ are currently the most commonly used, and have been demonstrated to be superior to previous schemes for the diagnosis of infective endocarditis in children.⁶²

Figure 55-7 A, Transoesophageal echocardiogram in a patient with an extra-anatomic conduit placed between his ascending and descending aorta. B, An abscess cavity can be seen surrounding the conduit.

Figure 55-8 Magnetic resonance imaging in a patient who presented with a fever. The femoral pulses were absent, and an echocardiogram demonstrated the present of aortic coarctation. A, Magnetic resonance imaging demonstrated the shelf lesion in the aorta, with irregularity and dilation of the aorta distal to it. B, Further imaging demonstrated the presence of an abscess.

These criteria use similar principles to the ones employed for the diagnosis of rheumatic fever. They are made up of major and minor criteria (Table 55-1),⁶³ and incorporate a combination of clinical, microbiological, pathological, and echocardiographic findings. In a modification of the criteria, it has been proposed that the infection caused by *Staphylococcus aureus* should be a major criterion, regardless of whether the infection is nosocomially or community acquired, or whether a primary source of infection is present or absent.⁶⁴

MEDICAL MANAGEMENT OF INFECTIVE ENDOCARDITIS

Therapy consists of prolonged use of the appropriate antibiotics that are adjusted to microbiological findings. In most cases, this is all that is required to cure the infection and prevent life-threatening complications. Surgical intervention may be necessary in selected patients. Optimal management requires early and on-going consultation between multidisciplinary teams consisting of the cardiologist, microbiologist, the specialist in infectious diseases, and the cardiac surgeon.

Principles of Treatment with Antibiotics

Isolation and susceptibility testing of the infecting organism is important in order to guide therapy. Cultures of blood must always be taken before treatment is commenced. In stable patients, treatment may be postponed for up to 48 hours, or even longer, until the results of initial cultures are obtained. This is particularly important if the patient has been treated with antibiotics within the last 8 days.⁶⁵ In acutely ill patients, empirical antimicrobial therapy should be commenced after three blood cultures have been obtained. Treatment will later be adjusted according to microbiological test results. Blind therapy should use a combination of antibiotics that are effective against both streptococci and staphylococci.

Penetration by antibiotics is hampered because the vegetation consists of organisms in very high concentrations

embedded within a mixture of fibrin and platelets, often enclosed in a layer of exopolysaccharides. A prolonged course of antibiotics is therefore required for complete eradication, usually between 4 and 8 weeks.

The large inoculum of organisms that exist within the vegetation has relatively low rates of metabolism and division. This results in decreased susceptibility to antibiotics that work against actively growing organisms, such as β -lactam, glycopeptides, and other cell wall-active antimicrobials. There may be variable penetration of antibiotics within the vegetation.

Concentrations of antibiotics within the vegetation must be sufficiently high and sustained in order to be effective. The parenteral route of administration is required for maximal bioavailability. Intravenous administration is preferred over intramuscular injections in infants and children due to their small muscle mass. Therapy should be commenced in hospital to ensure compliance and to monitor the clinical condition. Some patients may have treatment continued out of hospital when they are haemodynamically stable, afebrile with negative cultures, and at low risk of complications.

Whenever possible, bactericidal drugs should be chosen. Bacteriostatic drugs, such as sulphonamides, tetracyclines, and chloramphenicol, may increase the chance of failure of treatment and relapses. Although these agents may suppress fever, the infection is usually not eradicated, and progressive damage to valves may occur.

It is often necessary to monitor the concentrations of antibiotics such as aminoglycosides and vancomycin in the blood in order to achieve therapeutic levels and to prevent potential side effects such as nephrotoxicity and ototoxicity. The efficacy of therapy is indicated by the disappearance of fever, the sterilisation of cultures, and the normalisation of inflammatory markers. Clinical surveillance is necessary to ensure that complications of endocarditis have not occurred. Blood should be cultured during and after treatment. Cessation of bacteraemia generally occurs within several days of appropriate treatment. Bacteraemia produced by *Staphylococcus aureus* may persist for 3 to 5 days subsequent to the start of β -lactam anti-staphylococcal therapy, and from 5 to 10 days when treating with vancomycin. Clinical and

TABLE 55-1

USE OF MODIFIED DUKE CRITERIONS FOR THE DIAGNOSIS OF INFECTIVE ENDOCARDITIS

Major Criteria

- I. Positive blood culture for infective endocarditis
 - A. Typical microorganism consistent with endocarditis from two separate blood cultures as noted below:
 1. *Viridans* streptococci, *Streptococcus bovis*, or HACEK group,* or
 2. Community-acquired *Staphylococcus aureus* or enterococci, in the absence of a primary focus, or
 - B. Microorganisms consistent with endocarditis from persistently positive blood cultures defined as
 1. Two positive cultures of blood samples drawn >12 hours apart, or
 2. All of three or a majority of more than four separate cultures of blood (with first and last sample drawn >1 hour apart)
- II. Evidence of endocardial involvement
 - A. Positive echocardiogram for endocarditis defined as
 1. Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, or
 2. Abscess, or
 3. New partial dehiscence of prosthetic valve, or
 - B. New valvular regurgitation (worsening or changing of pre-existing murmur not sufficient)

Minor Criteria

- I. Predisposition: predisposing cardiac condition or intravenous drug use
- II. Fever: temperature greater than 38.0°C
- III. Vascular phenomena: major arterial embolisation, septic pulmonary infarcts, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, and Janeway lesions
- IV. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
- V. Microbiological evidence: positive blood culture but does not meet a major criterion as noted above or serological evidence of active infection with organism consistent with endocarditis
- VI. Echocardiographic findings: consistent with endocarditis but do not meet a major criterion as noted above

Diagnosis

- I. Definite
 - A. Pathology or bacteriology of vegetations, major emboli, or intracardiac abscess specimen, or
 - B. Two major criteria, or
 - C. One major and three minor criteria, or
 - D. Five minor criteria
- II. Possible
 - A. One major and one minor criterion, or
 - B. Three minor criteria
- III. Rejected
 - A. Firm alternative diagnosis, or
 - B. Resolution of syndrome after ≤4 days of antimicrobial therapy, or
 - C. No pathologic evidence at surgery or autopsy after ≤4 days of antimicrobial therapy, or
 - D. Does not meet definite or possible criteria

HACEK indicates *Haemophilus* species, *Actinobacillus* (*Haemophilus*) *actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*.

*Includes nutritionally variant strains (*Abiotrophia* species infective endocarditis). Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

Modified from Haldar SM, O'Gara PT: Infective endocarditis: Diagnosis and management. *Nat Clin Pract Cardiovasc Med* 2006;3:310–317.

biological surveillance should continue in the subsequent 4 weeks after completion of therapy when the risk of relapse is highest.⁶⁶

Specific Treatment for Infection with Gram-positive organisms

Streptococci

Penicillin G, or ampicillin if penicillin G is unavailable, or ceftriaxone for 4 weeks, results in almost universal recovery. In patients with prosthetic valves, the duration of therapy should be extended to at least 6 weeks. When there is a

relative resistance to penicillin, combination with an aminoglycoside is recommended.

Staphylococcus aureus

More than nine-tenths of these organisms are highly resistant to penicillin G and ampicillin as a result of production of β-lactamase. For endocarditis due to methicillin-susceptible *Staphylococcus aureus* involving a native valve or other native cardiac tissue, therapy should include a semisynthetic β-lactamase-resistant penicillin, such as nafcillin or oxacillin, given for a minimum of 6 weeks. There is some evidence that combination with an aminoglycoside might result in earlier sterilisation of the blood and faster resolution of fever, but this

does not appear to change the outcome with respect to mortality.⁶⁷ Patients with methicillin-resistant strains should be given vancomycin for a minimum of 6 weeks, with or without gentamicin for the first 3 to 5 days of therapy. In patients with endocarditis involving a prosthetic valve, rifampicin should be added for the entire duration of therapy, with the duration of the aminoglycoside treatment being extended to 2 weeks.

Coagulase-negative *Staphylococcus*

Staphylococcal endocarditis on a prosthetic cardiac valve or other cardiac prosthetic material is usually caused by coagulase-negative organisms that are methicillin resistant, especially if the endocarditis develops within 1 year after cardiac surgery. Initial therapy of such patients should include a combination of vancomycin with an aminoglycoside. Therapy should be changed to a β -lactamase-resistant penicillin in proven susceptibility to methicillin.

Enterococci

Such infection is rare in children. These organisms display a relative resistance to penicillin and ampicillin, and a variable resistance to aminoglycosides and vancomycin. In patients with endocarditis on native valves caused by susceptible strains, a combination of penicillin G or ampicillin, together with gentamicin, should be given for 4 to 6 weeks. When prosthetic material is infected, a minimum duration of 6 weeks is recommended.

Fungal Endocarditis

Antimycotic therapy should continue for at least 6 weeks following surgery. Successful medical therapy alone can occur in neonates with mural endocarditis, and occasionally in some older children. The first-line antifungal therapy remains amphotericin B, although it does not penetrate vegetations well. Many patients will require surgery, as medical therapy alone is often unsuccessful.

Anticoagulation and Antiplatelet Treatments

While these treatments have been used to either prevent embolic complications or enhance the effects of antibiotics, there are no systematic studies which support the use of these agents in infective endocarditis. On the contrary, it might be expected that these agents may be detrimental in the acute phase of endocarditis, which is associated with an increased risk of haemorrhage. A number of small studies suggest that the risk of intracerebral haemorrhage following embolisation to the central nervous system may be increased by treatment with anticoagulants.^{68,69} It has been recommended that, for patients who require anticoagulants for other reasons (for example, a prosthetic valve) warfarin be replaced with intravenous heparin during the early stages of the disease, until it is clear that all invasive procedures have been completed and that embolisation to the brain has not occurred.⁷⁰

Surgical Management

While it is clear that some patients may benefit from surgical intervention, there is no data which has been prospectively gathered to examine the precise indications for surgical intervention for endocarditis in children. The decision to undertake surgery should be made in consultation with all members of the team caring for the patient. Bacteraemia,

or non-completion of antibiotic therapy, should not delay surgery.⁷¹ Several circumstances may require consideration for early surgery.

Severe Uncontrollable Cardiac Failure

Surgical intervention should be considered in patients with infective endocarditis and congestive cardiac failure. This mainly occurs in the setting of left-sided endocarditis, where progressive damage to valves can result in cardiac failure which is not amenable to medical therapy alone. Up to half of these patients may die if they do not undergo surgery.⁴¹ Surgery can substantially reduce this rate of mortality, and is particularly beneficial in those with moderate or severe cardiac failure.

Persistent or Particularly Severe Infection and Fungal

Endocarditis

Surgery should be considered if fever and bacteraemia persist for more than 7 to 10 days despite adequate antibiotic therapy. This is a common situation in patients with fungal endocarditis, in whom antifungal therapy and surgery are both commonly required for successful treatment.

Endocarditis on Surgically Created Shunts or Conduits, or Infected Patches and Intracardiac Devices

Endocarditis on prosthetic valves, particularly in the first year after surgery, is commonly due to staphylococcal infection. It may be severe, resulting in dysfunction of the valve, and can be complicated by the formation of an abscess. Infection of shunts or conduits is a potentially life-threatening condition which typically does not respond well to antibiotics alone.⁷² Infection on pacing leads is also associated with high mortality and morbidity, commonly necessitating surgical or percutaneous removal of the lead, together with prolonged treatment with antibiotics.

Embolic Indications

The decision for surgery to prevent embolism is more complex, and is made on an individual basis. The greatest risk of embolisation occurs early in the course of the illness, if vegetations are large and mobile, longer than 1 cm, or situated on the aortic leaflet of the mitral valve. Early surgery may be beneficial in such patients, and in those with evidence of recurrent embolism despite appropriate antibiotics.⁷³

PREVENTION OF INFECTIVE ENDOCARDITIS

Despite advances in modern antimicrobial and surgical treatments, the morbidity and mortality from endocarditis remain substantial. Prevention, therefore, has become a priority. The organisms that cause endocarditis are part of the normal oral flora, such as *Streptococcus viridans*, as well as the normal gastrointestinal and genitourinary flora. It has long been recognised that certain procedures produce bacteraemia with organisms that can cause endocarditis. Bacteraemia caused by the *viridans* group of streptococci is known to follow dental procedures. Bacteraemia also occurs after dental extractions, particularly in patients with periodontal disease and those who undergo multiple extractions.

Bacteraemia and Dental Procedures

Transient bacteraemia produced by streptococci of the *viridans* group may result from any dental procedure that involves manipulation of the gingival or periapical

region of the teeth, or perforation of the oral mucosa. The reported frequencies of bacteraemia due to these dental procedures are widely variable, varying from one-tenth to universal bacteraemia. Streptococcal bacteraemia may also occur simply from chewing food, brushing the teeth, or using dental floss, wooden toothpicks, or water irrigation devices.⁷⁴

While the literature emphasises the contribution of dental procedures to the development of endocarditis, this association is difficult to prove conclusively, the evidence being circumstantial. In the majority of patients, dental procedures will not have occurred within 2 weeks before symptoms. Scientific emphasis is now moving towards the cumulative effects of exposures to low inoculations of organisms due to the activities of daily living, rather than to dental treatment itself.⁷⁴

Prophylaxis with Antibiotics

The prophylactic administration of antibiotics to prevent endocarditis in the setting of dental or other procedures has become routine in most developed countries. Guidelines have evolved over the past 50 years, based mainly on expert opinion and case studies. These recommendations have become complicated and varied between different countries, and often contain ambiguities and inconsistencies. Recommendations in the past have recommended the administration of antibiotics at the time of dental treatment for all patients deemed to be at high or moderate risk for infective endocarditis. This is usually a single dose of oral amoxicillin, or clindamycin or azithromycin if allergic, 1 hour prior to the procedure.

The mechanism whereby antibiotics prevent endocarditis is not established, but has been thought to involve effects that occur after circulating organisms have adhered to the endocardium.⁷⁵ There is little published data to prove the effectiveness of prophylaxis. Dental prophylaxis and cardiac risk factors have been evaluated in a multicentric case-controlled study, with the conclusion that dental treatment was not a risk factor for infective endocarditis even in patients with valvar cardiac disease, and that few cases could be prevented with prophylaxis even if it were completely effective.⁷⁶

Recommendations

There is now consistent scientific evidence to suggest that the link between dentistry and infective endocarditis is tenuous. Prophylactic antibiotics prior to dental procedures may prevent an exceedingly small number of cases of infective endocarditis even if the prophylaxis was completely successful. New guidelines have now been published to take into account this growing body of evidence.^{74,77} Prevention of infective endocarditis is a complex and emotive issue stemming from a prudent attempt to prevent a life-threatening infection. Recent recommendations from the British Society for Antimicrobial Chemotherapy⁷⁷ make fewer patients eligible for endocarditis prophylaxis, contrary to long-standing expectations and practices. These new guidelines have been criticised by paediatric cardiologists.^{78–80}

Major changes were also included in the recently revised guidelines published by the American Heart Association.⁷⁴

The use of antibiotic prophylaxis was limited to patients whom the committee considered to be at highest risk. These include those with prosthetic cardiac valves, those with a previous episode of endocarditis, and those who develop cardiac valvar disease after transplantation. It was recommended that patients with congenital cardiac disease receive prophylaxis only if they had an unrepaired cyanotic defect, including palliative shunts or conduits, were within 6 months of complete repair with prosthetic material or device, or had a residual defect at the site or adjacent to the site of a prosthetic patch or device. For these patients, prophylaxis is recommended for all dental procedures that involve manipulation of gingival tissues or periapical region of teeth, or perforation of oral mucosa. Prophylaxis is also recommended for procedures on respiratory tract or infected skin, dermal structures or musculoskeletal tissue, but not for gastro-urinary or gastrointestinal procedures. It was suggested that the focus should shift towards a greater emphasis on good oral hygiene and access to dental care in patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis, along with those conditions that predispose to the acquisition of infective endocarditis.

Prospective studies will be required to examine the effects of these changes on the incidence of endocarditis, although given the low incidence of the condition, it will be many years before any effects are likely to be demonstrable. Meanwhile, the subject of antibiotic prophylaxis will remain a controversial issue, and guidelines will continue to evolve.

Guidelines for the prevention of infective endocarditis have changed considerably since previous editions of this book. These two articles present these changes. Although the changes have been somewhat controversial, they are now being widely adopted.

Pulmonary Vascular Disease

TILMAN HUMPL and INGRAM SCHULZE-NEICK

Pulmonary hypertension describes a number of different diseases involving the pulmonary vasculature, which have haemodynamic, histological, and therapeutic features in common. The hallmark of these diseases is an abnormally high pulmonary arterial pressure, which—except for large intracardiac shunts permitting transfer of pressure—is due to an increase in the resistance of the pulmonary vasculature, either arterial or venous, to the flow of blood. The histological changes are relatively uniform, and show only vaguely specific dependence on the cause, be it idiopathic, haemodynamic, inflammatory, toxic, or other. The haemodynamic and clinical consequences depend not only on the extent and speed of these changes, but also on the state of the subpulmonary ventricle, which is most usually the morphologically right ventricle.

The different diseases resulting in increased pulmonary vascular resistance show a spectrum of responses to the currently available specific pulmonary antihypertensive substances, with disease-specific profiles of response beginning to emerge. With regard to the individual patient, nonetheless, a correct understanding of the precise pathophysiological situation in which pulmonary vascular resistance is increased and causes pulmonary hypertension is of crucial importance for the correct commencement, and evaluation of efficacy, of treatment.

CLASSIFICATION OF PULMONARY HYPERTENSION

Already in 1891, Ernst von Romberg had described changes in the pulmonary vasculature, which he called sclerosis of the pulmonary arteries.¹ Subsequently, the term primary pulmonary hypertension was coined in 1951.² The original classification of chronic cor pulmonale was established by the World Health Organization in 1973,³ and basically covered three aetiologic groups:

- Diseases primarily affecting the airways of the lung and the alveoluses, such as chronic bronchitis, bronchial asthma, emphysema, pulmonary granulomata, pulmonary resection, congenital cystic disease of the lungs, and high-altitude hypoxia.
- Diseases primarily affecting the movement of the thoracic cage, such as kyphoscoliosis, thoracoplasty, pleural fibrosis, chronic neuromuscular weakness, obesity with alveolar hypoventilation, and idiopathic alveolar hypoventilation.
- Diseases primarily affecting the pulmonary vasculature, such as affections of the arterial wall, thrombotic

disorders, embolism, pressure on pulmonary arteries and veins by mediastinal tumours, and so on.

Over the past decades, the classification has been modified, bringing together clinical as well as aetiologic features with the biological expression of the disease. In 1998, during the Second World Symposium on Pulmonary Hypertension, held in Evian, France, the main focus was to establish categories with similar pathophysiological conditions and therapeutic options.⁴ From this meeting emerged the following classification:

- Pulmonary arterial hypertension
- Pulmonary venous hypertension
- Pulmonary hypoxaemic hypertension associated with disorders of the respiratory system
- Pulmonary hypertension caused by thrombotic or embolic diseases
- Pulmonary hypertension caused by diseases affecting the pulmonary vasculature itself

The Third World Symposium on Pulmonary Arterial Hypertension, held in Venice, Italy, in 2003, allowed an assessment of the usefulness of the classification produced in Evian and its minor modifications (Table 56-1).⁵ The clinically functional classification established by the New York Heart Association for cardiac disease (Table 56-2) is used in an adapted form to assess the clinical severity and progression of the pulmonary vascular disease.⁵ Currently, pulmonary arterial hypertension is defined as a mean pulmonary arterial pressure of greater than 25 mm Hg at rest, or greater than 30 mm Hg while exercising, with a normal pulmonary arterial wedge pressure of less than 15 mm Hg, and an increased pulmonary vascular resistance index of greater than 3 Wood units times m² body surface area. The Dana Point symposium (2008) introduced the term borderline pulmonary hypertension for those disease states in which mean pulmonary artery pressure exceeds 20 mm Hg (personal communication).

PULMONARY HYPERTENSIVE DISEASES

Idiopathic Pulmonary Arterial Hypertension

Idiopathic pulmonary arterial hypertension is characterised by progressive and sustained elevation of pulmonary arterial pressure in the absence of any distinct cause. The diagnosis is made by exclusion of other aetiologies for pulmonary arterial hypertension. There is also some thought that the disease may be a neoplastic and angioproliferative disorder, rather than a vasomotor model centred on vasoconstriction or impaired vasodilation.⁶

TABLE 56-1
CLASSIFICATION OF PULMONARY HYPERTENSIVE DISEASES AS MADE BY THE WORLD HEALTH ORGANIZATION (VENICE, 2003)

1.	Pulmonary arterial hypertension
1.1.	Idiopathic
1.2.	Familial
1.3.	Associated with
1.3.1.	Collagen vascular disease
1.3.2.	Congenital systemic-to-pulmonary shunts
1.3.3.	Portal hypertension
1.3.4.	Human immunodeficiency viral infection
1.3.5.	Drugs and toxins
1.3.6.	Other (thyroid disorders, glycogen storage disease, Gaucher's disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy)
1.4.	Associated with significant venous or capillary involvement
1.4.1.	Pulmonary veno-occlusive disease
1.4.2.	Pulmonary capillary haemangiomatosis
1.5.	Persistent pulmonary hypertension of the newborn
2.	Pulmonary hypertension with left heart disease
2.1.	Left-sided atrial or ventricular heart disease
2.2.	Left-sided valvar heart disease
3.	Pulmonary hypertension associated with lung diseases and/or hypoxemia
3.1.	Chronic obstructive pulmonary disease
3.2.	Interstitial lung disease
3.3.	Sleep-disordered breathing
3.4.	Alveolar hypoventilation disorders
3.5.	Chronic exposure to high altitude
3.6.	Developmental abnormalities
4.	Pulmonary hypertension due to chronic thrombotic and/or embolic disease
4.1.	Thromboembolic obstruction of proximal pulmonary arteries
4.2.	Thromboembolic obstruction of distal pulmonary arteries
4.3.	Non-thrombotic pulmonary embolism (tumor, parasites, foreign material)
5.	Miscellaneous
	Sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumour, fibrosing mediastinitis)

Pulmonary Veno-occlusive Disease

This is a very rare condition which affects mainly, but not exclusively, children and young adults. Multiple possible factors for its development have been discussed, including infections, genetic aspects, toxic exposure, and autoimmune disorders.⁷⁻¹³ The clinical presentation is very similar to idiopathic pulmonary arterial hypertension, with shortness of breath, chest pain, syncope, hypoxaemia, and later signs of right-sided cardiac failure. Histological findings (Fig. 56-1) include intimal fibrosis of the pulmonary veins, leading to narrowing and occlusion of affected vessels.^{14,15} From the

TABLE 56-2
CLASSIFICATION OF THE CLINICAL FUNCTIONAL STATE IN PATIENTS WITH PULMONARY HYPERTENSION ACCORDING TO THE WORLD HEALTH ORGANIZATION/NYHA

Class I	Patients with pulmonary hypertension, but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnoea or fatigue, chest pain, or near syncope.
Class II	Patients with pulmonary hypertension resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity causes undue dyspnoea or fatigue, chest pain, or near syncope.
Class III	Patients with pulmonary hypertension resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes undue dyspnoea or fatigue, chest pain, or near syncope.
Class IV	Patients with pulmonary hypertension with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnoea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

Figure 56-1 Bronchiolovascular unit showing preacinar artery (A) with intimal thickening and adjacent displaced pulmonary vein (V). The alveolar septa are thickened and show centralised capillaries with reduction of alveolar-capillary membranes (original magnification x 100; Movat stain). (Courtesy of Dr. G. Taylor, Hospital for Sick Children, Toronto, Ontario, Canada.)

haemodynamic aspect, there is elevated pulmonary arterial pressure, with a normal pulmonary capillary wedge pressure. The chest radiograph (see Fig. 56-3A) typically shows enlargement of the pulmonary trunk, pulmonary oedema with prominent Kerley B lines, and pleural effusions. On computed tomography (see Fig. 56-3B and C), the disease manifests with thickened interlobular septa, enlarged lymph nodes, and ground-glass opacities.¹⁶ Definite diagnosis requires lung biopsy, a high-risk procedure where the benefit for the patient needs to be taken into account. Cardiac catheterisation, with testing for vasodilation, may be indicated, but acute pulmonary oedema has been described.¹⁷ Therapy includes supplemental

oxygen and diuresis, as well as anticoagulation.¹⁸ There are also reports on the use of immunosuppressive therapy with corticosteroids¹⁹ and azathioprine,²⁰ but this approach should be limited to patients with suspected or proven collagen vascular disease. Lung transplantation is most likely the only option for treatment, but the long waiting time for organs may limit the final outcome.

Alveolar Capillary Dysplasia

This is a relatively rare cause of persistent pulmonary hypertension of the newborn, but its incidence is most likely underestimated. A retrospective study on neonates treated with extracorporeal membrane oxygenation in the United Kingdom between 1997 and 2000 identified a total of nine patients with such irreversible lung dysplasia.²¹ The aetiology is still uncertain, with familial cases suggesting a possible genetic mutation.^{22,23} The histological findings include muscularisation of the pulmonary arterioles, a deficiency in the number of alveolar units and pulmonary capillary vessels with thickening of the interalveolar septums, anomalous pulmonary veins accompanying the pulmonary arteries and bronchuses, and dilated lymphatics.^{24–26} The newborn usually presents with severe hypoxaemia, without response to treatment with oxygen or pulmonary vasodilators. Open lung biopsy has been recommended if a neonate with persistent pulmonary hypertension shows no clinical improvement after 72 hours despite maximal medical therapy.^{25,26} Cardiac catheterisation may be helpful to complete the diagnostic work-up.²⁷ Currently the disease is incurable, with a maximum reported survival time of about 3 months, albeit sometimes with a phase of mild improvement with the administration of vasodilating agents.^{28,29}

Congenital Diaphragmatic Hernia

This entity is characterised by pulmonary hypoplasia, with structural as well as functional anomalies, leading to a high pulmonary vascular resistance and pulmonary hypertension. A combination of compression of the lungs during fetal life, limited flow of blood to the lungs, and intrinsic pulmonary developmental arrest are essentially responsible for the parenchymal pulmonary hypoplasia.^{30–33} In addition, a dysregulation of the expression of the receptors for endothelin-1 has been documented.³⁴ This leads to failure of postnatal remodelling, resulting in increased right ventricular pressure and perfusion bias to the unaffected side. The clinical management includes surgical repair in the early neonatal phase, followed by care over the long term. With newer options for treatment like high-frequency oscillatory ventilation, intravenous infusion of prostaglandin, inhaled nitric oxide and extracorporeal membrane oxygenation, better neonatal survival is achieved,^{35–37} but the number of patients with chronic lung disease, or recurrent or residual pulmonary hypertension, is also increasing. There are no controlled clinical trials on the use of vasodilators in long-term survivors with elevated pulmonary arterial pressures. Maximal exercise capacity was shown to be mildly decreased when a cohort

of patients with this problem was compared to normal controls.³⁸

Pulmonary Hypertension Associated with Bronchopulmonary Dysplasia or Chronic Lung Disease

Persistently elevated pulmonary arterial pressure related to bronchopulmonary dysplasia is a common finding in ex-preterm infants born with low weight,^{39,40} despite preventive therapy,⁴¹ but the pressures tend to fall with increasing age during the first year of life. Improved survival of very immature infants has led to increased numbers of infants with chronic lung disease. Histological findings suggest an arrested alveolar development, or loss of alveoluses, and it was hypothesised that disruption of angiogenesis impairs alveolarisation. In contrast, preservation of vascular growth and endothelial survival may promote growth, and may sustain the architecture of the distal air space.⁴² Currently, supplemental oxygen is provided to children with chronic lung disease to prevent hypoxaemia. Other vasodilators, such as oral sildenafil and intravenous or aerosolised prostacyclin, may be considered after careful evaluation and exclusion of fixed pulmonary vascular resistance.

Pulmonary Hypertension Associated with Pulmonary Venous Obstruction

Pulmonary venous obstruction induces both pulmonary arterial and pulmonary venous hypertension. The condition may be related to anatomical abnormalities of the pulmonary veins, such as partially or totally anomalous pulmonary venous connection or scimitar syndrome, a structural variation such as divided left atrium, or varying occlusion of one or more pulmonary veins, be the occlusion congenital or acquired. In the majority of cases, a surgical or interventional approach is warranted,^{43–46} followed by individual assessment for residual pulmonary hypertension and tailored therapy. Whereas the long-term prognosis in the presence of divided left atrium is usually benign, the intrinsic pathology of the pulmonary veins is often progressive.

Pulmonary Hypertension Associated with Congenitally Malformed Hearts: General Considerations

Epidemiology

Pulmonary hypertension in the context of the congenitally malformed heart has a rather small place in the overall classification of pulmonary hypertension (see Table 56-1). Such classification is nowadays seen as insufficient,⁴⁷ and is currently under revision. There are a multitude of haemodynamic situations in which pulmonary vascular resistance is increased and plays an important part in the state and prognosis of the patient. Furthermore, almost one in every hundred newborns is born with a congenitally malformed heart, and more than 90% of these now survive well into adulthood, albeit 10% to 18% of these have some form of pulmonary hypertension.⁴⁸ These are adults with congenitally malformed hearts and pulmonary hypertension, a combination which is quite complex. The number of these patients is already several-fold higher than the number with idiopathic pulmonary arterial hypertension. The patients with congenitally malformed

hearts require their own very specialised cardiopulmonary management.

Pathophysiological Considerations

The pulmonary vasculature is located haemodynamically between the right and left ventricles, with the two ventricles sharing the ventricular septum. This truism results in complex interactions. Damage to the arterial side of the pulmonary endothelium may be the result of shear stress due to pulmonary over-circulation in the setting of congenital interatrial communications, ventricular septal defects, or shunts at arterial level, or to the venous side in the setting of malformations that oppose the blood leaving the lungs, such as stenoses of the pulmonary veins, of the mitral and aortic valve and of the aortic isthmus. This last category includes hypoplasia and systolic and diastolic malfunction of the left heart. The pulmonary vasculature may also be congenitally hypoplastic, as in tetralogy with pulmonary atresia or pulmonary hypoplasia due to diaphragmatic hernia and so on, thus producing an intrinsically increased vascular resistance. In these pathophysiological situations, the pulmonary vascular resistance becomes a major factor influencing morbidity and mortality.⁴⁹ To estimate the risk of the development and progression of increased pulmonary vascular resistance in these circumstances, it is necessary to factor in the time, pressure, and volume with which the respective lesion is exerting its damaging stimulus to the pulmonary vasculature. Table 56-3 provides a classification of pulmonary hypertension in the setting of congenital heart disease.

Fontan Physiology

In those with the Fontan circulation, a small change in pulmonary vascular resistance will have an over-proportionate effect. This means that, while being too small to be measured, with the measurement in itself being a challenge, therapeutic reduction may result in palpable clinical benefits. The increase in pulmonary vascular resistance may be due to pulmonary factors or due to ventricular factors, such as disease of the left heart, that may be intricately entangled.

Pulmonary Vascular Resistance in the Child Prior to Operation or Transplantation

This should be low in the child submitted for a timely procedure, but should be measured later, particularly if

it cannot be measured accurately in the setting of large shunts, transposition, common arterial trunk, or atrioventricular septal defect. It correlates with the likelihood, as with transplantation, of post-operative pulmonary hypertensive crises or right ventricular failure.

Chronic Postoperative Pulmonary Hypertension

Successful surgery will reconstitute the normal haemodynamic sequence of flow into and out of the two ventricles. In this situation, it is reasonable to transfer most considerations regarding idiopathic pulmonary arterial hypertension. The congenital cardiac malformation itself, nonetheless, coupled with the length of time the pulmonary vasculature was stressed pre-operatively, along with the surgical interventions, increase the vulnerability to abnormal loading conditions and the likelihood of cardiac failure.

Left Heart Disease

This may cause pulmonary venous hypertension, which results in an over-reactive increase of pulmonary vascular resistance. The consequences of the ensuing right ventricular stress, with right ventricular dilation and hypertrophy, result in an important shift of the septum into the left ventricle, which again inhibits left ventricular function. Thus, although the original cause of pulmonary vascular resistance increase is left-sided, an acute test using vasodilators is justified to differentiate the amount of independent overshooting of pulmonary vascular resistance, which may justify pharmacological treatment to increase the overall ventricular performance and cardiac output.

Eisenmenger Physiology

In this setting, changes in pulmonary vascular resistance will not change right ventricular afterload. This is fixed and, by definition, at systemic level due to the large unrestricted shunt. Changes in resistance, nonetheless, will determine the ratio of systemic to pulmonary flows, and thereby the resulting saturation.

Tetralogy with Pulmonary Atresia

If the flow of blood to the lungs is multifocal, through major aortopulmonary collaterals that are mostly mechanically obstructed, as can occur in very cyanosed patients, any amount of successful reduction of pulmonary vascular resistance due to acute vasodilation or chronic

TABLE 56-3

CLASSIFICATION OF PULMONARY HYPERTENSION IN THE SETTING OF CONGENITAL CARDIAC DISEASE

Condition	Fontan Circulation	Pre-operative/ Transplantation	Post-operative	Left Heart Disease	Eisenmenger Physiology	Pulmonary Atresia
Resulting clinical problem of pulmonary vascular resistance elevation	Signs of right heart failure, low cardiac output	Post-operative or post-transplant right heart failure, excluding operation/heart transplantation alone	Increased right ventricular afterload ultimately with circulatory collapse and death	Reduced LV preload, septum pushed to the left ventricle; low cardiac output	Reduced transpulmonary flow of oxygenated blood, increased cyanosis	Less transpulmonary blood flow and pulmonary venous return and systemic oxygenation, increased cyanosis
Treatment aim	Reduced symptoms of right ventricular failure	Decreased likelihood of post-operative failure	Decreased RV afterload	Improved LV function and septum position	Increased peripheral saturation	Increased peripheral saturation
Indication	mPAP > 15 mm Hg, low CO	> 3–4 WU × m ² BSA	RP > 2/3 R _s low RV function	Low cardiac output	PVRI > SVRI saturation <82%–85%	Saturation <82%–85%
End point	mPAP or CO	WU × m ² BSA	mPAP or PVRI	CO, R/LVEDP	Saturation	Saturation

BSA, body surface area; CO, cardiac output; LV, left ventricular; mPAP, mean pulmonary artery pressure; PVRI, pulmonary vascular resistance index; R/LVEDP, right/left ventricular end-diastolic pressure; RP, pulmonary resistance; R_s, subsystemic resistance; RV, right ventricular; SVRI, systemic vascular resistance index; WU, Wood units.

vascular remodeling will clinically justify pharmacological treatment.

Measurement of Pulmonary Vascular Resistance in Congenital Cardiac Disease

Due to the now established early timing for surgical correction of many congenital cardiac lesions, the likelihood of increased pulmonary vascular resistance in the absence of other risk factors at this early time point is low, and can reasonably be neglected when considering surgery. Late presentation, or presentation without a history of pulmonary over-circulation and cardiac failure despite an unrestrictive shunt, would characterise the typical candidate in whom invasive evaluation of pulmonary vascular resistance is indicated.

The pulmonary vascular resistance is very important, but is not the only criterion on which depend the decisions for the type of cardiac surgery or transplantation, pharmacological treatment, or combinations thereof. The gold standard for obtaining such data remains cardiac catheterisation. This invasive method, however, is increasingly challenged by an increased perception of its risk, especially when compared to the non-invasive measurements and increasingly better and more sophisticated approximations that are provided by magnetic resonance imaging.^{50,51} Indeed, the measurement of pulmonary vascular resistance in the setting of congenital cardiac disease presents special challenges regarding the indication for catheterisation, the risk and protocol for anaesthesia, and the techniques of measurement and calculations for pulmonary vascular resistance at baseline and under maximum pharmacological pulmonary vasodilation.

While older patients and children may be catheterised under local anaesthesia, general anaesthesia is usually seen as the safer approach for neonates and infants. Its risk⁵² is increasingly perceived as prohibitive, and not justifying the value of the obtained data for clinical decision-making, especially in children in whom the dynamics of the process of disease tend to be more aggressive. As in all patients with increased pulmonary vascular resistance, the risk of general anaesthesia occurs specifically during the phase of induction, and during extubation. The risk is exacerbated by a weak clinical state, especially loss of weight, by specific episodes in the past, and by reduced right ventricular function. A steady state during the procedure, aided by continuous administration of agents to avoid haemodynamic variations, especially towards the end of the examination, is crucial. This should provide stable levels of carbon dioxide, and saturations near those achieved during spontaneous ventilation.

The calculation of pulmonary vascular resistance in the presence of shunts requires meticulous attention to achievement of a steady state, and the site of sampling. Multiple catheters may be used. Correct calculations require the inclusion of the dissolved oxygen into the calculation of the content of a blood sample, and measurement rather than estimation of oxygen consumption, this being especially important for cyanotic patients and candidates for Glenn or Fontan operations.^{53,54} The widely used solution of cancelling out the consumption of oxygen from the corresponding equations leads to the fact that flow of blood to the lungs and pulmonary vascular resistance are put in relation to their systemic counterparts, which makes pulmonary vascular resistance a function of systemic vascular

resistance. In this way, not only the individual measurements, but also comparisons between multiple catheterisations with the aim of comparing the effects of specific and pulmonary selective treatments, become unreliable.

The difference of mere pulmonary endothelial dysfunction, as opposed to fixed structural decrease and constriction of pulmonary vascular diameter, may be tested with inhalable or intravenous pulmonary vasodilators, providing maximum pulmonary vasodilation. Although, during the last 15 years, a multitude of substances and protocols have been developed for such evaluations and still exist, most institutions use a combination of oxygen and inhaled nitric oxide, nebulised iloprost, or combinations thereof.⁵⁵ If normal values are measured during baseline investigations or pulmonary vasodilation, then the surgical and peri-operative risk is assumed to be acceptably low. If, in the presence of increased values for pulmonary vascular resistance, the decrease of either pulmonary vascular resistance, mean pulmonary arterial pressure, or the ratio of pulmonary to systemic vascular resistance ratio exceeds 20%, the patient is considered a responder to pulmonary vasodilation, with the implication that the pulmonary vascular system still possesses endogenous vasodilatory capacity without perivascular fibrosis. This is associated with longer survival, and is an indication for treatment with calcium channel antagonists as an inexpensive therapeutic option.^{56,57}

Evaluation of Pulmonary Vascular Resistance Prior to Operative Intervention or Transplantation

In general, pulmonary congestion with cardiac failure in those with shunting defects within the first 3 months of life is taken by most as virtual absence of increased pulmonary vascular resistance. Absence of such an episode, or an age older than 12 months, indicates potentially increased pulmonary vascular resistance needing evaluation. The precise calculation of pulmonary vascular resistance is mandatory for patients considered for operations crucially relying on lowest possible pulmonary vascular resistance, such as creation of a Glenn shunt or conversion to the Fontan circulation.⁵⁸ As the results of operation and long-term follow-up depend so much on institutional skill and experience, clear data does not exist as a cutoff for when operation is possible as opposed to being contraindicated. It is customary to assume that values of less than 4 to 6 Wood units times m^2 body surface area, and ratios for pulmonary to systemic resistances from 0.25 to 0.3, indicate operability without the need for further testing using pulmonary vasodilators. Values of up to 7 to 10 Wood units times m^2 body surface area and ratios of resistances in the range of 0.4 to 0.5, are acceptable only if the testing with vasodilators achieves values unequivocally in the lower ranges given above. For those considered for Glenn or Fontan operations, still lower values are required, with less than 3 Wood units times m^2 body surface area and ratios of resistances of 0.2.

Treatment of Pulmonary Hypertension Associated with Congenital Cardiac Disease

Aside from the haemodynamic stressors, other factors such as arterial hypoxaemia in cyanosis, and hypercarbia in hypoventilation, as well as certain syndromes such as Down, Noonan's, and Edwards', are known to enhance or predispose for increased pulmonary vascular resistance. Whatever the precise pathogenetic stimulus, the pulmonary vasculature probably has a limited arsenal of different patterns to

react to it. Hence, the result is a uniform change of cellular and histological appearance of the pulmonary vasculature, as delineated by Heath and Edwards⁵⁹ or Wagenvoort,⁶⁰ beginning with pulmonary endothelial dysfunction, leading to intimal and smooth muscle cell hypertrophy in a complex vascular-adventitial interaction, and eventually ending in complete obstruction of the pulmonary vessel due to the formation of plexiform lesions. The speed of the increase of pulmonary vascular resistance, together with volume loading of the pulmonary circulation, then provides for the macroscopic effects on pulmonary arterial diameter, right ventricular dilation and hypertrophy, and eventually reduction of myocardial contractility. This relative paucity of patterns of reaction is probably the reason that most forms of pulmonary hypertension do react to the current specific options for treatment, which merely replace pulmonary endothelial factors and favour general vasodilation. No drugs yet in routine clinical use provide inhibition or reversal of cell growth. Treatment of the pulmonary vascular resistance is indicated in all those situations where increased flow to the lungs would result in an improvement in delivery of oxygen, or where reduction of the afterload to the right ventricle would increase cardiac output and decrease right-sided cardiac failure. There are also clear contraindications. These include defects permitting large shunts without an increased, and hence protective, pulmonary vascular resistance, and therefore without reduced pulmonary perfusion. In this setting, further pulmonary vasodilation would increase the pulmonary overcirculation and lead to cardiac failure. Pulmonary venous obstructive disease is another contraindication. Because the pulmonary venules in this setting are lined with obstructing non-dilating endothelial cells not reactive to pulmonary vasodilators, pulmonary vasodilation would only inhibit the protective pulmonary arterial capillary vasoconstriction, and thus lead to pulmonary oedema. Hypoplasia or reduced diastolic or systolic function of the left ventricle constitutes a further contraindication, because pulmonary vasodilation would overcome the protective increase in pulmonary vascular resistance and again lead to pulmonary oedema.

Neonatal Pulmonary Hypertension Due to Congenital Cardiac Disease

In some neonates, the high fetal pulmonary vascular resistance does not rapidly fall as is usually the case at birth. This may be due to endothelial and smooth muscle injury as a result of co-existent cardiac anomalies and increased flow of blood to the lungs. The resulting endothelial shear stress may cause alterations of the signaling pathways involving nitric oxide and endothelin, which precede anatomical changes and pulmonary vascular remodeling. In addition, changes in mediators such as transforming growth factor- β , vascular endothelial growth factor, and vascular potassium channels, as well as upregulation of collagens, have been noted in both animal models and children with congenital cardiac disease with increased flow of blood to the lungs.

Pulmonary hypertension in the presence of large unrestricted shunting in the setting of lesions such as the persistently patent arterial duct, transposition, and common arterial trunk is simply a consequence of communicating tubes, and will be corrected only by surgical treatment. There are a few lesions such as pulmonary hypertension

and cyanosis in transposition or Ebstein's malformation, where the use of inhaled nitric oxide may be indicated pre-operatively to enhance the flow to the lungs, enhance oxygenation, and normalise future post-operative right ventricular afterload. Surgical creation of an aortopulmonary shunt may be more effective if the increased pulmonary vascular resistance is due to general pulmonary vascular hypoplasia.⁶¹ In general, the earlier the indicated surgery is performed, the less persistent will be the damage to the pulmonary endothelium and vascular tree. Besides timing, surgical and neonatal intensive care experience will decide on the need for a corrective as opposed to a palliative approach. In doubtful cases, leaving or creating an atrial shunt to bridge the peri-operative period may be useful, the shunt being closed interventionally at a later date.

Acute Post-operative Pulmonary Hypertension

This transient clinical and pathophysiological condition can result from cardiopulmonary bypass surgery. The activation of inflammatory pathways occurs in all organs, with specific problems in each. In the lung, it leads to, and augments, any pre-existing pulmonary endothelial dysfunction. Especially in neonates and infants, but also in larger children, important bronchomechanical interactions exist so that the fluctuations in pulmonary vascular resistance post-operatively have a direct impact on lung compliance and gas exchange. In the high-risk patient, these make the meticulous monitoring of both haemodynamic and pulmonary mechanical parameters mandatory so as to achieve optimal clinical management.

Following cardiopulmonary bypass operations, the pulmonary vascular system experiences for a few days or longer an increase in resistance and sensitivity to vasoconstrictive stimuli. The resistance can be lowered by supplementation of elements from the L-arginine-nitric oxide pathway, and by blockade of the endothelin receptors, suggesting a combined pathophysiology of different pathways as a cause. This pathophysiology persists for several days, making the lung very vulnerable to different stimuli such as handling, suctioning, movement, and hypoventilation. Such stimuli are answered within seconds with an exponential, and very dangerous, life-threatening pulmonary vasospasm. This is the so-called pulmonary hypertensive crisis, which results in a sharp increase in pulmonary vascular resistance and pulmonary arterial pressure, acute right ventricular decompensation with raised central venous pressure, decreased pulmonary blood flow with cyanosis, and left atrial and systemic hypotension (Fig. 56-2A). In infants and young patients, this phase is directly associated with a decrease in lung compliance (see Fig. 56-2B), hypoventilation, hypercarbia, and further pulmonary vascular restriction, producing a vicious circle which can only be interrupted by manual forced and energetic hyperventilation, and which may require other immediate measures aimed at resuscitation. This bronchopulmonary interaction has also been described elsewhere, such as in the variation of both pulmonary compliance and flow of blood to the lungs, and asthma in pulmonary hypertension.

The incidence of life-threatening pulmonary hypertensive crises has markedly decreased, from around 20% of cases in the 1980s to only 1% to 2% 25 years later. This

Figure 56-2 A, Original haemodynamic pressure tracing of a pulmonary hypertensive crisis, which resolved with the prompt administration of inhaled nitric oxide (inh. NO). The sharp increase of the pulmonary arterial pressures (lower half of the panel, upper tracing) is accompanied by systemic hypotension (upper half of panel) and an increase of central venous pressure as a sign of acute right heart decompensation (lower half of panel, lower tracing). The situation reverses promptly within less than a minute upon inhalation of 20 ppm nitric oxide. B, The bronchopulmonary interaction during such a pulmonary hypertensive crisis. The rise and fall of mean pulmonary arterial pressure (mPA) is accompanied by reverse changes in dynamic lung compliance, in response to the unsuccessful attempt to wean from inhaled nitric oxide (5 ppm) and the decision to recommence the inhalation.

reflects better techniques for surgical repair, cardiopulmonary bypass, post-operative handling, mechanical ventilation, and most importantly, timely operation before the sixth month of life. The pathophysiology nevertheless remains relevant for complex patients, particularly for those with the Fontan circulation. While the basic strategies for avoidance include alkalotic hyperventilation, sedation and paralysis, and sometimes also hypothermia, advanced strategies such as extracorporeal membrane oxygenation are only indicated for bridging a situation that may be expected to recover. Such situations are the post-operative inflammation-related increase of pulmonary vascular resistance, and depressed left or right ventricular function. Other strategies include negative pressure ventilation, ventilation with nitric oxide, and use of specific pulmonary antihypertensive drugs, such as the intravenous or inhaled use of the nucleotide adenosine, the phosphodiesterase 5 inhibitor sildenafil, the calcium channel sensitizer levosimendan, and the endothelin receptor antagonist tezosentan.

Chronic Post-operative Pulmonary Hypertension

The patient in this setting will have a surgically corrected, normal circulation without significant residual shunting defects or obstructions. Pulmonary vascular resistance is increased most likely due to the persisting pre-operative pulmonary vascular damage, as well as the effects of cardiopulmonary bypass surgery. Any left-sided component, such as pulmonary venous stenosis, mitral valvar

obstruction or regurgitation, or left ventricular restriction, should clearly be recognised as such, and may warrant cardiac catheterisation to reveal the attributable increase in pulmonary vascular resistance, thus differentiating the increase from the independent overshooting reaction of the arterial pulmonary vascular tree, with the latter potentially accessible to pharmacological treatment.

It is important to make sure that patients and physicians understand that this form of pulmonary hypertension is not idiopathic. It may be stable, regress over time, or progress gradually and then require careful monitoring of cardiac function, which may be more vulnerable because of the surgical repair. The strategies for such treatment are similar to those for idiopathic pulmonary hypertension. This includes the use of anticoagulation, calcium channel blockers, balloon atrioseptostomy, and all specific drugs including phosphodiesterase 5 inhibitors, endothelin receptor antagonists, and intravenous epoprostenol. The reaction to these drugs is probably similar.

Pulmonary Hypertension Due to Left-Sided Cardiac Anomalies

Left-sided obstructions to flow of blood from the lungs includes pulmonary venous stenosis, divided left atrium, mitral valvar stenosis or regurgitation, and left heart systolic or diastolic dysfunction, either without or due to aortic stenosis or coarctation. The increased pressure upstream from the obstruction causes dilation of the involved structures, in

other words, the pulmonary veins. Increases in pulmonary venous pressure directly translate into increases of pulmonary arterial pressure, while the transpulmonary gradient, and thus the calculated pulmonary vascular resistance, remains low. Invasive measurement of pulmonary venous pressure or left ventricular end-diastolic pressure, respectively, is necessary, and then calculation of the transpulmonary gradient and pulmonary arterial vascular resistance.

If the lesion is longstanding, the arterial side of the pulmonary vascular tree will react to this increased pressure and develop increased pulmonary vascular resistance via the cellular mechanisms described for idiopathic pulmonary hypertension. This may overshoot and increase out of proportion. The continuing increase of pulmonary vascular resistance will cause an increase of right ventricular diameter, with septal shift into the left ventricle, and reduced cardiac output due to right ventricular failure as described for idiopathic pulmonary arterial hypertension.

Treatment of this form of pulmonary hypertension is only warranted if the primary condition is optimised as far as possible, and invasive demonstration has shown, first, that cardiac output is reduced due to increased pulmonary vascular resistance and, second, that reduction of pulmonary vascular resistance results in improved cardiac output without any increase in pulmonary venous pressure. If the left-sided obstruction is relieved temporarily or chronically by pharmacologic treatment, corrective surgery, or assist devices, the pulmonary vascular resistance may normalise instantly or over a longer time span. In patients with end-stage left-sided cardiac failure, the long-term administration of inotropic agents, or the implantation of ventricular assist devices, to off-load the left ventricle is an accepted and often successful option to permit normalisation of the increased pulmonary vascular resistance and allow for transplantation of the heart in isolation. Unfortunately, the pulmonary hypertension due to pulmonary venous stenosis or mitral valvar disease may persist tenaciously due to the impossibility of completely relieving the lesion surgically or interventionally, this being a far from rare situation.

Fontan Circulation

The serial Fontan circulation amplifies the interdependence of all its circulatory elements. The flow of blood into the thorax and pulmonary vasculature is augmented during inspiration by negative intrathoracic pressure, while the flow of blood out of the thorax is supported by the diastolic function of the systemic ventricle. For both of these mechanisms to function, it is vital to retain as low a pulmonary vascular resistance as possible. Even a mild increase in resistance has an appreciable influence on the Fontan circulation, and leads to its failure. Several factors, with some of them being part of the Fontan state itself, may lead to an increase of pulmonary vascular resistance and reduction on the flow of blood to the lungs.

Anatomical and Mechanical Factors

These include small pulmonary arteries, the presence of stenoses, discontinuous pulmonary arteries, and distal abnormalities of arborisation, all of which increase the pulmonary vascular resistance. The detrimental effect of paralysis of the diaphragm on the dynamics of flow in the Fontan circulation has been clearly demonstrated.

Pathophysiological Factors

Too little flow, or too much flow, can result in either a hypoplastic pulmonary arterial tree or, as a reaction to the additional left-to-right flow, an increased medial thickness of the pulmonary arterioles. Both factors elevate pulmonary vascular resistance, and both have an unknown chronic time course.

Pulmonary Arterio-venous Malformations

These channels occur in around one-sixth of patients, bypassing the exchange of gases by connecting the arterial side directly to the venous side of the pulmonary vasculature. These vessels may be large and allow a right-to-left shunt at low resistance as cyanotic admixture to the systemic blood in patients with increased pulmonary vascular resistance, or in those with previous Glenn operations, where the flow of venous blood from the lower body, including the hepatic contribution, remains connected to the heart, thus bypassing the lung.

Pulsatility of Pulmonary Flow and Pulmonary Endothelial Dysfunction

Pulsatility is greatest in those patients having an atriopulmonary connection. In contrast, the pulsatility is almost lacking in patients with a lateral tunnel or total cavopulmonary connection, causing persistent pulmonary endothelial dysfunction, which can be shown by inhalation of nitric oxide to provoke a fall in pulmonary vascular resistance.⁶² Even in those with pulsatile flow, the mean pulmonary arterial pulse pressure is lower than normal.

Reduced Growth of the Pulmonary Arteries

There is insufficient growth of the pulmonary arteries in relation to growth of body surface area over an observation period of 3 to 5 years. This may be due to early reduction of volume from staged cavopulmonary anastomosis to prevent ventricular volume overload and preserve systemic ventricular function. The reduction of pulmonary flow, and early introduction of non-pulsatile flow in the pulmonary circulation, may also affect the growth of the pulmonary arteries.

Micro- and Macro-thromboses in the Pulmonary Circulation

For several reasons, the Fontan patients are at increased risk for the formation of silent or clinically apparent macro- and micro-thrombus, namely, the low, non-pulsatile systemic venous flow, the thrombogenic material of the conduit itself, and altered hepatic function due to the Fontan state.⁶³ The threat of pulmonary thromboembolism to a pulmonary circulation with already decreased overall diameter is clear from the experience of increased mortality in such patients with idiopathic pulmonary hypertension, and justifies effective anticoagulation.

Reduced Ventricular Function after the Fontan Operation

The acute reduction in preload resulting from the Fontan operation leads to an increase in the ratio of ventricular mass to volume ratio, with concomitant impaired ventricular relaxation and patterns of filling.⁶⁴ Although this hypertrophy has been shown to regress 1 to 3 years after surgery, the abnormal ventricular relaxation and reduced ventricular compliance persist over the long term. A progressive increase in ventricular stiffness, which naturally occurs with age, could also potentially contribute to a steady rise in pulmonary venous pressure, with ensuing increase of pulmonary vascular resistance.

In the attempt to modulate therapeutically pulmonary vascular resistance in patients with the Fontan circulation,

both inhaled nitric oxide and the phosphodiesterase inhibitor sildenafil have been used successfully in the acute post-operative setting. Sildenafil was also used for chronic problems like protein-losing enteropathy,⁶⁵ improving diastolic mesenteric blood flow, exercise tolerance, pulmonary arterial pressure and pulmonary vascular resistance, and plastic bronchitis, with similar effects as the use of fenestrated stents.⁶⁶ Improvement was also reported after treatment with bosentan, an antagonist of endothelin receptors. Although the occurrence of these complications over the long term is correlated in some but not all patients with an increase in pulmonary vascular resistance and central venous and pulmonary arterial pressures, the clinical success of targeted pharmacological modulation of the pulmonary circulation indicates that there may be a role for such treatment on a broader basis, if not even in an anticipatory prophylactic way.

Eisenmenger Syndrome and Its Pathophysiology

Anatomy

The strict definition of Eisenmenger's syndrome as severe systemic cyanosis due to reversal of the shunting at atrial, ventricular or great arterial level theoretically excludes the settings of common atrium and anomalous pulmonary venous drainages, functionally single ventricle, and common arterial trunk, as the cyanosis in these lesions is not a result of shunt reversal, but of obligate intracardiac mixing of desaturated and oxygenised blood. Such considerations are important for proper management. Practically however, the working definition does include the latter diagnoses, and implies inoperability due to suprasystemic pulmonary vascular resistance.^{67,68}

The natural history of Eisenmenger's syndrome is quite variable, but eventually leads to severe hypoxaemia, cyanosis, and cardiac failure. In one study, half of a cohort of patients with unrepaired ventricular septal defect was alive 20 years after the diagnosis was made.⁶⁹ Other symptoms include progressive shortness of breath, polycythaemia, headache, and haemoptysis. Therapeutic options are limited, and include supplemental oxygen therapy, anticoagulation, vasodilator therapy, and endothelin receptor antagonists.^{70–76} There is some controversy about the impact of the drugs. Lung and heart-lung transplantation may be offered with an acceptable risk, and a favourable long-term outcome.⁷⁷ Oral contraceptives should be prescribed for females, as pregnancy in such patients has a high incidence of maternal and perinatal death.⁷⁸

While the process is usually interrupted with early surgical correction of the shunting lesion, it may progress in those undergoing late correction. In such cases, a haemodynamic situation similar to idiopathic pulmonary arterial hypertension will result. In cases of significant residual defects, right-to-left shunting can occur, with establishment of the syndrome in a patient who earlier underwent successful surgical correction in the absence of pulmonary vascular disease.

Pathophysiology

The effect of the shunt depends on its exact location and size. This can cause different loading conditions, both to the pulmonary vascular tree and the subpulmonary ventricle, with specific morbidity and mortality.

Atrial Level

The defects with shunting at atrial level deliver large volumes of blood without pressure, causing shear stress to the pulmonary endothelium. In the case of abnormally draining pulmonary veins, the shunt is fixed by the abnormal connection, and only indirectly reflects increasing pulmonary vascular resistance by a reduction of pulmonary flow. In the case of interatrial communications, the left-to-right shunt correlates with the strength of right ventricular systolic opening pull, and right atrial and ventricular diastolic compliance. Due to the continuous venous flow, the shunted volume can be huge, and causes right ventricular dilation. The increase of the pulmonary vascular resistance in the third and fourth decades stretches still further the right ventricular myocytes so that they do not cope well with the increasing afterload, and tend to fail early. The Eisenmenger pathophysiology with cardiac cyanosis is then a result of the atrial right-to-left shunting due to right ventricular failure, and only indirectly due to increased pulmonary vascular resistance.

Ventricular Level

These defects deliver volume and, depending on their restrictive or unrestrictive size, also left ventricular pressure. In systole, and only then, the direction and volume of the shunt is directly ejected into the great arteries, and depends on the ratio of pulmonary to systemic resistance and the ejecting power of the ventricles, ending with closure of the arterial valves. In early and late diastole, there may be different directions and volumes of the shunt depending on ventricular compliance, thus explaining the angiographic and haemodynamic findings of left-to-right shunting during systole and right-to-left shunting in diastole in the presence of a hypertrophied and stiff right ventricle. In an atrioventricular septal defect, the addition of atrial shunting contributes also a volume load, causing ventricular dilation.

In the case of a large defect, the high pressure postnatally maintains a high, near-systemic pulmonary vascular resistance, avoiding severe cyanosis or loud heart sounds, but also avoiding a period of cardiac failure which would stimulate a diagnosis. The cyanosis may not be marked, and may be discovered only later, when pulmonary vascular resistance becomes suprasystemic. Both right and left ventricles deliver blood to both great arteries and thus see the same afterload and work as one unit.^{79,80} The peripheral saturation of oxygen is a function of the ratio of pulmonary to systemic flows. Pharmacologically induced pulmonary vasodilation to augment pulmonary venous return may counteract severe cyanosis, but may be hazardous to the oft-compromised myocardial function.

Arterial Level

In the setting of transposition physiology, cyanosis is due to interatrial and intraventricular streaming and morphology, which impairs mixing so that desaturated systemic venous blood enters the subaortic ventricle or the aorta, and pulmonary venous blood returns to the subpulmonary ventricle or the pulmonary artery while pulmonary vascular resistance is low. Saturation can then only be increased anatomically by either separating the atriums in the case of common atrium and anomalously connected pulmonary veins, or in the case of transposition, by creating a left-to-right shunt at atrial level.

All lesions with arterial shunting deliver the shunt flow at systemic pressures to the pulmonary vascular tree continuously during both systole and diastole. They are associated, therefore, with an early and aggressive rise in the pulmonary vascular resistance. Below a certain size, the exact diameter of the defect does matter, and the Eisenmenger syndrome will not be manifest. That threshold appears to be from 2 to 3 cm at atrial level, limiting the ratio of pulmonary to systemic flows to four- to sixfold, and from 1 to 1.5 cm at ventricular level, limiting the ratio to three- or fourfold. The size at arterial level is from 0.5 to 0.7 cm. If the septum is almost entirely missing, as in common atrium, and in those with functionally single ventricles or common arterial trunk, there is complete mixing of the venous and arterialised blood. The resulting saturation is a function of the ratio of pulmonary to systemic flows, and is equal in both great arteries, with univentricular cardiac function. Uncorrected defects of medium size, or residual defects which are neither restrictive nor univentricular, produce a classical Eisenmenger syndrome, where the degree of cyanosis depends on pulmonary vascular resistance.

Differences between Idiopathic and Congenital, Cardiac-Disease-associated Pulmonary Arterial Hypertension

Known Trigger

In contrast to those with idiopathic pulmonary arterial hypertension, the cause for the development of increased pulmonary vascular resistance in patients with congenitally malformed hearts is well known and monitored. In some groups, however, the increase in pulmonary vascular resistance seems to be out of proportion to the stimulus, such as in children with small, persistently patent arterial ducts or insignificant interatrial communications, and in those who have undergone timely correction of transposition.^{81–83} It is as yet unclear whether these patients have a latent form of idiopathic pulmonary arterial hypertension, which was triggered by these defects.

Different Dynamics

Those with idiopathic pulmonary arterial hypertension have a broad range of age, with the problem occurring as late as the seventh decade, or as early as the first months of life. The paediatric form shows an aggressive course, which only recently has been modified by available pharmacological treatment.^{84–86} In contrast, the development of increased pulmonary vascular resistance in those with congenitally malformed hearts is more predictable, being avoidable by surgical correction at less than 6 months of life, and showing stability over decades in those with the Eisenmenger syndrome.

Right Ventricular Function

When given time, the morphologically right ventricle can adapt to a large extent to increased afterload, and will maintain cardiac output until contractility decreases, at which time the ejection period, stroke volume, and peak systolic pressure correlate with contractility. Morbidity and increased mortality^{87–89} are seen when the ventricle is congenitally malformed or surgically altered, with direct effects on the pattern of contraction.

DIAGNOSIS OF PULMONARY HYPERTENSION

Presenting Symptoms

Pulmonary hypertension may be asymptomatic in early stages, but dyspnoea with exertion that progresses over months is the most frequent symptom. Chest pain, syncope, and oedema of the legs may become evident with more severe pulmonary hypertension and impaired right ventricular function. Classifying the limitations in exercise is aided with help of the classification provided by the World Health Organization for clinical severity (see [Table 56-2](#)).

Physical Findings

A loud second heart sound is present in most patients with elevated right-sided pressures. Murmurs due to tricuspid regurgitation and pulmonary flow may also be heard. With progression of the disease, jugular venous distension, hepatomegaly, peripheral oedema, and ascites become evident.

Chest Radiography

Typically the central pulmonary arteries are enlarged and the right ventricle is dilated. In addition, there are diminished peripheral pulmonary vascular markings. The presence of underlying conditions, such as interstitial lung disease, may become apparent on the chest film ([Fig. 56-3A](#)).

Electrocardiogram

In most patients the electrocardiogram demonstrates right-axis deviation, right atrial enlargement and right ventricular hypertrophy with strain, but the sensitivity and specificity are low. A minority of patients with pulmonary hypertension have a normal electrocardiogram.

Six-minute Walk Test

This test has been used as submaximal exercise test, and as a surrogate marker of physical function. The test is useful for longitudinal follow-up, and to monitor response to treatment.⁹⁰ Its disadvantages include its subjective nature, and that cooperation and motivation greatly affect results.⁹¹ Currently, nonetheless, the test is approved by regulatory bodies such as the U. S. Food and Drug Administration as an endpoint for prospective clinical trials in patients with pulmonary hypertension.

Cardiopulmonary Exercise Testing

Over the past years, this form of testing became an additional tool to evaluate patients with pulmonary hypertension.⁹¹ The test includes monitoring of the electrocardiogram and blood pressure, as well as measurement of consumption of oxygen, production of carbon dioxide, and minute ventilation. A change in exercise capacity seems to match other factors of severity, such as survival, haemodynamics, and time to clinical worsening.

Figure 56-3 A, Chest radiograph from a 16-year-old patient with pulmonary hypertension shows mild cardiomegaly with dilated central pulmonary vessels and increased interstitial markings in both lungs. B and C, Computed tomogram from the same patient reformatted in axial and coronal plane show ground-glass appearance with a mosaic pattern. The pulmonary arteries in the mediastinum are markedly dilated. Note the diffusely thickened interlobular septa. The thickened septa in the peripheral lungs extend to the pleural surface. The central pulmonary veins were all unobstructed. There is mediastinal oedema. These findings are classic features of pulmonary veno-occlusive disease.

Echocardiography

The hallmark of non-invasive diagnostic imaging for pulmonary hypertension is transthoracic echocardiography. Structural cardiac disease can be diagnosed or excluded, and enlargement of the right atrium, right ventricle and pulmonary arteries may be visualised. In addition, right ventricular function can be assessed. Doppler echocardiography allows estimating the right ventricular systolic pressure by assessing the tricuspid regurgitant jet. Echocardiography fails, however, to detect a measurable tricuspid regurgitant jet in a significant number of patients at high risk, and the absence of the jet does not rule out the presence of severe pulmonary hypertension.⁹² Indirect signs of pulmonary hypertension are paradoxical ventricular septal movement, and a decreased or absent collapse of the inferior caval vein. Functional testing involves description of the dimensions and systolic performance of the right ventricle. Size indexed for body surface area should be evaluated in children. Tissue Doppler

imaging is able to demonstrate abnormal diastolic and systolic right ventricular function, as well as left ventricular diastolic function. In adults, only right ventricular dysfunctions seem to correlate with pulmonary arterial pressures.⁹³

Ventilation-perfusion Lung Scintigraphy

Ventilation-perfusion scintigraphy has high sensitivity and specificity to detect embolic disease, and can reliably differentiate between large-vessel occlusive disease and small-vessel pulmonary vascular disease.^{94,95}

Computed Tomography

Findings on computed tomography include cardiomegaly with right-sided cardiac enlargement, enlargement of the central pulmonary arteries, and possible bronchial compression. Major intrapulmonary characteristics are

peripheral vasculopathy, with enlarged tortuous vessels and ground-glass centrilobular opacities.⁹³

Magnetic Resonance Imaging

Phase-contrast magnetic resonance measurements of flow in the pulmonary trunk seem to correlate with haemodynamic changes, and the average velocity throughout the cardiac circle appears to mirror the pulmonary pressures and resistance.⁹⁶ In patients clinically known to have pulmonary hypertension, the cardiac magnetic resonance imaging ratio–derived left ventricular septal-to-free wall curvature was an accurate and reproducible index for estimation of right ventricular systolic pressure if compared to measurement at right heart catheterisation.⁹⁷

Cardiac Catheterisation

Catheterisation of the right heart remains the gold standard for diagnosis of pulmonary hypertension, but the procedure for patients with advanced pulmonary vascular disease carries some risks.^{52,98} Right atrial pressure, pulmonary arterial pressures, pulmonary capillary wedge pressure, systemic blood pressure, and mixed venous saturation should be routinely assessed.⁹⁹ Cardiac output is determined by thermodilution, or estimated with the modified Fick technique,^{100,101} but measurement rather than estimation of oxygen consumption is recommended. Pulmonary vascular resistance, in Woods units times m² body surface area, is calculated as mean pulmonary arterial pressure minus pulmonary capillary wedge pressure or left atrial pressure divided by cardiac output. Testing with a short-acting vasodilator allows detection of the remaining potential of reactivity of small pulmonary arteries and arterioles, or demonstrates fixed resistance. Younger children at the time of diagnosis tend to have a more positive response to acute testing, but there is significant variability.⁸⁴ Currently, a significant response to acute pulmonary vasodilator testing is defined as a reduction of mean pulmonary arterial pressure of more than 20% without an increase in cardiac output.

Lung Biopsy

Nowadays this procedure is rarely indicated. In some instances, histopathology may establish the diagnosis of vasculitis, pulmonary veno-occlusive disease, or pulmonary capillary hemangiomatosis.¹⁰² The most important limitation of an open lung biopsy is the high risk of mortality during anaesthesia and the surgical procedure.

Genetics

A gene responsible for familial pulmonary hypertension has been found on chromosome 2.¹⁰³ The familial form of idiopathic pulmonary hypertension accounts for 5% of all cases. The presentation is usually at younger age. Mutations of the bone morphogenetic receptor 2 gene have been identified in approximately half of patients with the familial form, and in up to 30% of sporadic cases.^{104,105} In affected families, half of the siblings or children of patients with the mutation in the familial form have an overall risk of inheriting the gene.¹⁰⁶ In about 30%, however, no mutations can be identified by existing strategies for screening.¹³

Carriers with pulmonary arterial hypertension present approximately 10 years earlier than non-carriers, and have more severe haemodynamic compromise at diagnosis.¹⁰⁷ Children with mutations of the bone morphogenetic protein 2 gene are less likely to respond to acute vasodilator testing than mutation-negative patients, and they also seem to have a more severe disease at diagnosis.¹⁰⁸ According to current guidelines, genetic testing and professional counseling should be offered to relatives of those patients with familial disease. Prenatal testing has not been reported.¹⁰⁹ Pulmonary hypertension may also be found in association with hereditary haemorrhagic telangiectasia, which can be caused by mutation in the ALK1 gene.¹¹⁰

INTERVENTIONAL AND SURGICAL THERAPIES

Balloon Atrial Septostomy

This procedure is indicated in children with the idiopathic form who are suffering from syncope and/or severe right-sided cardiac failure.^{111,112} Careful selection is warranted, as patients with severe right-sided cardiac failure and markedly elevated pulmonary vascular resistance may not tolerate atrial septostomy, the ensuing massive right-to-left shunting potentially resulting in insufficient flow of blood to the lungs and severe hypoxaemia. Puncture of the atrial septum, nonetheless, and subsequent dilations with balloons of increasing diameter, has been shown to relieve symptoms of pulmonary hypertension by increasing systemic flow and reducing right ventricular preload, with improvement of cardiac index and functional class.¹¹³ The incidence of spontaneous decrease in the size of the defect created is relatively high, but insertion of fenestrated devices may help ensure indefinite patency of the atrial communication.

Potts Shunt

In this surgical procedure, which was originally designed to augment blood flow to the pulmonary artery tree, the left pulmonary artery is anastomosed to the descending aorta, permitting the desaturated blood to run from the left pulmonary artery to the lower part of the body.¹¹⁴ Its purpose is to decrease right ventricular afterload, leading to improvement of right ventricular function, and potential prevention of syncope and sudden death.

Transplantation

It is patients with end-stage pulmonary hypertension, in NYHA classes III and IV who are no longer responding to maximal pharmacological therapy who are generally considered for transplantation. Combined heart-lung transplantation is offered to patients with Eisenmenger's syndrome, albeit that transplantation of both lungs, with repair of the intracardiac defect, may also be considered. Survival at 5 years after transplantation of the heart and lungs has been lower, at around 40%, than that after transplantation only of both lungs, at around 45%.¹¹⁵ Most centres prefer to transplant both lungs, rather than a single lung, because of the mismatch between ventilation and perfusion that can occur both early from ischaemic reperfusion injury, and later during any rejection of the lung. The timing of transplantation is challenging because of the

shortage of organs and the length of the waiting list, but referral to the transplantation team for an initial evaluation is indicated with the initiation of intravenous or subcutaneous prostanoid therapy. Contra-indications include significant extrapulmonary disease, notably renal failure or neurologic conditions, active and uncontrolled extrapulmonary infection, active or recent malignancy, and active infection with the human immunodeficiency virus.

PHARMACOLOGICAL AGENTS

Oxygen

There is currently no consistent data for the effects of long-term treatment with oxygen for patients with pulmonary hypertension. Supplemental oxygen is recommended for patients with chronic hypoxaemia in order to prevent systemic saturations falling below 90%.^{116,117} There seems to be a trend towards improved survival for children with Eisenmenger's syndrome receiving long-term treatment with oxygen,¹¹⁸ whereas in a controlled study, nocturnal administration of oxygen had no effects on haematology, exercise capacity, and quality of life.⁷⁵

Oral Anticoagulation

The benefit of oral anticoagulation has never been documented in a prospective randomised trial.¹¹⁹ The treatment is based on postmortem observations of embolic thrombosis in small vessels of patients with proven pulmonary hypertension.^{109,120} The targeted international normalised ratio in anticoagulated patients varies between centres in North America, aiming at ratios between 1.5 and 2.5, and those working in European centres, who aim at 2.0 to 3.0.^{116,117} A lower ratio should be considered for very active children and toddlers because of the higher risk of bleeding complications. There is conflicting data on anticoagulation in Eisenmenger patients, as they are at increased risk of haemoptysis.

Calcium Channel Blockers

These agents inhibit the influx of calcium into vascular smooth muscle cells, and accomplish pulmonary vasodilation. A number of uncontrolled studies have suggested that long-term treatment with such agents given in high doses improves haemodynamics, relieves symptoms, and prolongs survival in children and adults with pulmonary hypertension.^{57,84} Only around 40% of children, however, show an acute response during vasodilatory testing in the cardiac catheterisation laboratory, and thus would qualify for chronic therapy.⁸⁴ Side effects of treatment include systemic hypotension, tachycardia, shortness of breath, and pulmonary oedema. This therapeutic option is now less used subsequent to the introduction of more targeted drugs.

Prostanoids

Prostacyclin and its analogues play a pivotal role in the treatment of pulmonary arterial hypertension, the approach being supported by the known imbalance of thromboxane A₂ to prostacyclin metabolites in patients with pulmonary hypertension.^{121,122} Options for administration include

continuous intravenous, continuous subcutaneous, oral, and inhaled applications.

Intravenous Epoprostenol

This agent, when given chronically, improves exercise capacity, haemodynamics, and survival in children with pulmonary arterial hypertension^{84,123–125} and is still the most effective substance.¹²⁶ This therapeutic pathway usually requires a placement of a permanent central line, and continuous infusion using a small ambulatory pump. The half-time is less than 6 minutes. Major side effects include flushing, hypotension, headache, and jaw and musculoskeletal pain.

Subcutaneous Prostacyclin Analogues

Treprostinil is a stable prostacyclin analogue, with a similar pharmacological spectrum to epoprostenol but with a significantly longer half-time of 3 to 4 hours. It has been shown to be effective in adults,¹²⁷ but data in children is still sparse.¹²⁸ The drug is usually delivered subcutaneously through the abdominal wall using a portable infusion pump. This limits the use to older children with enough subcutaneous fat, as the development of dermal irritation, or pain at the site of infusion, is frequent. Other side effects are similar to those for epoprostenol.

Oral Prostacyclin Analogues

Beraprost is the first orally active analogue, albeit only approved for treatment of the idiopathic form of the disease in Japan. After oral administration, peak concentrations are reached after 30 minutes. There are two randomised controlled trials using beraprost.^{73,129} In the first trial, patients were randomised to receive the maximal tolerated dose of beraprost or placebo for 12 weeks. The agent improved exercise capacity, particularly in patients with idiopathic arterial pulmonary hypertension, while those with associated conditions showed no significant changes. There were, however, no relevant beneficial effects in cardiopulmonary haemodynamics or functional class. The second trial studied the long-term effects of beraprost up to 1 year. During the earlier phases of treatment, the data suggested less progression of the disease, with the effect persisting up to 6 months, but then attenuating with time. After 1 year, there were no longer any differences between the patients receiving beraprost and those having the placebo. Beraprost, therefore, does not play any crucial role in the treatment of pulmonary arterial hypertension related to congenital cardiac lesions and Eisenmenger's syndrome.

Endothelin Receptor Antagonists

The endothelin system has long been implicated in the pathogenesis of pulmonary arterial hypertension.^{130–132} It has been shown that antagonism of endothelin receptors improves exercise tolerance, pulmonary haemodynamics, right ventricular hypertrophy, and survival. Other favourable effects are the reduction of pulmonary fibrosis and the remodeling of pulmonary arteries.^{133–137} Side effects include flushing, peripheral oedema, both found in less than 10% of patients, and elevations in hepatic function tests, observed

in about 3% of children.^{138,139} Currently there are three different oral antagonists available for treatment, namely bosentan, which has an almost equal affinity for both endothelin receptors, sitaxsentan, a selective antagonist of endothelin receptor_A, and ambrisentan, also a selective antagonist of the A receptor. Several reports have demonstrated the benefits of therapy in children.^{138–141} Most of the current knowledge is based on experience with bosentan, with information related to sitaxsentan and ambrisentan mostly gained from experience with adults.^{135,142,143}

Phosphodiesterase Inhibitors

This class of drugs inhibits the degradation of cyclic guanosine monophosphate, the second messenger of nitric oxide, by interacting with different subclasses of phosphodiesterases, thus prolonging the effect of endogenous nitric oxide. The currently used sildenafil was developed from its precursor zaprinast, and has a 20-fold higher specificity for phosphodiesterase type 5, which is the subtype acting mainly in the lung. Sildenafil has been studied most often, and may be seen as the prototype of this class of drugs. It has immediate effects when given intravenously, and reaches a maximum after 30 to 45 minutes when given by the usual oral route. It is effective in the short and long term, in infants, adolescents, and adults, immediately post-operatively, and when used chronically. It increases 6-minute walking distance, decreases pulmonary vascular resistance,^{144,145} and has remodelling effects on the right ventricle and pulmonary vasculature. Tadalafil is a next-generation phosphodiesterase inhibitor, with even more specificity to phosphodiesterase type 5, and a half-life of 17.5 hours. Udenafil is a newer agent, with a half-life of 34 hours.¹⁴⁶ These substances not only have pulmonary preference as compared with their systemic effect, but also an intrapulmonary selectivity for the ventilated areas. They seem to have some inotropic properties.^{147–149}

Combination Therapy

Over the last decade, three classes of substances—prostanoids, endothelin receptor antagonists, and phosphodiesterase 5 inhibitors—have been more closely examined by randomised placebo-controlled trials to prove their beneficial effects.^{136,150–156} As these substances act by different modes of action and through different intracellular pathways, it might be expected that combining them would exert synergistic effects, albeit that they can also interfere pharmacologically. For example, when sildenafil and bosentan are combined in individual patients, sildenafil is cleared mostly by hepatic metabolism, predominantly by the P450 enzyme CYP3A4. Bosentan, however, is a known inducer of CYP3A4, as well as a substrate for the enzyme. Thus, steady-state concentrations of sildenafil in the presence of bosentan are 50% lower after 3 to 5 days, probably because of induction.¹⁵⁷ The levels of bosentan, nonetheless, increase in both unaffected people and patients. A recent study assessing the effect of addition of bosentan to existing epoprostenol therapy showed a stronger haemodynamic effect, albeit one which did not translate into clear differences in clinical exercise, functional class, or survival.¹⁵³

Currently, there are two approaches to combination therapy. The first is to start monotherapy with an active

substance, and to add a second substance when predefined treatment goals are not met. The alternative concept is immediately to start combination therapy, following the principle to hit hard and early. Despite such advances, pulmonary arterial hypertension remains incurable. Although long-term improvement or stabilisation can be achieved, at least with epoprostenol or bosentan, the idiopathic form remains a progressive disease, and deterioration eventually occurs in a substantial proportion of patients. In two recent studies in adults, survival was 63% after 3 years for the adult form of the disease.^{158,159}

All the current questions regarding superiority of combination therapy as opposed to monotherapy, for whom, when, and in what combinations, considering not only pharmacodynamic and kinetic aspects, but also the ratios of cost to benefit, will only be solved in stepwise fashion by major international multi-centric studies in which the most appropriate therapy is used in experienced hands. Indeed, with further progress of development of drugs, a major benefit may be derived not from the effects, but rather out of the meticulous use of the logistics and wider circumstances in which these patients are treated.

OUTLOOK FOR THE FUTURE

While the current therapeutic goal is to use vasodilators and blockers of vasoconstriction in a well thought out way, it is the normal remodelling of the pulmonary vasculature, with the restoration of endothelial function and the growth of new peripheral pulmonary arteries, which should be the ultimate goal of therapy. In the field of paediatric cardiology, combining these drugs with the well-established mechanical method of protecting the pulmonary vascular bed by banding the pulmonary trunk, avoiding extremes of pressure overload to the subpulmonary ventricle, and avoiding systemic desaturation, in patients with congenital shunting lesions and pulmonary vascular resistance too high to operate, may deserve a new and justified interest as a method to allow for recovery of the remodeled pulmonary vascular bed and later surgical correction.

Certainly one important direction for progress is the further development of drug therapy, and while the modes of administration and different formulations have all been exhaustively studied, and while new analogues of existing drugs show some improved effects, other drugs, like vasoactive intestinal peptide, the statins, inhibitors of RhoA and metalloproteinases, openers of the potassium channel, anti-growth factors, as well as stem cell and gene therapy, are all under avid investigation. However, without properly detailed and structured studies, the information in the small groups of patients with pulmonary hypertension will show limited gain and will be repetitive. So, future studies not only need to define valid and practical endpoints but also to look closely into the many possible effects of the studied substances. Finally, the development of dedicated clinical services to optimise the use of drugs and logistics for the care of patients with the different forms of pulmonary hypertension will be as important, if not the predominant aspect, to improve survival and quality of life.

These papers discuss different pathophysiological situations involving the congenitally malformed heart and assess the role of pulmonary vascular resistance. While the last paper is a review of the topic, the other two excel in the use of their methodology and the discussion.

Cardiological Aspects of Systemic Disease

ROBERT F. ENGLISH and JOSÉ A. ETTEGUI

Cardiac involvement in systemic disease can be broadly divided into those conditions in which the heart is involved in the disease process itself, and those in which a structural or functional cardiac abnormality is associated with other anomalies, usually in a recognisable syndrome. Many of the conditions in this latter group have received attention in the sections of this book dealing with aetiology and genetics. These will not be dealt with again, although they may be mentioned, or the discussion amplified, as necessary. A vast number of systemic diseases, nonetheless, can involve the heart during childhood. It is the cardiac aspects of these latter diseases we discuss in this chapter (Table 57-1).

METABOLIC DISORDERS: STORAGE DISEASES

We have chosen to group together here the glycogen storage diseases, the mucopolysaccharidoses, the mucolipidoses, disorders of glycoprotein degradation, acid lipase deficiency, the sphingolipidoses, and the gangliosidoses.

Glycogen Storage Diseases

Glycogen storage diseases can involve the various steps in the storage and degradation of glycogen. There may be an inability to synthesise normal glycogen. Alternatively, there may be an inability to break down glycogen. In the extreme form, abnormal glycogen is synthesised but cannot be broken down. There are eleven described types within this range of disease, and most types involve two or more subtypes. Cardiac involvement has been documented in types I to VIII.

Glycogen Storage Disease Type I (von Gierke's Disease, Glucose-6-Phosphatase Deficiency [Type Ia], Glucose-6-Phosphatase Translocase Deficiency [Type Ib])

Clinical manifestations of type I glycogen storage disease are profound hypoglycaemia, associated with hyperlipidaemia, hyperuricaemia and lactic acidosis. It presents in childhood, primarily involving the liver, kidneys, and mucous layers of the small intestine. Pulmonary hypertension has been described in association with the type Ia variant. Postulated mechanisms include chronic stimulation of the smooth muscle of the pulmonary arterioles by the persistent hepatic metabolism of circulating catecholamines such as serotonin. Levels of serotonin have been shown to be elevated in patients with glycogen storage disease type I. Such elevation of the levels of serotonin in isolation do not appear to confer pulmonary vascular disease on these patients. Rather, it is hypothesised that other mediating factors working in concert with persistently

elevated levels of serotonin increase the risk for pulmonary vascular changes.¹⁻³

Glycogen Storage Disease Type II (Pompe's Disease, α -1,4-Glucosidase Deficiency)

Pompe's disease is a generalised glycogen storage disease in which glycogen of normal structure is accumulated in the myocardium, skeletal muscle, and liver. The disease is progressive, and is associated with deficiency of lysosomal α -1,4-glucosidase. There are four subtypes based upon age at onset of clinical symptoms. It is the form presenting in infancy that is recognised as classical Pompe's disease, but patients can also present in childhood, adolescence (giving rise to the juvenile form), or adulthood. The age at onset correlates inversely with the measured activity of lysosomal α -1,4-glucosidase in myocytes or fibroblasts. In the infantile form, which is more severe in its cardiac involvement than those forms of later onset, there is generalised accumulation of glycogen in the heart, including the conduction tissues, in skeletal muscle, notably the tongue and diaphragm, and in the liver. Central and peripheral neurons and smooth muscle are also affected. The results are cardiomegaly, hepatomegaly, a thickened diaphragm, and macroglossia. In the heart, the glycogen is deposited mainly in ventricular muscle. There is gross thickening of the ventricular walls, with impairment of both diastolic and systolic performance. The infants typically appear normal at birth, though cases of severe neonatal ventricular hypertrophy have been reported.⁴ The median age at onset of clinical symptoms is 1.6 months. Muscular weakness and hypotonia along with loss of motor milestones are noted during the first 6 months of life, and signs of congestive cardiac failure become evident. Although there is excess glycogen in the liver, hepatomegaly is not commonly present until cardiac failure is apparent. The disease is progressive, and most affected babies die before the age of 1 year. The clinical course may be complicated by arrhythmias. Since patients with Pompe's disease appear very sensitive to digoxin, this drug must be used with extreme caution. Irritability and poor feeding often draw attention to the disease. The cardiac physical signs are not characteristic, variable murmurs being heard. Unexplained cardiomegaly and congestive cardiac failure in a generally floppy baby should suggest the diagnosis.⁵

The chest radiograph may be normal at birth, but in all affected infants the heart becomes enlarged within a few weeks. There is no specific cardiac silhouette, but rather a generalised smooth enlargement of the contour. The characteristic electrocardiographic features are a short PR interval, wider than normal QRS complexes, and voltage evidence of left or biventricular hypertrophy, which can be

severe (Fig. 57-1). In addition, in the majority there are Q waves and inverted T waves in leads I and II and the left chest leads.⁶ Electrophysiological studies have shown a short AH interval.⁷ Both M-mode and cross sectional echocardiograms demonstrate gross increase in the thickness of the ventricular free walls and the ventricular septum (Fig. 57-2). An impairment of ventricular filling in diastole has been noted,⁸ together with reduction of the rate and extent of systolic shortening. Angiocardiography is rarely performed, as it adds little to the diagnosis or management.

The complete clinical picture, together with the characteristic electrocardiographic and echocardiographic findings, will lead immediately to the definitive diagnostic investigation. This is the demonstration of deficiency of lysosomal α -1,4-glucosidase in fibroblasts grown from a skin biopsy. Sometimes the skeletal muscular abnormalities are less evident. The presentation is then as a cardiomyopathy alone. Pompe's disease should be considered in any such case, and skin biopsy performed. Until recently, there was no specific treatment available, and supportive and decongestive measures failed to improve outcomes. Recent studies using recombinant human lysosomal acid α -glucosidase show promise in improving survival.⁹ Since the disease appears to be inherited in an autosomal recessive fashion, parents should be advised of the availability of prenatal diagnosis via culture of amniocytes obtained by amniocentesis.

We include Danon disease in this section because it was previously considered to be a variant of Pompe's disease known as glycogen storage disease type IIb with normal acid maltase. The disease is due to a deficiency of lysosome-associated protein 2, and it manifests as a progressive hypertrophic cardiomyopathy with skeletal myopathy. Other similar diseases in this family of autophagic vacuolar myopathies are still being studied. Some demonstrate autosomal recessive inheritance while others are X-linked,

and the degree of cardiac and skeletal involvement is variable.¹⁰

Glycogen Storage Disease Type III (Cori's Disease, Amylo-1, 6-Glucosidase [Debrancher] Deficiency)

In Cori's disease, an autosomal recessive condition, glycogen accumulates in skeletal muscle, in the liver, and in cardiac muscle. The disease is due to a deficiency of amylo-1,6-glucosidase, the enzyme necessary for breaking down branch points in glycogen chains. There are three subtypes dependent upon the primary site of abnormal glycogen storage. Type IIIa involves the liver and muscle, Type IIIb the liver, and Type IIIc the muscle.^{4,11} A fourth subtype, IIId, involves normal debrancher enzymic activity but a deficiency of debrancher enzyme transferase activity. Patients with types IIIa and IIIc have a tendency to develop weakness of the skeletal muscles and left ventricular hypertrophy,¹² which is progressive. The clinical course appears to be less severe, with fewer symptoms as compared to hypertrophic obstructive cardiomyopathy.^{13,14}

Glycogen Storage Disease Type IV (Andersen's Disease, α -1, 4-Glucan-6-Glucosyltransferase [Brancher] Deficiency)

Andersen's disease is a rare heterogeneous glycogen storage disease characterised by deposition of glycogen of abnormal structure in the liver, leading to cirrhosis. There may also be deposition of polysaccharide in the heart. While liver dysfunction is the most common clinical manifestation, the disease can rarely present with dilated cardiomyopathy, which is typically severe.¹⁵⁻¹⁷

Glycogen Storage Disease Type V (McArdle's Disease, Muscle Phosphorylase Deficiency)

McArdle's disease results from a deficiency of muscle phosphorylase. It is usually recognised in adolescence or adult life. Its main clinical features are muscular fatigability, muscular cramps, and myoglobinuria. Rare lethal variants have been reported in infants,¹⁸ but the heart is typically spared. This may be due to activity of a distinct cardiac

Figure 57-1 The typical electrocardiogram of a patient with Pompe's disease demonstrates striking biventricular hypertrophy.

Figure 57-2 Typical echocardiographic findings in glycogen storage disease type II. A shows a diastolic frame in long axis, revealing severe concentric left ventricular hypertrophy, while the systolic frame from the same child (B) shows the absence of subaortic obstruction.

phosphorylase isozyme, which retains activity in patients with deficiency of the skeletal isozyme.¹⁹ No clinical cardiac manifestations have been reported, but on occasion the electrocardiogram has features similar to those seen in Pompe's disease.²⁰

Glycogen Storage Disease Type VI (Hers' Disease, Phosphorylase B Kinase Deficiency, Liver Phosphorylase Deficiency)

Hers' disease involves both X-linked and autosomal recessive modes of inheritance. It results from deficiency of liver phosphorylase. Both types involve the liver in childhood, whereas involvement of muscles occurs in young adults with the autosomal recessive form of the disease. Rare forms of phosphorylase b kinase deficiency have been described in which deposition of glycogen is limited to the heart.²¹

Glycogen Storage Disease Type VII (Tarui's Disease, Muscle Phosphofructokinase I Deficiency)

Tarui's disease is a rare form of glycogen storage disease that presents in early childhood or adult life with fatigability, muscular weakness that can be progressive, muscular cramps, and myoglobinuria. Typically, the heart is spared. An infantile form of the disease has also been described in the members of one family. Cardiomyopathy occurred in addition to the progressive muscular weakness, and abnormal deposition of glycogen was noted in the cardiac muscle at autopsy.²² Progressive cardiomyopathy has also been reported in an adult.²³

Mucopolysaccharidoses

The mucopolysaccharidoses result from deficiency of lysosomal enzymes involved in the degradation of mucopolysaccharides. The incompletely degraded mucopolysaccharides then accumulate in the tissues. The substances accumulated are dermatan sulphate, heparan sulphate, and keratan sulphate, alone or in combination. In all forms, there is skeletal involvement. In most, there is glaucoma and corneal clouding. Retinal pigmentation frequently occurs. Deafness is a feature of all types. In most, there is hepatosplenomegaly. Involvement of the central nervous system is common, usually with cervical myelopathy as a consequence of pachymeningitis or atlanto-occipital subluxation.

Cardiovascular involvement is a feature of all types. The mucopolysaccharides are deposited in arterial walls, producing lesions similar to atherosclerosis.²⁴ Deposition in cardiac

valves leads to valvar stenosis or regurgitation. The various forms of these diseases are brought about by deficiencies of ten identifiable lysosomal enzymes. Specific deficiencies can be demonstrated in cultured fibroblasts, and prenatal diagnosis from culture of amniocytes is possible. The availability of such diagnosis is important, since there is genetic variability within the different forms of the diseases.

Mucopolysaccharidosis Type I (α -L-Iduronidase Deficiency)

The three major clinical forms of α -L-iduronidase deficiency are Hurler's syndrome, Scheie's syndrome, and a syndrome intermediate between the two, known unsurprisingly as Hurler-Scheie syndrome. These diseases are due to defects in the gene encoding α -L-iduronidase, and multiple defects have been elucidated. These include nonsense, missense, insertional, deletional, and splice-type gene defects. It is thought that the clinical severity of the disease is related to the level of new enzymic activity, which in turn is due to a specific genetic defect.^{25,26}

Hurler's Syndrome

The defect in Hurler's syndrome results in a virtual absence of lysosomal α -L-iduronidase. This enzyme is responsible for breakdown of heparan sulfate and dermatan sulfate to heparan and hyaluronic acid, respectively. The enzyme is completely absent in fibroblasts, but some activity is present in the liver. Consequently, traces of the breakdown products of heparan and dermatan may be found in the urine. As a consequence of this enzymic deficiency, both heparan and dermatan sulphates accumulate in the lysosomes of many tissues. When seen in neurons, the lesions bear some resemblance to those found in Tay-Sachs disease. Deposition in the arterial walls is associated with proliferation of smooth muscle cells, and the lesions are described as pseudo-atheromatosis. There is proliferation of both elastic fibres and collagen accompanying the lysosomal accumulation of mucopolysaccharides.

The babies seem to be normal at birth, the clinical features appearing after the age of 1 year when the facial features become coarse. Premature closure of the skull sutures, and hydrocephalus as a consequence of pachymeningitis, lead to cranial deformities. The characteristic lumbar lordosis develops because of stiff joints. Retardation of growth then becomes evident after the age of 2 or 3 years, with subsequent development of deafness, corneal clouding, and sometimes glaucoma. The liver and spleen are always enlarged. Although the heart is rarely spared, clinical evidence of cardiac involvement is seen only in

half the patients. Angina is an occasional symptom, but more frequently attention is drawn by the finding of a cardiac murmur or systemic hypertension. The murmurs are variable and usually not loud. Rarely the murmur of aortic or mitral insufficiency may be heard. Cardiac failure has been reported as the presenting feature associated with endocardial fibroelastosis.^{27,28}

There are typical skeletal radiological features. The clavicles have wide medial ends. The lower thoracic and upper lumbar vertebrae have a flared and hook-shaped appearance. There are also changes in the skull and long bones, the latter being more severely affected in the upper limbs. The heart is usually enlarged, but with no specific silhouette, although left atrial enlargement will occur with severe mitral regurgitation. Similarly, there are no specific electrocardiographic features, although combined ventricular hypertrophy is frequent. A long QT interval has been reported in some patients.²⁹

Pathological findings in the heart include deposition of mucopolysaccharide in structures such as the sinus and atrioventricular nodes, as well as in the myocardium and endocardium. The coronary arteries often demonstrate severe luminal narrowing. The mitral valve is most frequently involved, followed by the aortic and tricuspid valves. Pulmonary valvar involvement is only rarely reported. Valvar changes include nodular thickening along the free edges, which may lead to stenosis or regurgitation. Evidence suggests that the accumulation of dermatan sulphate leads to impaired elastogenesis, which may lead to some of the characteristic arterial and valvar deformities.³⁰

Thickening of the leaflets of the mitral valve and its annulus is seen echocardiographically. Left ventricular volume load, and diastolic flutter of the mitral valve, are seen when aortic regurgitation is present. Cardiac catheterisation and angiocardiology add little to the diagnostic findings, which include systemic and mild pulmonary hypertension. When present, the haemodynamics and angiography will reflect the severity of valvar insufficiency. The disease progresses inexorably, death occurring by the age of 10 years from cardiac failure, suddenly, or from chest infection. Transplantation of haematopoietic stem cells has been beneficial in selected patients for many aspects of the disease.³¹ The valvar lesions, however, can continue to progress. Enzymic replacement therapy with human recombinant α -L-iduronidase has also been proven beneficial, but, as with transplantation of stem cells, the valvar lesions remain and may progress.³²

Scheie's Syndrome

Patients with Scheie's syndrome are less severely affected, having normal stature and intellect. They also have a near-normal lifespan. The most striking features are corneal clouding and stiff joints. Typical cardiac manifestations are aortic stenosis and regurgitation, or mitral regurgitation.^{33,34} These should be managed in a similar fashion as for otherwise normal subjects. Scheie's syndrome is inherited in autosomal recessive fashion.

Hurler-Scheie Syndrome

Hurler-Scheie syndrome falls in severity between the two extremes of α -L-iduronidase deficiency. The patients are of short stature, with mental retardation and multiple bony defects. There is clouding of the cornea and stiff joints, claw-hand being particularly common. Aortic and mitral valvar involvement are the primary manifestations.

Asymmetrical septal hypertrophy has also been reported.³⁵ The clinical course is intermediate between Hurler's and Scheie's syndromes, with patients living into adolescence or even to the third decade.

Mucopolysaccharidosis Type II (Hunter's Syndrome, Iduronate Sulfatase Deficiency)

Deficiency of iduronate sulfatase results in a block of degradation of dermatan sulphate. The difference in clinical profile between this and Hurler's and Scheie's syndromes, for example, the absence of corneal clouding in Hunter's syndrome, may result from specific variability in the degree of blockage of degradation of the mucopolysaccharide. Furthermore, it may be that the block to degradation caused by the accumulation of iduronate sulfate may be bypassed by hyaluronidase. The severe and mild forms of Hunter's syndrome both have total, or near total, deficiency of iduronate sulfatase. As with mucopolysaccharidosis type I, the clinical phenotype may be representative of the degree of residual enzymic activity specific to certain gene mutations, of which more than 300 have been found for Hunter's syndrome.³⁶

The condition can occur with a wide variety in severity. Apart from the extreme rarity of corneal clouding in Hunter's syndrome, and the presence of loss of hearing, the clinical features are those of Hurler's syndrome, although usually less severe. A positive distinguishing physical sign, pointed out by Hunter himself in 1916, is the occurrence of pebble-like ivory-coloured dermal lesions. These are seen over the scapulas and occasionally on the pectoral regions.

Cardiac involvement produces all the manifestations so far mentioned, namely, aortic and mitral regurgitation or stenosis, ischaemic changes, and evidence of myocardial dysfunction. Echocardiography is a useful method for evaluating cardiac involvement. The clinical course is extremely varied. Severely affected individuals die before the age of 15 years. At the opposite end of the spectrum, survival beyond the sixth decade has been reported. Death in younger patients is usually associated with progressive neurological deterioration. The disease is inherited as an X-linked recessive trait, though cases in females have been reported.³⁷ Since the reproductive fitness of the Hunter gene is low, a large minority of cases must result from new mutations.

A new treatment for Hunter's syndrome has recently emerged with the development of recombinant human iduronate-2-sulfatase. This was well tolerated, and demonstrated improvement in several parameters for outcome, including forced vital capacity, urinary excretion of glycosaminoglycans, the size of the liver and spleen, and 6-minute walk distance.^{38,39} The effect of enzymic therapy on the cardiac lesions, however, remains to be determined.

Mucopolysaccharidosis Type III (Sanfilippo's Syndrome)

The degradation of heparan sulphate and N-sulphated or N-acetylated α -linked glucosamine requires four enzymes: heparan N-sulphatase, N-acetyl- α -D-glucosaminidase, acetyl-CoA: α -glucosaminide N-acetyltransferase, and N-acetyl- α -D-glucosamine-6-sulphate sulphatase. Deficiency of one of the four enzymes required for this degradation results in Sanfilippo's syndrome. Consequently, there are four biochemically distinct types of the disease, designated A through D, although they all present the same clinical features.

The onset is usually evident in the first few years of life with behavioural problems. Mental and neurological deterioration are severe and lead to death in the first two decades. Bone, joint, and cardiac involvement are generally less severe than in Hurler's syndrome. Corneal clouding is never seen. There is wide variation in the severity and age at death in all four forms, but type A is likely to be the most severe. Inheritance is in an autosomal recessive fashion. A number of patients with mitral valvar involvement have been reported.^{40,41} Cardiac involvement is similar to that of other mucopolysaccharidoses, with thickening of the valvar leaflets. While treatment is primarily supportive, animal studies have been undertaken to assess replacement of the enzymes in a mouse model with mucopolysaccharidosis type III-B.⁴²

Mucopolysaccharidosis Type IV (Morquio's Syndrome)

Morquio's syndrome results from defective degradation of keratan sulphate. It occurs in two biochemically distinct forms. The so-called type A is due to a deficiency of N-acetylgalactosamine-6-sulfate sulfatase, while type B results from deficiency of β -galactosidase. The two types have similar clinical features, but type B is less severe, sometimes called the long-legged variant. Despite the generally increased severity of features in type A, more mild forms of type A can occur. Keratan sulphate is excreted in the urine in type A, but this is less evident in type B.

Keratan sulphate is found in cartilage, intervertebral discs, and the cornea. Thus, skeletal involvement with dwarfism, pectus deformities, and bow legs are the most obvious manifestations. Corneal clouding is common. In contrast to the mucopolysaccharidoses described above, the joints in patients with Morquio's syndrome are hyperextensible. Absence or severe hypoplasia of the odontoid process, together with laxity of its associated ligaments, leads to atlanto-occipital subluxation, and consequent cervical myelopathy. The heart is clinically involved only in the severe type. Valves of the heart are primarily involved, with thickening of mitral and aortic leaflets. Concentric left ventricular hypertrophy and, rarely, asymmetrical septal hypertrophy have been described.^{40,43} Survival beyond the third or fourth decade is not unusual. The effects of the cervical myelopathy and respiratory problems are the usual cause of death. Experimentation with enzymic replacement therapy in animals has been undertaken and holds some promise.⁴⁴

Mucopolysaccharidosis Type VI (Maroteaux-Lamy Syndrome)

Deficiency of arylsulfatase B results in an inability to hydrolyse the sulfate groups in dermatan sulfate. The clinical picture is similar to that of Hurler's syndrome, but normal intelligence is usually maintained. Although severe in its classical form, milder variations exist. Affected infants can present with an acute cardiopathy.⁴⁵ Thickened mitral and aortic valvar leaflets necessitating valvar replacement has been noted in young adults.⁴⁶ A left ventricular aneurysm has also been reported.⁴⁷ Death usually occurs in the third decade. The condition is inherited in autosomal recessive fashion, though some cases have been presumed to be X-linked.⁴⁸ Enzymic replacement therapy with human recombinant arylsulfatase B has been studied, and found to be safe and beneficial in terms of exertional tolerance and urinary excretion of glycosaminoglycan.⁴⁹

Mucopolysaccharidosis Type VII (Sly's Syndrome)

Deficiency of β -glucuronidase results in a clinical syndrome of extremely variable severity. Included in the features are coarse facies, corneal clouding, abdominal and inguinal

hernias, puffy hands and feet, hepatosplenomegaly, and a small thoracolumbar hump. Cardiovascular manifestations include hypertension, aortic aneurysm, aortic regurgitation, obstructive arterial disease, and cardiomyopathy.^{50,51} Fetal hydrops has also been reported.⁵² This extremely rare condition is inherited in autosomal recessive fashion. Duration of survival varies widely, and depends on the severity of the disease. Death as early as 30 months has occurred in one child with severe disease. Animal studies involving enzymic replacement therapy have been performed and are encouraging in terms of improving the cardiovascular changes associated with this disease.⁵³

Mucolipidoses

The mucolipidoses present with clinical features similar to the mucopolysaccharidoses, but are biochemically distinct. Leroy and Demars⁵⁴ observed inclusions in cultured fibroblasts that occupied the whole cytoplasmic space apart from the Golgi apparatus. It was because of this that the name inclusion cell, or I-cell, disease was coined. The cause of the defect in lysosomal storage is deficiency of several acid hydrolases in the lysosome. But this is not the primary problem, since the plasma abounds in these acid hydrolases, albeit in unstable forms. The problem is failure to locate the hydrolases within the lysosome. Failure of phosphorylation of mannose residues of the hydrolases is the primary defect. Hydrolases without mannose 6-phosphate components are then not recognised by the lysosome, and are not transported across the lysosomal membrane, particularly in connective tissue. In this way, inclusion cell disease and pseudo-Hurler polydystrophy differ from sialidosis, previously called mucopolipidosis type I, in which there is a single lysosomal enzyme defect. Mucolipidoses type II, or inclusion cell disease, and type III, or pseudo-Hurler polydystrophy, result from a deficiency of uridine diphosphate-N-acetylglucosamine:lysosomal enzyme N-acetylglucosamine-1-phosphotransferase. The degree to which this enzyme is deficient determines the ultimate phenotype. Diagnosis is suggested by clinical features resembling mucopolysaccharidoses, but without their biochemical abnormalities. Findings of high levels of β -hexosaminidases, iduronate sulphatase, and arylsulphatase A in the serum are diagnostic. The characteristic enzymatic deficiencies in fibroblasts can be identified in cultured cells.

Mucopolipidosis Type II (Inclusion Cell Disease, I-Cell Disease)

I-cell disease results from a severe deficiency of the phosphotransferase enzyme due to specific genetic mutations which result in a marked reduction in enzymic activity. Various defects in the gene encoding this enzyme have been discovered in patients with this disorder.⁵⁵ The patients with inclusion cell disease present with clinical features very similar to those with Hurler's syndrome. Hepatosplenomegaly is not so obvious, while striking gingival hypertrophy is a feature not encountered in Hurler's syndrome. Furthermore, the disease becomes evident earlier than does Hurler's syndrome. Corneal clouding is the rule. The skeletal and joint abnormalities, together with myocardial infiltration, usually lead to death by the age of 5 years, either from respiratory causes or cardiac failure. Asymmetrical septal hypertrophy has been reported.⁵⁶ Treatment of the cardiac manifestations is usually supportive, though

surgical management of valvar involvement has been reported.⁵⁷ Transplantation of allogeneic stem cells has stemmed the progression of disease in a small number of reported cases.⁵⁸

Mucopolipidosis Type III (Pseudo-Hurler Polydystrophy)

Mucopolipidosis type III is less severe, and also less common, than type II, and is due to a deficiency of the same phosphotransferase enzyme. In type III, the enzymic activity is less severely reduced, and the manifestations are less severe. There is a fair amount of variability in clinical severity.⁵⁹ This is likely due to various genetic defects leading to different levels of enzymic activity. Patients are usually spared the joint manifestations of I-cell disease early in life, and often present with joint stiffness at the age of 4 or 5 years. Growth is moderately retarded, and corneal clouding is present by the age of 7 or 8 years. The patients are disabled by carpal tunnel syndrome and destruction of the hip joints. Cardiac involvement, particularly aortic regurgitation, does occur but is usually not sufficiently severe to cause clinical problems. Patients with pseudo-Hurler polydystrophy survive into the fourth decade.

Disorders of Glycoprotein Degradation

Specific lysosomal enzymic deficiencies result in failure of degradation of glycoproteins, with consequent accumulation of glycoproteins in many tissues, especially the nervous system. They became recognised when patients with appearances similar to those with mucopolysaccharidoses were found to have biochemically distinct diseases.

The five primary disorders of glycoprotein degradation—mannosidosis, fucosidosis, sialidosis, galactosialidosis, and aspartylglycosaminuria—can all be diagnosed by demonstration of the enzyme defect in cultured fibroblasts. Prenatal diagnosis is often possible.

Mannosidosis

Deficiency of α -mannosidase results in the accumulation of oligosaccharides, as their degradation is dependent upon lysosomal activity of this enzyme. Oligosaccharides are excreted in the urine. Several defects in the gene encoding α -mannosidase have been discovered. The specific defect may result in decreased enzymic synthesis, decreased enzymic activity within the lysosomal environment, decreased localisation of the enzyme within the lysosome, or faulty post-translational modification of the enzyme. The patients present with features suggestive of mucopolysaccharidosis but have an increased susceptibility to infections. Progressive mental retardation is typical. Early onset of the disease shown as type I is associated with increased severity. Death occurs between 3 and 10 years of age. Late-onset, or type II, runs a more benign course. Cardiac manifestations are not frequently reported. A short PR interval has been reported in several patients, albeit that its mechanism is unknown.⁶⁰ Treatment has been attempted with transplantation of bone marrow, and current strategies under investigation include various forms of enzymic replacement therapy.⁶¹

Fucosidosis

Deficiency of α -L-fucosidase results in the accumulation of fucosylated oligosaccharides and glycolipids. Two clinical types are recognised. The first type presents in infancy with coarse facies, growth retardation, mental retardation, and

neurological deterioration. Convulsions and respiratory infections often occur. The second type has a more benign course and a later onset. Cardiomegaly, probably as a part of a generalised visceromegaly, is the most common cardiac feature. These two types probably represent both ends of a continuum which is dictated by specific enzymic activity as determined by the specific genetic defect. Transplantation of bone marrow has been performed with good results, and further experimentation with enzymic replacement therapy is under way.⁶²

Sialidosis

The basic defect in sialidosis is deficiency of α -neuraminidase, with accumulation of sialoglycoconjugates. There are two forms. The first is of late onset. Patients are of normal appearance, but develop the cherry red spot myoclonus syndrome. Decreased visual acuity is associated with a cherry red spot in the macular region. Neurological, and occasionally renal, manifestations dominate the clinical picture. The second type has an early onset, even upon occasion being obvious at birth. The patients have coarse features and enlargement of various organs, including the heart. Echocardiography has shown a thickened left ventricular wall along with thickening of the mitral valve.⁶³ There is great variability in the spectrum of severity, even in the group with early onset. Survival beyond 20 years is rare, while, occasionally, affected subjects are stillborn. Fetal hydrops has been reported as a presenting feature.⁶⁴ Sialidosis is inherited in autosomal recessive fashion. Enzymic replacement therapy and gene transfer are under investigation.⁶⁵

Galactosialidosis

In galactosialidosis, patients have a defect in the production of lysosomal protective protein/cathepsin A, which helps form a stable and activated complex with β -galactosidase and α -neuraminidase.⁶⁶ Thus, the symptoms are a combination of those seen in sialidosis and Morquio's syndrome, the severity of which is likely determined by the specific genetic defect and its overall effect on production of functional levels of the protein. An infantile form has been described,⁶⁷ though there appears to be clinical variation even in those diagnosed as infants.⁶⁸ Complex congenital cardiac malformations have been reported in patients with galactosialidosis.⁶⁹ The cardiac manifestations are similar to those seen in Morquio's syndrome and sialidosis, with aortic and mitral valvar thickening which is progressive.^{70,71} Recently, the role of these enzymes and protective protein/cathepsin A in elastogenesis has begun to be unraveled, helping further to explain the phenotype associated with these genetic disorders.⁷² Early work has begun on therapies involving enzymic replacement or gene transfer.^{65,73}

Aspartylglycosaminuria

Aspartylglycosaminuria is a lysosomal storage disease produced by defective or deficient glycosylasparaginase. This enzyme is required for complete breakdown of asparagine-linked glycoproteins within the lysosome.⁷⁴ Accumulation of these glycoprotein residues leads to severe and progressive neurologic impairment. It is associated with coarse features, joint laxity, early rapid somatic growth followed by a reduced adolescent growth spurt leading ultimately to short stature, and mental retardation. Animal models demonstrate accumulation of residues within the heart, but clinical cardiac involvement does not appear to

predominate. Enzymic replacement is currently being studied in animal models.⁷⁵

Acid Lipase Deficiency (Wolman's Disease and Cholesteryl Ester Storage Disease)

Lysosomal acid lipase is necessary for the cleavage of triglycerides and cholesteryl esters from lipoproteins delivered to the lysosome. Complete or severe deficiency of lysosomal acid lipase results in accumulation of cholesterol in most tissues of the body. The disease occurs in two forms. Wolman's disease is a disease of infancy presenting with vomiting, diarrhoea, hepatosplenomegaly, anaemia and calcification of the adrenal glands. Cardiac manifestations are not usually evident, but microscopic examination of the arteries shows excess fatty deposits. Hepatomegaly is frequently the only sign in the milder form of the disease, known as cholesteryl ester storage disease, though premature atherosclerosis is also seen.⁷⁶ The diagnosis of Wolman disease is suggested by the association of hepatosplenomegaly with adrenal calcification. Definitive diagnosis of either disease can be made by assessing acid lipase activity in cultured skin fibroblasts. The disease is inherited in an autosomal recessive fashion. Successful treatment with transplantation of both bone marrow and cord blood has been reported.^{77,78}

Sphingolipidoses

Sphingomyelin Lipidosis (Niemann-Pick Disease)

In Niemann-Pick disease, there is accumulation of sphingomyelin in the cells as a result of deficiency of sphingomyelinase. The primary cells affected are those of monocyte-macrophage lineage, as they are frequently employed in the metabolic turnover of these substances. At least four variants exist, but the most frequently encountered is the infantile acute neuronopathic form. Many of these patients are of Ashkenazi Jewish heritage. The disease is characterised by hepatosplenomegaly and the occurrence of foam storage cells in many tissues. The heart is not usually affected, but one infant with acute neuronopathic disease had endocardial fibroelastosis.⁷⁹ Since there were no storage cells in the heart, however, this may have been a chance association. Abnormalities in the lipid profile have also been described in children with Niemann-Pick disease types A and B, possibly leading to premature atherosclerosis.⁸⁰ Low levels of high density lipid cholesterol were the most consistent finding, while elevated levels of triglyceride and low density lipid cholesterol were seen in approximately two-thirds. These abnormalities were noted at an early age, and may reflect deranged cholesterol metabolism in these cells as a result of sphingomyelin accumulation. Niemann-Pick disease in most of its forms is inherited in an autosomal recessive fashion.

Glucosylceramidosis (Gaucher's Disease)

Gaucher's disease is the most common inherited disorder of glycolipid metabolism. In his original description,⁸¹ Phillippe Gaucher ascribed the changes to a primary epithelioma of the spleen. There is excessive accumulation of glucosylceramide in cells of the reticuloendothelial system in organs throughout the body, resulting from deficiency of the enzyme glucocerebrosidase, which cleaves glucose from glucocerebroside. While over 150 different mutations of the gene encoding glucocerebrosidase have been described, the disease occurs in three varieties based

upon the presence or absence of, and rate of progression of, neurologic manifestations. Type I, or the chronic non-neuronopathic form, can be diagnosed at any age. It is the most common form, being characterised by hypersplenism, hepatomegaly with evidence of abnormal hepatic function, and skeletal lesions, including aseptic necrosis of the femoral head. Other long bones and vertebrae may also be eroded. In patients with this type of disease, cardiac involvement may be seen with myocardial infiltration or restrictive pericardial disease.⁸² The most frequently encountered cardiac problem, however, is cor pulmonale secondary to pulmonary involvement. Mitral and aortic stenosis and insufficiency can also be seen,⁸³ and severe valvar and aortic arch calcification has been reported.⁸⁴ The course is variable. Death may occur in early childhood or, particularly when onset is late, there may be a normal life expectancy. Further variability is apparently the consequence of the non-neuronopathic form at onset changing to one of the other forms with a poorer prognosis.

The acute neuronopathic form, or type II, is usually recognised within the second half of the first year of life. Neurological involvement is evident early, afflicting particularly the cranial nerves and extrapyramidal tracts. The mechanism of death is usually a respiratory infection, since aspiration is common owing to incoordination of the nasopharynx. The subacute neuronopathic form, or type III, falls between the acute and chronic forms. The neurological involvement renders it less benign than the chronic variant, but its course usually stretches over many years.

While describing Gaucher's disease in terms of three distinct phenotypes is convenient, the observed characteristics of this disease are much less well defined. Patients with the same genotype can have widely differing phenotypes, and patients even within a particular type can have markedly differing clinical courses. Thus, while the genetic defects leading to Gaucher's disease are being elucidated, and include over 150 specific mutations already identified, the link between genotype and phenotype is still unclear.

The diagnosis of Gaucher's disease is confirmed by the finding of typical storage cells in the bone marrow, or by liver biopsy. The Gaucher cell is large and lipid laden. The cytoplasm is described as having an appearance of wrinkled tissue paper or crumpled silk. The nucleus is eccentric. These cells have to be differentiated from cells found in multiple myeloma, leukaemia, thalassaemia, and congenital dyserythropoietic anaemia. Demonstration of the enzymic deficiency in cultured skin fibroblasts, or in leucocytes, confirms the diagnosis. Approaches to treatment have included transplantation of organs and enzymic replacement. Improvement in the visceral involvement is common, but neurologic damage is generally not responsive to exogenous enzymic therapy. All three variants are inherited as autosomal recessive traits. Intra-uterine diagnosis is available, and heterozygotes can be identified at least for the acute and chronic types.

α -Galactosidase A Deficiency (Fabry's Disease)

Deficiency of α -galactosidase, a lysosomal enzyme, results in accumulation of phosphosphingolipids in the lysosomes of many tissues and also in the body fluids. The most frequently affected tissue is the vascular endothelium. The disease is of X-linked inheritance, but heterozygous women can show severe manifestations of the disease.⁸⁵ The gene locus for the enzyme is on the long arm of the X chromosome.

The disease usually presents in childhood in the male homozygote, often with periodic crises of severe pain of burning character, which usually start in the hands and feet. Crises occur most usually in the afternoon. Development of crises, which become less frequent and severe with time, may be followed by eruption of skin lesions, by angiokeratomas, and by typical opacities of the cornea and the lens. The angiokeratomas are clusters of dark red to purple punctate lesions which are usually flat or slightly raised. They occur most frequently between the umbilicus and the knees. They do not blanch on pressure. Hyperkeratosis and hypohidrosis usually accompany the angiokeratomas. Ocular lesions include typical creamy whorl-like opacities in the cornea. They are frequently found in the female heterozygote as well as the male homozygote. Cardiac disease is manifest with increasing age. Myocardial ischaemia and infarction are common and are secondary to the vascular lesions. Mitral regurgitation and aortic stenosis are the most frequently encountered valvar lesions.⁸⁶ Infiltration of the conduction tissues occurs. This results in progressive shortening of the PR interval as in other storage diseases that affect the specialised atrioventricular conduction axis.⁸⁷ Myocardial deposition can be detected echocardiographically by demonstration of septal and left ventricular wall thickening.⁸⁸ Progressive deposition of glycosphingolipid means that the cardiac problems themselves are also progressive. Since there is concomitant renal involvement, the cardiac effects are exacerbated by, for example, renal hypertension. The clinical course in the male homozygote is one of steady deterioration during early adult life, death being from cardiac or renal disease. The heterozygote female experiences little limitation of style and length of life. The diagnosis can be confirmed, and heterozygotes identified, by demonstrating the enzymic deficiency in leucocytes, and by finding an abnormally high content of accumulated substrates in tears or urinary sediment. Prenatal diagnosis is available. Enzymic replacement was reported in 2002,⁸⁹ and positive effects on cardiac involvement are evident.⁹⁰

Gangliosidoses

The gangliosidoses are lysosomal storage diseases characterised by accumulation of gangliosides GM₁ or GM₂, or their related conjugates, owing to deficiency of specific lysosomal hydrolases. The enzyme deficient in GM₁ gangliosidosis is acid β -galactosidase. Deficiency of hexosaminidase A or B, or both, or a deficiency of an enzymic activator, results in GM₂ gangliosidosis.

GM₁ Gangliosidosis

There are many enzymatic and clinical subdivisions of GM₁ gangliosidosis. The gene locus is on the short arm of chromosome 3. Mutation at this locus results in absence of enzymic activity for acid β -galactosidase, leading to accumulation of GM₁ ganglioside in the brain and organs. The wide variation in clinical picture has resulted in a broad classification of infant, juvenile, and adult forms. All forms of GM₁ gangliosidosis are inherited as autosomal recessive traits.

When seen in infancy, the disease is rapidly progressive, characterised by hypotonia, poor feeding, and failure to make motor or intellectual progress. Progressive neurological deterioration results in spastic quadriplegia or decerebrate rigidity. Rarified bones and beaked vertebrae are some

of the skeletal lesions encountered. As in Tay-Sachs disease, to be discussed below, a cherry red spot is seen in the macular region of the retina. Death usually occurs by the age of 3 years, frequently from bronchopneumonia. The heart is frequently involved. The spectrum from congestive cardiac failure with systolic dysfunction to isolated valvar thickening has been observed.^{91,92} Neonatal ascites has also been reported.⁹³ Cardiac involvement usually includes cardiomegaly on chest radiography, left ventricular hypertrophy on the echocardiogram, and congestive cardiac failure.⁹⁴ Patients with GM₁ gangliosidosis have a defect in the same enzyme which is involved in patients with Morquio's syndrome type B. The clinical heterogeneity among patients with this enzymatic defect is unclear, but probably is related to residual activity of the enzyme, post-processing of the enzyme, and other proteins involved, such as saposin B.⁹⁵ A novel therapeutic strategy is under investigation, and involves molecular chaperones, substances which stabilise the configuration of defective enzymes and enable them to remain enzymatically active.⁹⁶ Treatment in a mouse model demonstrated improved enzymic activity,⁹⁷ and reduced the quantity of substrate in neuronal tissues.⁹⁸

GM₂ Gangliosidoses

The GM₂ gangliosidoses result in variable deficiency of hexosaminidase, the locus for which has been mapped to the q arm of chromosome 5. This enzyme, which is composed of alpha and beta subunits, comes in two forms. Hexosaminidase A, found in the central nervous system, is composed of an alpha and beta subunit, while hexosaminidase B, found in peripheral tissues, is composed of two beta subunits. Thus, the GM₂ gangliosidoses result from a defect in either the alpha subunit, producing Tay-Sachs disease and severe deficiency of hexosaminidase A, or the beta subunit, which produces Sandhoff's disease, with severe deficiency of both types A and B of the enzyme. The juvenile and adult chronic GM₂ gangliosidoses result from less severe deficiencies of hexosaminidase A. Treatment for these disorders is still under investigation and has included gene therapy, substrate reduction, and transplantation of bone marrow.^{99–101}

Tay-Sachs Disease

Tay-Sachs disease is the most common of the gangliosidoses. It presents with motor weakness in the first 6 months of life. There is progressive motor and mental deterioration, with convulsions, spasticity, and decerebrate rigidity. Death usually occurs by the age of 3 years, the most frequent cause being bronchopneumonia. The children have doll-like facies. Examination of the retina shows the typical cherry red macula, which later becomes brown. Cardiac accumulation of substrate is usual. Save for a prolonged QT interval and non-specific T wave changes, however, cardiac manifestations are rare. While the hallmark of the disease is accumulation of GM₂ ganglioside in the central nervous system, evidence of involvement of the peripheral and autonomic nervous system has been reported in patients with chronic disease.¹⁰²

Sandhoff's Disease

Sandhoff's disease is similar to Tay-Sachs disease in its presentation and course, but is biochemically distinct. Clinically relevant cardiac involvement is rare, but a cardiomyopathy has been described, along with thickening of the mitral valve and its tension apparatus.¹⁰³ Another separate report described a case of congestive cardiac failure

due to aortic and mitral valvar thickening with severe mitral regurgitation.¹⁰⁴ The coronary arteries may also be narrowed.¹⁰⁵ As for GM₁ gangliosidoses, inheritance is autosomal recessive.

METABOLIC DISORDERS: INHERITED ENDOCRINE DYSFUNCTION

Diabetes Mellitus

The annual incidence of juvenile diabetes is between 8 and 10 per 100,000 of the population at risk.^{106,107} New cases are half as frequent under the age of 10 years as they are between 10 and 20 years of age. Since cardiovascular complications are manifested later in the disease, they are exceedingly rare in childhood.¹⁰⁸ There will be problems presented to the paediatric cardiologist by diabetes because fetal mortality is high in pregnant diabetics. Furthermore, congenital cardiac anomalies occur in approximately one-sixth of offspring of diabetic women, with a wide variety of defects reported. The most frequent cardiac complication is hypertrophic cardiomyopathy,¹⁰⁹ produced by elevated levels of insulin and insulin-like growth factor I.

The most obvious complication, however, is macrosomia. Even in the absence of congenital cardiac disease, infants of diabetic mothers have a host of problems. The syndrome is seen both in mothers with established diabetes and in those who develop the disease during pregnancy. The babies have a characteristic appearance, with high birth weight, plumpness, and puffy plethoric facies. They are jittery owing to hypoglycaemia secondary to hyperinsulinism. The organs, including the heart, are enlarged. The babies are frequently tachypnoeic, but this may not be of cardiac aetiology. Respiratory distress syndrome is quite common. Cardiac murmurs are frequent. Approximately one-third have radiological cardiomegaly. The electrocardiogram is rarely diagnostic.

Echocardiography shows thickening of the right and left ventricular walls together with the septum. Indeed, the ventricular septum is usually thicker than the free walls. Septal thickness, is, in general, most pronounced in those infants in congestive cardiac failure.¹¹⁰ A spectrum of abnormality exists from that of simple hypertrophy to hypertrophic obstructive cardiomyopathy. Obstruction of the left ventricular outflow tract can occur, as has been demonstrated in the past by cardiac catheterisation. Treatment of the hypertrophic cardiomyopathy is fairly standard in that β -blockade helps in terms of diastolic dysfunction. Diuretics must be used judiciously, as the thickened myocardium requires a higher filling pressure. The clinical and echocardiographic signs of hypertrophic cardiomyopathy usually resolve over the early weeks of life, but myocardial thickening can take up to 6 months to resolve.¹¹¹

More important than diagnosis and treatment is prevention. It is suggested that the most severely affected newborns are those in whom maternal control of diabetes has been poor.^{112,113} The importance of late glycaemic control, and the correlation of maternal levels of haemoglobin A_{1c} to severity of disease, has been questioned.¹¹⁴

Pituitary Gigantism and Acromegaly

Adenomas of the pituitary that secrete growth hormones cause gigantism in growing children and acromegaly in adults. Acromegalic cardiomyopathy results from elevated

levels of growth hormone and the resultant elevated levels of insulin-like growth factor 1. The cardiomyopathy is characterised by biventricular and concentric involvement, which is progressive and may lead to congestive cardiac failure with myocardial fibrosis. The severity of disease relates to the age of the patient. Treatment with somatostatin analogues, which reduce growth levels, is beneficial in terms of clinical symptoms and indexes of myocardial morphology and physiology.¹¹⁵

Disorders of Thyroid Function

Hypothyroidism

Congenital Hypothyroidism

Congenital hypothyroidism has many aetiologies. The most common cause is congenital thyroid dysplasia, present in approximately 1 in 6000 live births. There are rarer causes, including endemic deficiency of iodine, diminished responsiveness to thyrotrophin in familial goitre, and administration of antithyroid drugs to pregnant mothers. The cardiac features of cretinism are not dramatic. Normal to slow heart rates, and radiological cardiomegaly, are usually the only manifestations. The enlarged cardiac silhouette is usually caused by pericardial effusion, which is an extremely common feature. Cardiac performance is usually well preserved. Abnormalities of heart rate and the pericardial effusions resolve when substitution treatment of the hypothyroidism is successful. A pericardial effusion can be detected by echocardiography in approximately half of these patients.¹¹⁶

Juvenile Hypothyroidism

As with congenital forms, juvenile hypothyroidism has multiple aetiologies. It is generally the result of autoimmune thyroiditis, or Hashimoto's disease. Growth retardation is the most common form of presentation. It can lead to delayed sexual maturation. Cardiac signs and symptoms are few, and cardiac failure is very rare. Bradycardia, low pulse pressure, poor peripheral circulation, and non-specific murmurs may be present. Pericardial effusions, with no evidence of pericarditis, occur in some patients. Tamponade is rarely seen because of the slow rate of fluid accumulation. About one-half of the patients with pericardial effusions have associated pleural effusions. Establishment of a euthyroid state reverses the cardiac manifestations.

Hyperthyroidism

Juvenile Hyperthyroidism

The most common cause of juvenile hyperthyroidism is diffuse toxic goitre, also known as Graves' disease. This is an autoimmune disease in which IgG immunoglobulins, which stimulate excessive production of thyroid hormones, can be demonstrated. It is more common in girls, with a ratio of females to males of approximately 5 to 1. Its greatest incidence is between the ages of 11 and 19 years, and it is rarely seen in children under the age of 3 years. Presenting symptoms include restlessness, poor performance at school, irritability, loss of weight, and occasionally diarrhoea. On examination, patients have warm skin, and a fine tremor is visible in outstretched hands. Enlargement of the thyroid gland is always present, and bruits are audible over the enlarged gland because of its increased vascularity. Exophthalmos is common, but is not marked. Cardiovascular involvement is secondary to an increased adrenergic drive and to direct myocardial stimulation by

thyroid hormones. The pulse is fast with a wide pulse pressure. The systolic blood pressure is increased, and the apical impulse is hyperdynamic. On auscultation, the first heart sound is accentuated, and non-specific systolic murmurs may be present. A high incidence of mitral valvar prolapse has been reported in adults with Graves' disease^{117,118} but has not been demonstrated in children.¹¹⁹ This suggests that the appearance of the prolapse is related to the duration of the disease.

The electrocardiogram is atypical. Sinus tachycardia, first-degree atrioventricular block, and non-specific ST segment and T wave changes may be present. Signs of atrial and left ventricular enlargement are more common in children than in adults.¹²⁰ Although atrial fibrillation is quite common in adults, it is extremely rare in children. Radiographic cardiomegaly, and a slight increase in pulmonary vascular markings, may be seen, especially in the setting of cardiac failure. The echocardiogram reveals hyperdynamic contractions of the ventricular septum and the left ventricular posterior wall.

Evaluation of cardiac function by radionuclide angiography in the presence of hyperthyroidism has shown a fall in left ventricular ejection fraction with exercise. Upon restoration of a normal thyroid state, the ejection fraction shows its normal exercise-induced increase.¹²¹ In general, the cardiovascular system in childhood tolerates well the effects of hyperthyroidism. In the presence of cardiac failure, however, concomitant cardiovascular lesions must be excluded. Cardiovascular manifestations of hyperthyroidism are reversible with treatment but, if long-standing or poorly treated, the disease may predispose to irreversible cardiac dysfunction.¹²²

Addison's Disease

Adrenal insufficiency may occur at any age and demonstrates no predilection for gender. It usually results from autoimmune destruction of the adrenal cortex and is manifested by weakness, hyperpigmentation, nausea, vomiting, loss of weight, and hypotension. When acute in onset, or when seen in patients who are metabolically stressed by a concomitant illness, the disease may present with shock or coma.

Cardiac involvement is due to the chronic hypotension and hypovolemia. Chest radiography may demonstrate diminished cardiac size, presumably due to disuse atrophy.¹²³ The electrocardiogram may demonstrate diffusely low voltages, sinus bradycardia, and first-degree atrioventricular block. Treatment involves replacement of mineralocorticoid hormones and must be carried out with caution as congestive cardiac failure can ensue. This is presumably due to the acute load of salt and water that is thrust upon the previously unloaded myocardium. This complication is readily treatable and is generally transient.¹²⁴

DISORDERS OF ENERGY METABOLISM

Mitochondrial Myopathies

The mitochondrial myopathies are muscle and systemic disorders characterised by the presence of mitochondria with abnormal structure, number and/or function. They are typically caused by deletions in mitochondrial deoxyribonucleic acid, though some are caused by defects in nuclear deoxyribonucleic acid. These disorders involve

complexes of the respiratory chain, and thus affect oxidative phosphorylation.

Chronic progressive ophthalmoplegia, or Kearns-Sayre syndrome, is frequently encountered among these diseases. It is associated with pigmentary degeneration of the retina, lack of coordination, facial and limb weaknesses, short stature, and endocrinal anomalies. The disease appears in childhood and has a progressive course. The most frequently reported cardiac anomaly is progressive heart block. Electrocardiograms should be performed frequently for early recognition and appropriate implantation of a pacemaker (see Chapter 19).¹²⁵ Cardiomyopathy, prolonged QT interval, torsades de pointes, atrial arrhythmias, and mitral valvar prolapse have also been described.^{126–130}

Myoclonic epilepsy with ragged red fibers (MERRF) and mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS) can present with a dilated cardiomyopathy.¹³¹ Patients with Leigh syndrome, or subacute necrotizing encephalomyelopathy, can develop hypertrophic cardiomyopathy and conduction system defects.¹³² Mitochondrial deoxyribonucleic acid is maternally transmitted. Inheritance, therefore, follows non-Mendelian patterns.

Barth Syndrome

Barth syndrome is an X-linked disorder due to a defect in the tafazzin gene, which produces a deficiency of cardiolipin. While the precise pathogenetic mechanism linking this deficiency to the clinical features of Barth syndrome remains to be elucidated, it is known that cardiolipin plays an important role in the processes of mitochondrial energy metabolism.¹³³ The disease is characterised by a dilated cardiomyopathy, skeletal myopathy, cyclic neutropenia, and retardation of growth. The heart typically displays poor contractility, and is often hypertrabeculated, showing features of ventricular non-compaction. Hypertrophy has also been noted. Cardiac involvement usually becomes manifest in the first decade of life.¹³⁴ Sudden death has been reported, and may be due to the increased risk of ventricular arrhythmias, which may require implantation of a defibrillator.¹³⁵ Treatment of the cardiomyopathy rests with traditional medical therapy, but cardiac transplantation has been successfully performed.¹³⁶ Death typically results from infectious complications or from cardiac disease.

Propionic Acidemia

Propionic acidemia is a rare metabolic disorder due to a deficiency of propionyl-CoA carboxylase, an enzyme involved in the catabolism of valine, leucine, isoleucine, methionine, threonine, cholesterol, and fatty acids. Gene mutations mapped to chromosomes 3 and 13 have been described.¹³⁷ Diagnosis is suspected by analysis of urinary organic acids, with elevations of propionate, propionylglycine, and methylcitrate. Confirmation of the diagnosis rests with demonstration of reduced activity of propionyl-CoA carboxylase in skin fibroblasts. There is a wide spectrum in clinical presentation, from severe early onset of the disease in the first days of life to relatively mild forms presenting in adulthood. Patients develop hypoglycinaemia, hyperammonaemia, hypoglycaemia, and deficits in the central nervous system, particularly in times of metabolic stress such as occurs with minor infections. Cardiomyopathy and

sudden death are relatively frequent late complications.¹³⁸ The latter may be due to an increased prevalence of prolongation of the QT interval in these patients, a phenomenon seen more frequently with age.¹³⁹ Because of this, regular electrocardiographic screening is necessary. When involved, the heart is typically dilated with depressed function, though hypertrophy is also seen.¹⁴⁰ Poor ventricular contractility can complicate acute metabolic crises, and patients presenting with encephalopathy should be assessed for left ventricular systolic dysfunction. The precise aetiology of the cardiomyopathy is not known, but disordered carnitine metabolism and toxicity of byproducts in the metabolic pathway of propionyl-CoA carboxylase are leading suspects. Treatment consists of restriction of proteins and supplemental oral carnitine.

Methylmalonic Aciduria

Methylmalonic aciduria is clinically similar to propionic acidemia and is due to a deficiency of methylmalonyl-CoA mutase. It can also be due to defects in its cofactor, adenosylcobalamin.¹⁴¹ The enzyme is required for the metabolism of valine, leucine, isoleucine, methionine and threonine and yields succinyl-CoA for the tricarboxylic acid cycle. Deficiency can lead to cardiomyopathy. Some patients, who likely have residual enzymatic activity, or whose disease is the result of defective or deficient cofactor, can respond favorably to supplemental cyanocobalamin. Those with deficiency of the enzyme itself are managed on a low-protein diet with carnitine supplementation. Despite therapy, however, the risk of metabolic crisis during acute illnesses remains high. Recently, hepatocyte-directed gene delivery has been shown to correct the enzymic activity, and may hold promise as a future corrective therapy.¹⁴²

Disorders of Fatty Acid Metabolism

The heart utilises fatty acids for energy production by converting long-chain free fatty acids to long-chain acyl-CoA via acyl-CoA synthetase. These acyl-CoA compounds are then transferred into the mitochondria, where they are degraded to produce acetyl-CoA for use in the tricarboxylic acid cycle.

Carnitine-acylcarnitine translocase mediates entry of fatty acyl-CoA compounds into the mitochondria. Deficiency often results in early death due to severe metabolic collapse with encephalopathy and hypertrophic cardiomyopathy, though patients with milder variants can present later. Treatment with medium chain triglycerides and carnitine supplementation can potentially avert the severe neurologic outcomes usually associated with this disease.¹⁴³

Carnitine palmitoyltransferase II converts acylcarnitine back to acyl-CoA for β -oxidation once it has crossed the inner mitochondrial membrane. Deficiency of this enzyme leads to nonketotic hypoglycaemia with seizures, hepatomegaly, and hypertrophic cardiomyopathy. Milder forms can present later with fasting or during periods of metabolic stress. Treatment consists of a low-fat diet, supplementation with medium-chain triglycerides, carnitine supplementation, and avoidance of fasting.¹⁴⁴

The acyl-CoA dehydrogenases mediate the reactions yielding acetyl-CoA from acyl-CoA compounds of varying lengths. These enzymes are referred to as short, medium,

long, and very long acyl dehydrogenases. Deficiency of any of these can yield a generalised myopathy along with nonketotic hypoglycemia and cardiomyopathy.⁹¹

DISORDERS OF COLLAGEN SYNTHESIS OR EXTRACELLULAR MATRIX

The group of disorders of collagen synthesis includes several diseases with cardiac involvement. Included in this discussion are Ehlers-Danlos syndrome, cutis laxa, osteogenesis imperfecta, and Marfan syndrome. Alcaptonuria also comes into this general group but, as yet, cardiac disease has not become manifest in childhood. Direct cardiac involvement does not occur in epidermolysis bullosa, but the heart may be affected when the condition is complicated by amyloidosis.

Ehlers-Danlos Syndrome

Phenotypical features unite the biochemically and genetically heterogeneous group of disorders included in Ehlers-Danlos syndrome. The stigmas are hyperextensible skin and joints, easy bruising, and poor healing of wounds. A distinctive facial appearance includes epicanthic folds, a flat bridge of the nose, and prominent downward pointing ears. The skin, apart from the palms and soles, is smooth and rubbery. In later life it may hang in folds from the elbows. Premature death is common in the most severe form, and the babies have poor muscular tone. In addition to the epicanthic folds, ocular signs include easy eversion of the upper eyelid, known as Metenier's sign, blue scleras, and a dislocated lens. A variety of congenital cardiac malformations have been reported,¹⁴⁵⁻¹⁴⁷ being found in approximately one-eighth of patients in one study. Prolapse of the mitral valve had previously been reported to be common in these patients, but a more recent study showed an incidence similar to that of the general population.¹⁴⁸

More than 10 subtypes of Ehlers-Danlos syndrome have been described, but six major subtypes are recognised and encompass nine-tenths of individuals affected. Patients typically fall into the hypermobility, classical or vascular type. Classic Ehlers-Danlos syndrome, incorporating types I and II, demonstrates the typical cutaneous findings. It most often results from defects in one or more of the collagen or procollagen genes. The hypermobility type is similar, with joint hypermobility the predominant clinical feature. Both of these types, while not characteristically demonstrating vascular changes, have been shown to be associated with dilation of the aortic root and valvar dysfunction.¹⁴⁹ The vascular type, also known as Ehlers-Danlos syndrome type IV, results from mutations in the gene encoding type III procollagen. These patients are at risk for arterial rupture, which typically occurs after the onset of the third decade of life.¹⁵⁰ A more severe recessive form has been reported, and includes both the cutaneous findings of the classic form coupled with cardiac valvar involvement.¹⁵¹

Cutis Laxa

Cutis laxa is, again, a genetically heterogeneous group of conditions characterised in the phenotype by the skin being so loose that it appears too large for the body. Unlike the Ehlers-Danlos syndrome, the lax skin is slow to recoil

after being stretched. Cutis laxa has some features in common with the Ehlers-Danlos syndrome, such as fragility of the skin, hypermobile joints, and easy bruising. There are characteristic facies, including a long upper lip, a hooked nose, and a short columella. The defect of connective tissue also results in a deep voice owing to lax vocal cords. Hernias and rectal or vaginal prolapse can also be seen. The disease can be inherited in both autosomal dominant and autosomal recessive forms. From the cardiac standpoint, peripheral pulmonary stenosis¹⁵² and aortic dilation have been reported.¹⁵³ These findings, coupled with reports of supralvalvular aortic stenosis,¹⁵⁴ have helped lead to the discovery that defects in the elastin gene are one cause of this disorder.¹⁵⁵ Defects in other genes, including fibulin-4 and fibulin-5, have also been implicated in some forms.^{156,157} Another major complication is cor pulmonale, since emphysema is frequently progressive and severe.¹⁵⁸ Patients with the neonatal variant of cutis laxa can have severe mitral regurgitation with dysplastic valvar leaflets.¹⁵⁹

Osteogenesis Imperfecta

Bone fragility is the main clinical feature of this condition. Although the fractures are subperiosteal with little displacement, the multiplicity of fractures leads to bowing of the long bones. Additionally, the vertebrae are biconcave, with the disc sometimes perforating the vertebral body to give the appearance known as Schmorl's nodes. The skull is frequently made up largely of wormian bones and shows frontal and parietal bossing. The skeletal deformities lead to short stature. The skin is thin but not lax. The sclerae are blue in most types. In the so-called type III variant of the disease, they may become less blue with age. The cardiovascular manifestations include aortic and mitral regurgitation owing to dilation of the valvar hinges or, in the latter, to prolapse from ruptured cords. It has been suggested that aortic root dilation may be present in a certain subset of patients with osteogenesis imperfecta, and that it appears to be nonprogressive.¹⁶⁰ In some patients, aortic or mitral valvar disease is severe and may require replacement surgery. This carries a higher than normal risk due to bleeding complications related to tissue friability. Administration of recombinant factor VIIa may be helpful in controlling bleeding in these patients.¹⁶¹ Aortic stenosis, defects of the oval fossa, and tetralogy of Fallot have also been reported.¹⁶²

Marfan Syndrome

Marfan syndrome is transmitted as an autosomal dominant disease with variable clinical expression. The prevalence is estimated at 2 to 3 per 10,000. The disease is due to defects in the FBN1 gene on chromosome 15q21, which encodes fibrillin-1, an important component of connective tissues. More than 500 mutations in the gene have been identified, and approximately one-quarter to three-tenths of cases represent new mutations. While the expression of the disease is highly variable, even among family members with the same genetic defect, some correlations between genotype and phenotype have been clarified.¹⁶³ More than seven-tenths of those affected are diagnosed before the age of 10 years. Physical features of the syndrome may be present at birth.¹⁶⁴ Affected persons are usually very tall, with an

increase in the length of the limbs compared with the trunk. Their arm span exceeds their height (Fig. 57-3A). They have long, thin fingers (Fig. 57-3B), hypermobile joints, kyphoscoliosis, and chest deformities. High arching of the palate, with dental crowding, is commonly seen, as are inguinal hernias. Ocular abnormalities occur in about three-quarters of patients. The most frequent are subluxation of the lenses and myopia. Because of the importance of identifying individuals with this disease, a multidisciplinary group of experts produced diagnostic criteria known as the Ghent nosology.¹⁶⁵ These criteria included skeletal findings as a major criterion, and also introduced molecular diagnostic tools into the clinical diagnosis of this disease (Table 57-2). Patients with a positive family history must meet the major criteria for at least one category, not including the genetic category, plus the criteria for involvement in a second category. Patients with no family history must meet the major criteria for two categories, plus the criterion for involvement in a third category.

Cardiac manifestations in childhood are usually less severe than in adults. Mitral valvar disease in the form of prolapse and incompetence are the most frequent abnormalities. They are present in approximately three-quarters of the patients.¹⁶⁶ Dilation of the aortic root, and fusiform aneurysms of the ascending aorta, are also common, particularly in males. The major consequences of these aortic lesions are valvar regurgitation and aortic dissection. Aortic involvement is progressive, and the risk of aortic dissection increases with increasing diameter due to increases in mural stress. Histopathological examination of the ascending aorta reveals degeneration of the elastic fibres, so-called cystic medial necrosis, which is most severe in patients with aneurysms. The leaflets of the aortic valves contain increased amounts of acid mucopolysaccharide. The mitral valvar annulus is dilated, and may become calcified. Pulmonary arterial dilation and aneurysmal formation have also been reported.¹⁶⁷ The electrocardiogram may show signs of left ventricular and left atrial enlargement when there is significant valvar insufficiency. Disturbances of rhythm, such as first-degree atrioventricular block, atrial ectopic beats, atrial flutter, fibrillation and tachycardia, are common. Ventricular arrhythmias are present in about one-third of the patients during childhood. Progressing with age, they appear to be closely related to mitral valvar prolapse and prolonged ventricular repolarisation.¹⁶⁸ Radiographic examination of the cardiac shadow is difficult in the presence of thoracic skeletal deformities. Cardiac enlargement may be seen in the presence of valvar insufficiency and dilation of the ascending aorta. Echocardiographic evaluation is essential. Mitral valvar prolapse is a very frequent finding. Dilation of the aortic root, sometimes with paradoxical motion of the posterior aortic wall, is common. Mitral and aortic incompetence will lead to left atrial and left ventricular volume overload. Doppler echocardiography should increase the early diagnosis of the valvar abnormalities. Cardiac catheterisation is useful for further assessment of these lesions. Aortic angiography will reveal the dilation of the aortic root. Evaluation with magnetic resonance imaging has demonstrated decreased aortic distensibility and increased stiffness in children with Marfan syndrome.¹⁶⁹

The pathophysiology of dilation of the aortic root is likely due to a complex interplay between altered vascular mural composition and other destructive processes. The

Figure 57-3 Typical body habitus of a patient with Marfan syndrome shows how the arm span exceeds the height by more than 5%. **B** shows the positive wrist sign, and **C** shows the positive thumb sign.

TABLE 57-2

DIAGNOSTIC CRITERIONS FOR MARFAN SYNDROME

Category	Major Criteria	Minor Criteria
Family history/ genetics	Positive diagnosis in a parent, sibling or child Known FBN1 mutation	None
Cardiac	Aortic root dilation Aortic dissection	Mitral valvar prolapse Calcific mitral valvar annulus (age < 40 years) Pulmonary arterial dilation with no other cause (age < 40 years) Other aortic dilation or dissection (age < 50 years)
Pulmonary	None	Spontaneous pneumothorax Apical blebs
Skin and integument	None	Striae atrophicae Recurrent or inci- sional hernias
Dura	Lumbosacral dural ectasia	None

defective collagen renders the arterial walls less distensible, but this alone has not proven to lead to arterial dilation. The dilation itself may be related to apoptosis of vascular smooth muscle cells, which has been shown to be related to angiotensin II receptor signaling pathways.¹⁷⁰ Additionally, defective microfibrils result in excessive activity of transforming growth factor- β , which is normally regulated by latent TGF- β binding proteins bound to microfibrils. This excessive TGF- β signaling leads to disordered formation of the matrix, and may be a principal cause of the vascular dilation found in these patients.¹⁷¹ Patients with Loeys-Dietz syndrome, and other disorders similar to Marfan syndrome, have been found to have defects in the gene encoding the TGF- β receptor.¹⁷² The complex interplay between fibrillin, microfibrils, LTBP (latent TGF- β binding proteins), TGF- β , and the TGF- β receptor probably accounts for the wide clinical variability in Marfan syndrome and other related disorders.

Life expectancy is very variable. Death usually occurs in the fourth decade, mainly from cardiovascular causes.¹⁷³ Cardiac failure, dissection or aneurysms of the aorta, and sudden death are the most frequent causes. Incompetence of both mitral and aortic valves carries a poor prognosis. There is no specific treatment for this condition. Cardiac failure is best treated with diuretics and vasodilators, since

the positive inotropic effects of digoxin may further damage the aortic root. Surgical replacement of the diseased valves, and of the ascending aorta, may be necessary. The benefits in children of prophylactic propranolol to delay the dilation of the aorta through its negative inotropic effects has been the subject of some debate. Arguments for¹⁷⁴ and against¹⁷⁵ a beneficial effect have been published. Additionally, with the discovery of a role for angiotensin II and TGF- β in the pathogenesis of aortic aneurysmal formation, investigations into inhibition of angiotensin converting enzyme and blockade of angiotensin receptors have begun.^{176,177}

The timing of surgery for repair or replacement of valves, or replacement of the aortic root, must be decided in light of the known risks of surgery, as well of the risks of not performing surgery. Elective replacement of the aortic root can be accomplished with a relatively low risk of mortality.¹⁷⁸ On the other hand, replacing the aortic root emergently due to acute dissection carries a much higher risk of short- and long-term mortality.¹⁷⁹ Early recommendations suggested elective replacement when the root reached an absolute diameter of 60 mm. Many patients suffer dissections at sizes significantly smaller than this, and an annual risk of mortality of nearly 5% has been described for patients with an aortic root greater than 50 mm.¹⁸⁰ Thus, recent recommendations concluded that replacement should occur electively before the root reaches a diameter of 55 mm.¹⁸¹ Additionally, it is difficult to determine which patients might have an increased risk for dissection at a relatively smaller size of the root. Certainly, for patients with a family history of aortic dissection, or for those in whom pregnancy is likely, intervention is encouraged at a relatively smaller size. Also, women appear to be at risk for dissection at a smaller size.¹⁸² Thus, some are now advocating elective replacement of the aortic root at sizes less than 50 mm.¹⁸³ In addition, procedures which allow for replacement while maintaining the native aortic valve have been evaluated and appear to be satisfactory, potentially eliminating the need for chronic anticoagulation.^{184,185}

Our group emphasises the importance of early diagnosis and follow-up, with serial measurement of the aortic root, and indexing this to document rates of relative growth, with respect to somatic growth. We institute β -blockade therapy early, and add inhibition of the angiotensin converting enzyme at the first sign of an increased rate of aortic dilation, and in patients with other risk factors such as a family history of aortic dissection. We review each patient carefully when the aortic root measures 45 mm to assess the need for surgical intervention, taking into consideration the specifics of each patient before deciding on the timing of elective repair.

Infantile Marfan Syndrome

An infantile variant of Marfan syndrome is seen on rare occasions. The skeletal and ocular manifestations are similar to the adult forms, but the cardiovascular features are distinct.¹⁸⁶ There is marked myxomatous thickening and redundancy of the leaflets of the mitral and tricuspid valves, with elongation of the tendinous cords leading to severe valvar insufficiency. Morbidity and mortality are primarily related to mitral and tricuspid valvar disease, as opposed to aortic dissection and rupture as seen in the adult form.¹⁸⁷ Additionally, patients with the infantile syndrome frequently exhibit pulmonary emphysematous changes. Because the infantile syndrome carries a poor

prognosis, it is important to differentiate it from the classic syndrome, which can occasionally be evident in a neonate. Neonates with the infantile syndrome present in congestive cardiac failure that responds poorly to conventional therapy. Death often occurs within the first 2 years of life, though surgical repair of mitral valvar disease at this age is feasible. A family history of Marfan syndrome is much less common in infants who present with severe cardiovascular symptoms early in life.¹⁸⁸ Most mutations resulting in the infantile syndrome occur between exons 24 and 32 in the fibrillin gene.

Loeys-Dietz Syndrome

Loeys-Dietz syndrome was first described in 2005 in a cohort of 10 families. It is characterised by hypertelorism, bifid uvula and/or cleft palate, and generalised arterial tortuosity with ascending aortic aneurysmal formation and dissection.¹⁸⁹ There is some phenotypical overlap with Marfan syndrome, but the hypertelorism, palatal involvement, and widespread arterial changes help to differentiate this from Marfan syndrome and other similar disorders. Recognition of this disease is critical, as early evaluation for aortic aneurysm formation may lead to operation at a young age. Because of the aggressive nature of root dilation, replacement is recommended at diameters of 40 mm in adults and at even smaller diameters in children.¹⁹⁰

Homocystinuria

Homocystinuria is an autosomal recessive disorder usually due to deficiency of cystathionine synthase, an enzyme needed for the metabolism of methionine. Affected patients have a bodily habitus similar to those with Marfan syndrome, albeit that their joints usually demonstrate restricted mobility. Cognitive deficits are also common. The primary cardiac complication is that of atherosclerotic disease, which often occurs by adolescence. Endothelial dysfunction contributes to the arterial complications and produces an increased risk for myocardial infarction.¹⁹¹ Vitamin B₆ helps to reduce levels of homocysteine in approximately half of patients, and this, along with supplementation of vitamin B₁₂ and folic acid, forms the mainstay of therapy.

NEUROMUSCULAR DISEASES

Muscular Dystrophies

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy is an X-linked recessive disease. Because of this, it almost always afflicts males. Its incidence in male children is calculated at between 13 and 33 cases for each 100,000 live births. Since females with Turner syndrome have only one X chromosome, they too can inherit the disease, and it is seen rarely in this setting. The disease is due to a defect in the gene encoding dystrophin. Dystrophin helps to form a complex which stabilises the sarcolemmal membrane during contraction. While the exact mechanism for muscle degeneration has not been elucidated, abnormal nitric oxide regulation, abnormal sarcolemmal fragility, and increased susceptibility to oxidative stress are felt to play important roles.¹⁹²

The earliest symptoms are clumsiness in walking, a tendency to fall, and an inability to run. Those with the disease

also have difficulty in climbing stairs and getting up from the floor. Clinical onset is usually manifested before 4 years of age, and the diagnosis is usually made around 6 years of age. Deterioration is continuous. Most are unable to walk by the age of 10 years. Life expectancy is increasing owing to improved medical therapies, including nocturnal ventilation, early and aggressive management of cardiomyopathy, and perhaps the use of corticosteroids.¹⁹³ Muscular weakness and atrophy initially affect the proximal muscle groups of the upper limbs. Involvement of the legs extends from the quadriceps and gluteal muscles to the anterior tibial muscles. Weakness later affects other muscle groups. More power is generally retained in the distal muscles. Slight facial weakness occurs in the late stages. Scapular winging is also a later phenomenon. Muscular hypertrophy of the calves, masticatory muscles, and deltoids is followed by a pseudohypertrophic phase of fatty replacement. Tendon reflexes are lost in the weak muscles. Contractures of the calves and flexor muscles of the hip develop around the age of 8 years. Contractures appear in the hips, knees, elbows, and wrist when the patients are confined to wheelchairs. Severe spinal and thoracic deformities are seen late in the disease. Kyphoscoliosis is common. These result from disuse and abnormal posture. Generalised decalcification of the bones leads to frequent pathological fractures.

Myocardial involvement is common. It is uncertain at what stage it begins, since the physical incapacity limits its manifestation. The heart can be involved from an early age, and in ambulatory patients, subclinical disease may become symptomatic with exercise. In non-ambulatory patients, a resting tachycardia,¹⁹⁴ decreased heart rate variability,¹⁹⁵ echocardiographic evidence of diastolic dysfunction,¹⁹⁶ and myocardial strain changes on magnetic resonance imaging¹⁹⁷ may help to alert the clinician to subclinical myocardial involvement so that medical therapy can be initiated. The roles of cardiac troponins and brain natriuretic peptide are also being evaluated in the assessment of these patients.¹⁹⁸ The cardiac dysfunction is progressive, ultimately resulting in a dilated cardiomyopathy, and the benefits of early medical therapy are controversial. Some advocate early use of afterload reduction therapy,^{199,200} but others have shown a benefit only when afterload reduction is combined with β -blockade.²⁰¹

There is a distinctive electrocardiographic pattern in from half to nine-tenths of patients. This includes tall R waves over the right precordial leads with increased R:S amplitude ratios, together with narrow and deep Q waves in the limb and left precordial leads. Female carriers may also have the abnormal electrocardiogram.²⁰² These findings correspond to pathological observations. There is fatty and fibrous tissue replacement of the myocardium, with selective scarring of the posterolateral wall of the left ventricle and, sometimes, involvement of the posterolateral papillary muscle. Conduction abnormalities are also frequently seen. Among these are prolonged intra-atrial conduction, right bundle branch block, a superior QRS axis, and a short PR interval. Histological studies of the conduction system show multifocal areas of fibrosis, vacuolisation and fatty infiltration.²⁰³ The echocardiogram reveals impairment of both systolic and diastolic function. The thickness of the left ventricular wall is decreased, and this is not related to physical inactivity. The end-diastolic and end-systolic dimensions of the left ventricle increase as systolic function deteriorates.

The diagnosis is made from the clinical characteristics, the high levels of activity of creatine kinase, and biopsy of the skeletal muscles. Creatine kinase activity is from 100 to 300 times the normal when the patients are aged from 1 to 5 years. Other muscle enzymes, like aldolase, glutamic oxalic transaminase, lactic dehydrogenase, and pyruvate kinase are also grossly elevated. The levels of creatine kinase diminish later in the disease, but still remain well above normal limits. Muscle biopsy shows scattered hyaline fibres with active muscular necrosis and regeneration. There is splitting of the muscle fibres, with fatty replacement. The nucleuses are of varied size. The muscle fascicles also become surrounded by perimysial and endomysial connective tissue. Electromyography reveals a decrease in the mean action potential voltage and its duration. An increase in the number of polyphasic potentials is also seen.

Careful general medical management is critical. Since bedrest is harmful, regular physical activity and exercise are to be encouraged. Avoidance of obesity is an important general measure, along with prevention of muscular contractures by passive stretching. Because of the risks of anaesthesia and immobilisation, the benefit from major orthopaedic procedures must be carefully considered. Prevention of scoliosis and thoracic deformities in the wheelchair phase help to avoid respiratory impairment and slow the deterioration of respiratory function. Death is usually from respiratory infections and insufficiency, and cardiac failure or arrhythmias. Detection of carriers is important for appropriate genetic counselling. More than half the carriers can be identified by their elevated levels of creatine kinase, by electromyography and by muscle biopsy. The analysis of the pedigree is particularly useful. Novel treatments for this myopathy are actively being investigated. They include gene therapy,²⁰⁴ use of inhibitors of proteases,²⁰⁵ membrane stabilisers,²⁰⁶ and transplantation of the muscle precursor cells.²⁰⁷

Childhood Limb-girdle Muscular Dystrophy

The childhood limb-girdle muscular dystrophies are a heterogeneous group of genetic muscular disorders. At least 17 different types have been described. They can be inherited in either an autosomal dominant or recessive fashion, with 7 genetic defects now identified in the dominant forms, and 11 in the recessive forms. The age at onset is variable, but symptoms generally appear between 5 and 10 years of age. Weakness of the pelvic and shoulder muscles predominates. The disease is slowly progressive, the patients often becoming unable to walk by their twenties. The disease is first suspected when weakness of the limb girdles becomes apparent, although Duchenne's and Becker's muscular dystrophy must be ruled out. An elevated level of creatine kinase will not differentiate between this entity and the dystrophinopathies. This can be done through analysis of the dystrophin gene, and by examination of a muscle biopsy. Various forms of the disease affect the heart. Those with the so-called 1B variant, produced by a mutation in the lamin A/C gene, frequently develop arrhythmias which can be lethal and which may require placement of an implantable defibrillator. Atrioventricular block can also occur, necessitating placement of a pacemaker.²⁰⁸ This disorder can also result in a dilated cardiomyopathy.

Those with the 2I variant, caused by a defect in the gene encoding the fukutin-related protein, may develop a dilated cardiomyopathy by the third decade. Evidence of

arrhythmias is not seen.²⁰⁹ The precise role of the fukutin-related protein is unknown, but it may play a role in the glycosylation of muscle membrane proteins.

Myotonic Muscular Dystrophy (Steinert Disease)

The involvement of systemic tissues, together with the presence of myotonia and muscular atrophy, separates myotonic muscular dystrophy from the other muscular dystrophies. It has a high incidence, calculated at 13.5 per 100,000 live births. Onset is usually between 20 and 50 years of age, but many cases are clinically apparent during childhood. It is due to an expansion of a CTG trinucleotide repeat on the q arm of chromosome 19.²¹⁰ It is transmitted in an autosomal dominant fashion and demonstrates genetic anticipation. Myotonia is the presenting clinical feature in one-third of cases. Others present with weakness of the hands, foot drop, or a tendency to fall. The heart may occasionally become involved prior to diagnosis of the neuromuscular disorder. The facial, masticatory, sternomastoid, forearm, anterior tibial and peroneal muscles are those first affected by weakness. Later it extends to neighbouring muscle groups. The typical facies are characterised by lack of facial expression, and difficulty in closing the eyes and moving the mouth. Ptosis and dysarthria are frequent. Myotonia is often limited to the tongue, forearms and hands, but it may be generalised. The tendon reflexes in the affected muscle groups are reduced.

Cataracts are present in almost all those affected. Impaired pulmonary vital capacity and maximum breathing capacity are common. Abnormal contractions of the oesophagus are thought to be the cause of dysphagia and pulmonary aspiration. Testicular atrophy, diabetes mellitus, increased metabolism of immunoglobulin G with low levels in the serum, progressive dementia, and subnormal intelligence are frequent associations. Cardiac involvement is common and manifests with conduction defects and arrhythmias. First-degree atrioventricular block is commonly seen, and this may progress to complete heart block requiring implantation of a pacemaker.²¹¹ No relationship exists between the degree of involvement of the cardiac and the skeletal muscles. Chest radiography will show the associated deformities of the bony thorax, together with elevated hemidiaphragms. The cardiac silhouette is normal. Death from cardiac involvement is almost always caused by complete atrioventricular block or ventricular tachycardia. It is very rarely caused by myocardial failure.

The most common abnormalities in the electrocardiogram are low amplitudes of the P wave, atrioventricular block of any degree, right and left bundle branch block, abnormal Q waves, and changes in the ST segment and T wave. It is believed that regional myocardial dystrophy is responsible for the abnormal Q waves.²¹² Rhythm disturbances include sinus brachycardia, premature atrial beats, atrial fibrillation, atrial flutter, ventricular premature beats and ventricular tachycardia. Four-fifths of the patients have electrophysiological evidence of disease of the atrioventricular conduction axis. A further one-fifth have evidence of intra-atrial conduction disturbances.²¹³ Disease of the atrioventricular conduction axis progresses with time. A correlative study revealed fibrosis of the right and left bundle branches and fatty infiltration and degeneration around the atrioventricular node, which corresponded accurately with the electrocardiographic and electrophysiological evaluation performed during life.¹⁸⁶

Mitral valvar prolapse is frequently associated with myotonic muscular dystrophy and is diagnosed echocardiographically. It is present in approximately one-third of patients. There is no relationship, however, between mitral valvar prolapse and the arrhythmias. Systolic and diastolic function are normal. Normal ejection fractions at rest are recorded with radionuclide angiography. Some patients fail to show an increase with exercise. Apical hypokinesia may be present but is of doubtful significance. Careful clinical examination and a high degree of suspicion are required for an early diagnosis. Electromyography and muscle biopsy are useful techniques, as is examination for cataracts using a slit lamp. Cardiological evaluation is required in all patients because of the frequent association of cardiac disease. The disease shows progressive deterioration, with physical incapacity usually occurring 15 to 20 years after the onset of muscular symptoms. Death is usually from respiratory infections, aspiration, cardiac arrhythmias, or anaesthetic complications. There is no specific treatment for the condition. Active exercise and control of weight are important general therapeutic measures. Systemic complications are treated as they arise. Myotonia is relieved by the use of procainamide or phenytoin. Caution must be exerted, however, since procainamide exacerbates pre-existing disturbances of conduction. Electrophysiological studies are warranted in symptomatic patients presenting with syncope or presyncope. A ventricular pacemaker is needed when there are significant abnormalities in the formation or conduction of the cardiac impulse. Myotonic muscular dystrophy appears and progresses during early adult life in the majority of those affected. In a proportion, however, the disease is present at birth. Such congenital cases are often treated as a separate entity. Indeed, as will be seen, they have a totally different presentation and clinical picture. In the fullness of time, they come to resemble the adult form.

The congenital form is characterised by bilateral facial weakness, hypotonia, and mental retardation with delayed motor and speech development. Neonatal respiratory distress is very frequent. Such infants have a high incidence of feeding difficulties owing to muscle weakness. Talipes are a common association. Clinical myotonia is absent but can be demonstrated electromyographically. The adult features of the disease appear during late childhood and adolescence. Cardiac involvement takes the form of a dilated cardiomyopathy. Non-specific electrocardiographic abnormalities appear with progression of the disease. Mortality occurs in the neonatal period as a result of respiratory distress. Beyond this time, there is a tendency to improve, only for the patients to deteriorate as the adult characteristics of the disease appear. The condition is transmitted by the mother. Her clinical involvement has often failed previously to be noted.

Autosomal Dominant Scapuloperoneal Myopathy

Scapuloperoneal myopathy is a very rare form of muscular dystrophy. It is possible to recognise two distinct groups according to the age of onset. They share an autosomal dominant form of inheritance, and involve the same muscle groups. Weakness and atrophy affect the neck, shoulder girdle, and upper arm muscles, together with the tibial and peroneal muscles in the legs. Foot drop and an awkward gait are frequent early symptoms. Deep tendon reflexes are commonly absent. Levels of creatine kinase are slightly

elevated in the serum. Electromyography and muscle biopsy show the changes common to muscular dystrophies.

The group of patients with early onset generally present under the age of 10 years. In these, the disease takes a rapid course. Patients develop early contractures and are severely incapacitated by their late teens. They frequently have clinical and electrocardiographic signs of a dilated cardiomyopathy with congestive cardiac failure.²¹⁴ Those patients having a late onset present over the age of 40 years, and their clinical course is slow. They seldom develop contractures. Cardiac involvement, usually late, could well be a result of ischaemic heart disease.²¹⁵

Becker's Muscular Dystrophy

Becker's muscular dystrophy is one of the most frequent types of muscular dystrophy. It is inherited in X-linked recessive fashion. The incidence is of the order of 3 to 6 per 100,000 male births. The muscular groups involved are very similar to those in Duchenne's muscular dystrophy. The peroneal and anterior tibial muscles are also affected in the Becker variant. The facial muscles are not involved. Calf hypertrophy and muscle cramps are frequent early symptoms. Club feet are often seen. Contractures appear in the final stages, and scoliosis is rare. Developmental delay is uncommon. The onset of the symptoms is between 5 and 15 years of age, with inability to walk being present by the third decade, and death occurring in the fifth. The individual range, however, is very wide. The diagnosis is primarily clinical. Activity of creatine kinase in the serum is 25 to 200 times the normal. The electromyogram and the muscle biopsy are nonspecific but help to rule out other conditions.

Cardiac abnormalities are infrequent in childhood but are almost always present in some form by the onset of the fourth decade.²¹⁶ Electrocardiographic abnormalities are common and include resting tachycardia, interventricular conduction delay, and Q waves in leads II, III, and aVF, suggesting damage to the lateral wall of the left ventricle.²¹⁷ Heart rate variability is also decreased and may indicate a risk for sudden death.²¹⁸ Dilated cardiomyopathy is seen, and the risk of ventricular dysfunction increases with age, though many patients are asymptomatic from a cardiac standpoint, exhibiting abnormalities only on the electrocardiogram or echocardiogram.²¹⁹ Transplantation of the heart for severe left ventricular systolic dysfunction is a well-established palliative option.²²⁰

Facioscapulohumeral Muscular Dystrophy (Landouzy-Dejerine Syndrome)

Facioscapulohumeral muscular dystrophy is inherited in an autosomal dominant fashion. It has an incidence of approximately 5 per 100,000 live births. Facial and shoulder weakness generally develop in the second or third decade and progress very slowly. Patients with severe forms of this disease will occasionally present early in life, and progression is then rapid. Characteristically, there are no facial lines and the eyelids are very weak. Winging of the scapulas is seen when the arms are abducted, and there is a marked thoracolumbar lordosis. Affected muscles include the neck flexors, the serrate and pectoral muscles, biceps and triceps in the upper limbs, the hip flexors, and the anterior tibial muscles. In the later stages, the quadriceps and sartorius in the lower limbs are also affected. Retinal vasculopathy is also seen frequently. The levels of creatine kinase in the serum are normal or else only mildly elevated. The precise molecular mechanism for expression

has not been elucidated, but patients are known to have a large deletion involving the q arm of chromosome 4. No gene has been identified within this region, and so various hypotheses have been presented to explain the mechanism whereby this deletion induces clinical disease.²²¹

Ventricular function is not affected. Supraventricular tachycardia has been reported with a frequency higher than that of the general population.²²² Sinus nodal dysfunction, abnormal atrioventricular nodal or infranodal conduction, and easily inducible atrial fibrillation or flutter have also been reported in around one-quarter of patients studied.²²³

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy typically presents between 5 and 15 years of age. It can be inherited in an X-linked recessive fashion, or in autosomal dominant or autosomal recessive forms. The biceps and triceps are more severely affected than the deltoid muscle. The peroneals are more involved than the proximal musculature of the legs. Contractures generally develop at the elbows, posterior cervical muscles, and Achilles tendon. Pseudohypertrophy is absent. Levels of creatine kinase are from 3 to 10 times above normal. Progression is very slow, and the physical limitations are minimal. There is normal intellectual function.

The X-linked form is due to a defect in the gene encoding emerin, a nuclear envelope protein which plays a role in the regulation of many cellular and nucleolar processes. Its role in the pathogenesis of muscle damage remains to be elucidated. The autosomal dominant form is due to defects in the lamin A/C gene, similar to variant 1B of limb-girdle muscular dystrophy. Again, the role of lamin A/C mutations in the development of the myopathy is not clear. The recessive form is also due to defects in the gene encoding lamins A and C.²²⁴ How and why defects in the same gene can cause dominant and recessive forms of the disease remains to be discerned.

Cardiac involvement is often manifested by atrial arrhythmias and atrioventricular block. Any degree of atrioventricular block can be present, and a slow junctional escape rhythm is common. Severe sinus bradycardia or sinus arrest is seen and may require implantation of a pacemaker because of the increased risk of sudden death.²²⁵ Atrial paralysis, with the absence of P waves and an inability to electrically pace the atrium, is seen. Ventricular function is often normal, but progressive left ventricular dysfunction occurs due to fibrous infiltration of the myocardium.²²⁶ Cardiac transplantation has been employed for end-stage disease.²²⁷ Those with bradycardia may have hypertrophied and dilated left ventricles, probably as a compensatory physiological response. Electrophysiological studies show prolonged HV intervals and, on some occasions, a complete absence of the His potential. This finding, together with the very slow junctional escape rhythms, suggests that the myopathic process extends into the atrioventricular conduction axis. The high risk of sudden death in this variety of muscular dystrophy makes early recognition important, since insertion of a ventricular pacemaker in patients with bradycardia will improve survival.

Centronuclear Myopathy

This uncommon muscular disorder is characterised by ptosis, strabismus, generalised muscle wasting, and weakness, together with absent or reduced deep tendon reflexes.

Developmental delay and dysarthria are common. A dilated cardiomyopathy has been occasionally observed, and cardiac transplantation has been performed.²²⁸ Patients have a prolonged PR interval and a superior axis on the electrocardiogram. The diagnosis is based on clinical findings, raised levels of creatine kinase in blood, evidence of a myopathy on electromyography, and a typical histological picture. This consists of central location of the nucleus, with variation in the diameter of the muscle fibres and a tendency for predominance of type 1 fibres. Inheritance is variable. The X-linked form is usually the most severe and involves the gene encoding myotubularin. An autosomal recessive form seems to have a milder course, though patients still present in childhood. The autosomal dominant form is milder, with patients reaching adulthood before the onset of symptoms.

Nemaline Myopathy

The nemaline myopathies are so named because muscle specimens demonstrate rods within the myocytes. This group of clinically heterogeneous disorders can result from defects involving actin, troponin, myosin, or tropomyosin. While the skeletal muscles are predominantly involved, cases of hypertrophic and dilated cardiomyopathy are becoming increasingly evident. The main focus is on the α -actin gene, ACTA1, in which numerous defects have been described.²²⁹ Patients can have a very mild course of skeletal muscle weakness or severe neonatal disease leading to respiratory failure. Hypertrophic cardiomyopathy is more commonly seen,²³⁰ but dilated forms of cardiomyopathy have also been reported.²³¹

Friedreich's Ataxia

Friedreich's ataxia is a rare spinocerebellar neuromyelopathy occurring in approximately 1 to 2 per 40,000 persons. The disease is inherited in an autosomal recessive fashion, and most cases are due to homozygosity for an expanded GAA triplet on chromosome 9q13.²³² This gene encodes frataxin, a precursor protein which may be involved in the maturation and assembly of iron and sulphur proteins of the mitochondria and cytosol.²³³ Children present around the age of 6 years. The most frequent early symptom is an abnormal gait. Neurological signs include the ataxic gait, absent tendon reflexes, incoordination, and a positive Romberg test.²³⁴ Weakness and muscular atrophy of the legs are common, as are dysarthria and loss of vibration and positional sense and extensor plantar responses. Some patients have nystagmus. The presence of brisk tendon reflexes makes the diagnosis of Friedreich's ataxia very unlikely. Skeletal involvement is common, with club feet and scoliosis among the most frequent manifestations. Apart from the clinical aspects of the disease, nerve conduction studies are essential to support the diagnosis. Motor conduction velocity is normal, and sensory conduction is absent or markedly reduced. Since clinical, electrocardiographic, and radiographic examination of the heart are non-specific for the evaluation of cardiac involvement, an echocardiogram is necessary in every patient.

The heart is involved in a very high percentage, and cardiac symptoms are an integral part of the clinical spectrum of the disease. Most usually, the heart exhibits a

symmetrical, concentric, and slowly progressive hypertrophic cardiomyopathy. Cardiac involvement may occasionally precede the onset of neurological manifestations.²³⁵ Cardiac symptoms are present in approximately one-third of the patients, and consist mainly of exertional dyspnoea, palpitations, and angina. Clinical findings of cardiac disease are not present in every case. When they are, they include systolic murmurs at the left sternal border and apex, together with third and fourth heart sounds. The pulse may have a rapid upstroke. Evaluation of the severity of disease by physical examination is often difficult because of the presence of scoliosis and the lack of consistent cardiovascular signs. Interestingly, the degree of cardiac involvement appears to correlate with the size of the GAA repeat of the smaller allele, or with the mean size of the repeats in both alleles.²³⁶

Pathological studies reveal cardiac dilation with ventricular hypertrophy. Histologically, there is a degeneration of myocardial cells with myocardial fibrosis. Intracellular granular deposits of calcium and iron are seen. It is hypothesised that iron-catalysed mitochondrial damage may lead to the pathologic findings in the myocardium.²³⁷ Electrocardiographic changes are present in over two-thirds of patients, and they progress in relation to the duration of the disease. The most frequent changes involve the ST segments and T waves. These are non-specific and are presumably caused by repolarisation disturbances from the underlying myocardial fibrosis. Signs of ventricular hypertrophy are also frequent, and right- or left-axis deviation is common. Arrhythmias are not frequent. When present they include supraventricular and ventricular premature beats, supraventricular tachycardia, atrial flutter and atrial fibrillation.²³⁸

The presence of scoliosis makes radiographic evaluation of the heart difficult, albeit that its size is usually normal. Most patients have an abnormal echocardiogram. The most common anomalies reflect the presence of symmetrical concentric hypertrophic cardiomyopathy. There is an increase in left ventricular mural and septal thickness. Asymmetrical septal hypertrophy is seen on occasion.²³⁹ Impaired left ventricular function has also been shown echocardiographically and may be the end-stage of the cardiomyopathic process, as reduced fractional shortening of the left ventricle is common. The systolic function of the posterior wall is more severely affected than that of the septum. Abnormal diastolic function may antedate systolic abnormalities. A constant feature is the delay in mitral valvar opening.

The clinical course is marked by steadily progressive deterioration. Cardiac failure, which appears late in the course of the disease, has a poor prognosis and is often a pre-terminal event. Most patients die from cardiac causes. Cardiac failure accounts for half of the deaths. Cardiac arrhythmias and respiratory complications are the other major causes of death. While conventional methods for treating hypertrophic and dilated cardiomyopathy are frequently employed, newer therapeutic options for patients with Friedreich's ataxia have come to light in recent years. Idebenone, a free-radical scavenger, was tested under the hypothesis that iron overload leads to damage of iron-sulfur cluster-containing enzymes, which may lead to the damage seen in the myocardium.²⁴⁰ Though the treatment remains somewhat controversial and is not universally accepted, several small trials show a consistent benefit in

terms of reduction of cardiac mass and improvement in function.^{241,242}

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita presents with joint contractures at birth in at least two different areas of the body. A typical presentation includes equinovarus deformities of the feet, abducted hips, incompletely extended knees and elbows, pronated forearms, and claw hands. The majority of those affected have a neurogenic cause with patchy loss of anterior horn cells, though some cases are caused by primary myopathic disorders. They may result from environmental factors, or may demonstrate a familial propensity. The heart is rarely involved. A report of the myopathic form of arthrogryposis multiplex congenita revealed congenital cardiac disease in one-quarter.²⁴³ These cases resulted from consanguineous matings, and 5 of 6 with congenital cardiac malformations resulted from one pairing.²⁴⁴ Patency of the arterial duct, congenital aortic stenosis, and mitral stenosis have been reported.^{221,245}

Hereditary Motor and Sensory Neuropathy (Peroneal Muscular Atrophy, Charcot-Marie-Tooth Disease)

The hereditary motor and sensory neuropathies are a diverse group of disorders typically inherited in an autosomal or X-linked dominant fashion. Links to defects in connexins and other Schwann cell proteins are well described.²⁴⁶ They are predominantly a motor neuropathy producing atrophy and weakness of the distal muscles. This determines the typical likeness of the legs to an inverted bottle. Bilateral club foot is a frequent association. The hand and forearm muscles may also be involved. There is a decrease or loss of the deep tendon reflexes. Electromyographic studies show slowing of nerve conduction velocity or signs of denervation. The cardiac involvement has classically been related to supraventricular arrhythmias and conduction system abnormalities. Sick sinus syndrome, right bundle branch block, complete heart block, Wolff-Parkinson-White syndrome, atrial fibrillation, and atrial flutter have been described.^{247,248} It has been postulated that there is a primary degeneration of the conduction system rather than changes secondary to a cardiomyopathy.²⁴⁹ In addition to arrhythmias, left ventricular hypertrabeculation or non-compaction has been reported in a patient with the type 1A variant of Charcot-Marie-Tooth disease, and a duplication defect on chromosome 17 involving the peripheral myelin protein 22.²⁵⁰ The Roussy-Lévy syndrome is a phenotypic variant of the type 1A, and shares many features with this disease.²⁵¹ Dilated cardiomyopathy has been reported.²⁵²

Spinal Muscular Atrophy Type III (Juvenile Spinal Muscular Atrophy, Kugelberg-Welander Syndrome)

Juvenile spinal muscular atrophy appears in childhood or adolescence. Initially it is manifested by weakness and atrophy of the proximal limb muscles, which is later followed by distal disease. The usual presentation is with difficulty in walking, climbing stairs and lifting the arms. Fasciculation is seen in half those affected. The clinical course is slowly progressive. There is evidence from electromyography and muscle biopsy to indicate disease of

the lower motor neurons. Some patients have an associated dilated cardiomyopathy, though this may be secondary to associated respiratory disturbances.²⁵³ Disturbances of rhythm are very frequent and include atrial premature beats, atrial fibrillation, atrial flutter, and advanced degrees of atrioventricular block. Some patients require the implantation of a pacemaker.²⁵⁴ The electrocardiogram frequently shows a fine tremor on the isoelectric line, which represents fasciculations characteristic of this disease.²⁵⁵ The syndrome is transmitted in autosomal recessive fashion and is due to defects in the survival motor neuron 1 gene.²⁵⁶ The infantile form of spinal muscular atrophy, or Werdnig-Hoffman disease, is a lethal variant presenting with severe hypotonia and respiratory failure. Various congenital cardiac malformations have been reported in patients with this disease, but these are likely chance associations.^{257,258}

Refsum Disease

Refsum disease is a rare neurological disorder due to the accumulation of phytanic acid in peroxisomes. Phytanic acid is a branched-chain fatty acid which is partially broken down by phytanoyl-CoA 2-hydroxylase. Many cases of the disease are due to defects in the gene encoding this enzyme.²⁵⁹ This leads to accumulation of phytanic acid in blood and tissues. Symptoms appear in the first and second decade of life, the initial presentation being weakness, unsteady gait and night blindness. These patients have a diagnostic tetrad made up of retinitis pigmentosa, peripheral polyneuropathy with diminished or absent deep tendon reflexes, cerebellar ataxia, and high levels of protein in cerebrospinal fluid without pleocytosis. Other frequent signs are neural deafness, anosmia, nystagmus, and abnormalities of the pupils. The heart is rarely affected. Conduction abnormalities, especially advanced degrees of atrioventricular block requiring pacemaker therapy, are well known. Cardiomyopathy is a rare association.²⁶⁰ Diets low in phytanic acid produce clinical improvement. Complete recovery is rarely obtained, but treatment will slow the progression of the disease. The addition of plasmapheresis to the diet reduces the levels of phytanic acid more rapidly.²⁶¹

DEFICIENCIES

Selenium

Selenium is a trace element that is an essential component of glutathione peroxidase. The enzyme removes organic hydroperoxides from the cell. Absence of selenium, possibly associated with absence of vitamin E, permits damage to the cell membrane by lipid peroxides. Deficiency of selenium, also known as Keshan disease, affects children living in areas with a poor content of selenium in the soil or those having a poor diet.²⁶² It gives rise to an endemic cardiomyopathy that affects children between 1 and 9 years of age living in an area extending from the northeast to the southwest of China where the content of selenium in the soil and food is very low. It has also been reported with nutritional changes related to bariatric surgery²⁶³ and with total parenteral nutrition.²⁶⁴ The incidence has been significantly reduced by supplementing oral sodium selenite in the diet, with no adverse side effects. Once fully developed, the cardiomyopathy is irreversible.²⁶⁵ Early recognition of the cause of the cardiomyopathy, with timely

institution of supplementation with selenium, can bring about resolution.²⁶⁶ Histopathological features of the heart are areas of myocytic loss with replacement fibrosis in the subepicardial surface of the ventricles.²⁶⁷

Carnitine

L-Carnitine, or hydroxy-trimethylammonium butyrate, is an essential cofactor in the transfer of long-chain fatty acids across the inner mitochondrial membrane. Depletion of carnitine blocks the mitochondrial oxidation of fatty acids and leads to cytoplasmic accumulation of lipids. Cardiac and skeletal muscles use fatty acids as their main substrate and, therefore, are very sensitive to carnitine.²⁶⁸ Primary syndromes due to deficiency of carnitine are divided into myopathic and systemic forms. Patients with muscular deficiency present with progressive weakness and are thought to have abnormal transport of carnitine into skeletal muscle. They have normal levels of carnitine in the plasma, but low concentrations in the muscles. Systemic deficiency presents early in life, with encephalopathy, hypoglycaemia, liver failure, and cardiomyopathy.²⁶⁹ Muscle weakness and developmental delay are common. Hypotheses for the cause of systemic deficiency include defects in synthesis, renal handling, gastrointestinal absorption and cellular transport, and excessive degradation. At least some cases have been demonstrated to be due to defects in the carnitine transporter gene.²⁷⁰ Accumulation of triglycerides in muscle often occurs, since fatty acids are not transported effectively into the mitochondria for oxidation. Patients often have low concentrations of carnitine in the plasma and tissues, though this is not a sensitive marker for the disease.

Cardiomyopathy has frequently been reported in association with either systemic or myopathic deficiency. Many patients are in cardiac failure when they come to medical attention.²⁷¹ The electrocardiogram is non-specific, with signs of left ventricular hypertrophy. Very tall and peaked T waves, like those seen in hyperkalaemia, have been described.²⁷² The echocardiogram reveals left ventricular and left atrial dilation with signs of poor left ventricular function. The last can also be demonstrated by nuclear angiography. Cardiac failure responds poorly to conventional therapy. Endocardial fibroelastosis as a result of systemic deficiency has been described.²⁷³ The diagnosis is dependent on the demonstration of low levels of carnitine in the tissues or blood, though normal levels do not rule out the disorder. Muscle biopsy shows large amounts of lipids in type I muscle fibres and abnormal mitochondria. The disease is usually fatal without treatment. Oral L-carnitine produces clinical improvement in many patients.²⁷⁴ Others fail to respond to therapy.²⁷⁵ Diarrhoea is the main side effect. Diets with only 20% of calories from fat are also useful in long-term treatment. Carnitine deficiency is inherited in autosomal recessive fashion.

Thiamine (Beriberi)

Thiamine, or vitamin B₁, is a water-soluble vitamin that is absorbed from the small intestine. In its active form of thiamine pyrophosphate, it is an essential coenzyme in the metabolism of pyruvate and in the transketolase reaction. Deficiency produces a disease known as beriberi, which has

been related to diets consisting of polished rice in oriental societies, and to alcoholism in occidental ones. Classically, the disease has been divided into two major types. In dry beriberi, the patients have peripheral neuropathy with varied disorders of sensation, sometimes amounting to anaesthesia, muscle weakness and atrophy, reduced deep tendon reflexes, fatigue, and difficulty in concentrating. In contrast, in wet beriberi, where the presenting features are a high output cardiac failure with peripheral oedema, the patients have diminished peripheral vascular resistance as a result of muscular arteriolar vasodilation, a wide pulse pressure, and a warm skin. The mechanism leading to a reduction of peripheral vascular resistance is believed to be directly related to the lack of thiamine, since after treatment this parameter returns rapidly to normal.²⁷⁶ Despite high cardiac output, oliguria is present owing to reduction of renal blood flow and glomerular filtration rate. Increased jugular venous pressure results from peripheral venoconstriction and from an increase in the circulating blood volume.²⁷⁷ Cutaneous vasoconstriction becomes evident with progression of cardiac failure, and this results in cold hands and peripheral cyanosis. It is not clear whether the cardiac failure results from primary myocardial involvement or whether it is secondary to the vascular changes. In some patients, the additional toxic effects of alcohol make this differentiation very difficult. Histological studies of the heart have shown hydropic degeneration, interstitial and perivascular oedema, and fibrosis and necrosis of myocardial tissue.²⁷⁸

An acute variant of the disease with vascular collapse, metabolic acidosis, and variable cardiac output is known as Shoshin beriberi. Patients present in severe biventricular failure. They have renal dysfunction leading to metabolic acidosis. There is a high arterial saturation of oxygen secondary to tachypnoea, which contrasts with peripheral cyanosis caused by cutaneous vasoconstriction.²⁷⁹ Cardiac catheterisation reveals increased right and left atrial pressures and a low peripheral vascular resistance.²⁸⁰ Early diagnosis is necessary because patients die rapidly if left untreated. The presentation varies with age. Affected infants are very rarely seen in Western countries. It appears in nursing babies of thiamine-deficient mothers around 1 to 4 months of age. Sometimes the clinical onset is sudden. Acute congestive cardiac failure may then appear in apparently healthy babies following a minor illness. In others, signs and symptoms mimicking meningitis are seen. Administration of thiamine produces a rapid recovery.

Beyond infancy, the dry form is seen in children fed polished rice. Signs and symptoms are of peripheral neuropathy. Cardiovascular involvement and oedema are rare. When presenting in adolescence, alcohol consumption must be considered in addition to poor dietary intake. Patients present with malaise, fatigue, palpitations, dyspnoea, and peripheral oedema. They have an increased jugular venous pressure, a high pulse pressure, a gallop rhythm with non-specific apical systolic murmurs, and a loud pulmonary component to the second sound. There is cardiomegaly on the chest radiograph in half, and the electrocardiogram shows non-specific T wave changes. Haemodynamic studies reveal high cardiac index, stroke index, and circulating blood volume and low peripheral vascular resistance.

Clinical suspicion and a dietary history of poor thiamine intake and/or excessive consumption of alcohol are necessary for diagnosis. Patients with beriberi exhibit low

transketolase activity in erythrocytes, which increases after the administration of thiamine pyrophosphate. Patients have low levels of thiamine in blood and urine. An acute response to intravenous thiamine during cardiac catheterisation, with an increase in peripheral vascular resistance and a reduction in cardiac output, has also been used as a diagnostic test.²⁸¹

Beriberi is a treatable cause of cardiac failure. There is a rapid response to administration of thiamine. Parenteral therapy is necessary in extreme cases. Administration can later be continued orally. Bed rest, oxygen, diuretics, and digitalis are useful therapeutic adjuncts. Shoshin beriberi is a medical emergency that is fatal without aggressive medical management. Correction of the acidosis with sodium bicarbonate is essential, together with the measures already described. A balanced diet, with an adequate intake of meat, fresh vegetables and whole grains, will supply the daily requirements of thiamine and prevent beriberi.

DEPOSITIONS

The major disease caused by disordered deposition that arises in childhood is haemochromatosis. The other depositions, such as amyloidosis, do not usually produce difficulties prior to adulthood.

Haemochromatosis

Haemochromatosis results from deposition of iron. It may be primary and hereditary, or secondary. Primary or hereditary haemochromatosis is a rare disease resulting from excessive absorption of iron from the diet. The normal rate of intestinal iron absorption is 1 to 2 mg per day, but this can increase when necessary. In patients with haemochromatosis, intestinal iron absorption can be as high as 8 to 10 mg per day. Also, most iron in the plasma is stored in macrophages, and in patients with haemochromatosis, macrophages more readily release their stores of iron. Intestinal absorption and macrophage release are under control of hepcidin, an antimicrobial peptide which is synthesised by the liver. Hepcidin acts to downregulate absorption and release through its degradation of ferroportin, a membrane protein critical for uptake and release of iron. Synthesis of hepcidin is regulated by multiple proteins in response to the need for and availability of iron. Thus, defects involving the hepcidin gene, the genes encoding its regulator proteins, or the ferroportin gene, can all lead to excessive uptake and release of iron, leading to deposition in the organs. These disorders are inherited in an autosomal recessive fashion. The specific gene affected determines the clinical phenotype.²⁸²

Secondary haemochromatosis is generally the result of excessive administration of iron through multiple blood transfusions in chronic transfusion-dependent non-haemorrhagic anaemias. The most frequent of these is β -thalassaemia. Each 250 mL of blood delivers approximately 200 mg of iron.²⁸³ Cardiac dysfunction generally occurs after 100 units of blood have been transfused.²⁸⁴ Though the primary and secondary diseases are quite different, the damaging effects of iron are similar. The excess iron in the tissues weakens the lysosomal membranes and produces damage to the cells.

Damage to organs due to primary haemochromatosis generally appears between 40 and 60 years of age, though those with the more rare juvenile form can exhibit symptoms much earlier. The secondary form may be clinically apparent in the second decade or earlier, depending on the frequency of transfusions. There is widespread deposition of iron in the liver, spleen, pancreas, gonads, skin and heart, which leads to the clinical manifestations. The classic triad consists of hepatic cirrhosis, bronze pigmentation of the skin, and diabetes mellitus. Splenomegaly is present in approximately half the patients with idiopathic haemochromatosis, and in virtually every patient with β -thalassaemia. Cardiac involvement results from excessive deposits of haemosiderin in the heart. This produces a dilated cardiomyopathy with cardiac failure. A restrictive cardiomyopathy has also been described.²⁸⁵

The heart is rusty-brown at postmortem, with dilation of all cardiac chambers. Concentration of iron is greater in the subepicardial part of the heart, therefore limiting the use of endomyocardial biopsies.²⁸⁶ Iron in the form of haemosiderin initially adopts a perinuclear distribution and then extends peripherally as the amount of deposits increases. These are greater in the ventricles than in the atriums and the conduction tissues.²⁸⁷

Low-voltage QRS complexes are seen electrocardiographically with non-specific ST segments and T wave changes. A prolonged QT interval may be present. There may be evidence of right or left ventricular hypertrophy. Disturbances of rhythm are common and include atrial and ventricular premature contractions, supraventricular and ventricular tachycardias, and varying degrees of atrioventricular block. Cardiac enlargement and signs of cardiac failure, when present, are seen in the chest radiograph. Echocardiography shows increased left ventricular mural thickness, increased left ventricular and left atrial dimensions, and a reduction in fractional shortening and ejection fraction.²⁸⁸

Laboratory studies should include measurements of plasma iron, ferritin, and saturation of transferrin. These typically are elevated. Measurement of the content of iron in samples obtained by needle biopsy of the liver allows accurate estimations of total body iron. Cardiac failure is the cause of death in about one-third of the patients. Early onset of cardiac failure and ventricular arrhythmias presage a poor prognosis. Malignant hepatoma is an important late complication in older patients. Removal of iron by repeated venesection or by chelation with desferrioxamine reverses all the cardiac manifestations except the disturbances of conduction.²⁸⁹ Symptomatic heart block requires insertion of a pacemaker.

AUTOIMMUNE DISEASES

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis is the most common form of chronic juvenile arthritis. It is typically characterised by the absence of positive serological tests. The aetiology is unknown, but HLA-B27 histocompatibility antigen is found in approximately one-quarter of patients. The disease is divided into several forms based upon the principal features and onset.

Patients with systemic-onset idiopathic arthritis, or Still's disease, frequently have a quotidian febrile pattern accompanied by an evanescent rash, hepatosplenomegaly,

and generalised lymphadenopathy. Arthritis may or may not be present. Pleuritis with interstitial pulmonary disease is frequent. The most common cardiac manifestation is pericarditis.²⁹⁰

Polyarticular disease is characterised by symmetrical involvement of the wrist, knee, and ankle joints. The cervical spine is frequently affected. Systemic manifestations are of a milder nature. Rash, splenomegaly, and lymphadenopathy may be present.

The pauci-articular variety affects small children. The joints involved are the knees, ankles, elbows, or wrists. Systemic manifestations are infrequent. Such patients are at risk of blindness from iridocyclitis. This form has the best prognosis. Pericarditis is the most common form of cardiac involvement, though myocarditis can occur as well.²⁹¹ Pericarditis is best managed with anti-inflammatories and, when necessary, pericardiocentesis.

Systemic Sclerosis (Scleroderma)

Systemic sclerosis is a disorder of unknown aetiology resulting in tightening and induration of the skin. Visceral manifestations include gastrointestinal disease with dysphagia and reflux related to oesophageal dysmotility; renal disease with azotemia, proteinuria and hypertension; pulmonary disease with interstitial fibrosis and pulmonary vascular changes leading to pulmonary arterial hypertension; and cardiac disease with conduction disturbances, myocardial fibrosis, coronary arterial disease, and autonomic dysfunction.^{292,293} Close monitoring for the development of pulmonary hypertension is required, as this remains an important cause of morbidity and mortality, affecting up to one-sixth of patients.²⁹⁴ Treatment of this complication includes currently available agents aimed at reducing pulmonary vascular resistance, coupled with cyclophosphamide to address the pulmonary interstitial fibrosis.²⁹⁵

Takayasu's Arteritis

Takayasu's arteritis, also known as pulseless disease, is a chronic large vessel vasculitis primarily affecting the aorta and the proximal arteries supplying the head and neck, along with the proximal pulmonary arteries. Inflammation of the arterial walls leads to thickening, fibrosis, and ultimately stenosis with formation of thrombus. The disease frequently presents in adolescents or young adults with non-specific symptoms of activation of the inflammatory system. Consequently, the diagnosis may be delayed until more overt evidence of the disease is manifested. This can include reduced pulses, hypertension, vascular bruits and aortic valvar disease.²⁹⁶ Treatment consists of immunosuppression with corticosteroids. When this is not effective, more aggressive cytotoxic drugs can be used, such as cyclophosphamide, methotrexate, or azathioprine.²⁹⁷ Angioplasty or implantation of stents is sometimes necessary for severe stenoses unresponsive to medical management.

Polyarteritis Nodosa

Polyarteritis nodosa is a vasculitic syndrome affecting small- to medium-sized arteries, primarily in the kidney, skin, and gastrointestinal tract. The inflammation results in vessel mural necrosis with subsequent fibrosis, thrombosis,

and microaneurysm formation. Myocarditis has also been reported.²⁹⁸ This may be the cause of the left ventricular systolic dysfunction and mitral valvar regurgitation that are frequently seen.²⁹⁹ Supportive care, coupled with immunomodulatory therapy, are the mainstays of treatment.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a generalised, progressive, multi-system connective tissue disease of unknown aetiology. During childhood, the mean age of onset is 12 years. Very rarely, is it present before the age of 5 years.³⁰⁰ The cutaneous, osteoarticular, renal, haematopoietic, central nervous, pulmonary, and gastrointestinal systems are commonly affected. Cardiac involvement is also very frequent and can be present at any time during the course of the disease. The most common manifestations are pericarditis, myocarditis, Libman-Sacks endocarditis leading to valvar stenosis and/or incompetence, disturbances of rhythm, coronary arterial disease, and systemic and pulmonary hypertension. Any of these can lead to congestive cardiac failure, which carries a poor prognosis.³⁰¹ Deposition of immune complexes and complement activation have a major pathogenetic role in these lesions. Pericarditis is the most common cardiac manifestation. Up to three-quarters of patients have echocardiographic evidence of pericardial disease. Clinical involvement is seen in one-third, generally as acute pericarditis, which may have a recurrent nature. Serous effusions are common, and complement levels in the fluid are very low. Cases of chronic constrictive pericarditis and tamponade are rare.

Evidence of myocarditis can be seen in about half the patients at postmortem, but clinical involvement is generally silent. Dyspnoea is the most common symptom. The presence of a gallop rhythm, cardiomegaly on the chest radiograph, and ventricular dilation on the echocardiogram complete the clinical picture. The electrocardiogram is non-specific. T wave inversion, ventricular premature beats and first-degree atrioventricular block may all be present. In approximately half the patients, there are non-bacterial verrucous vegetations, so-called Libman-Sacks endocarditis. These are clumps of fibrin with lymphocytes and plasma cell infiltrates which are most frequently seen on the mitral and/or aortic valves. They measure from 0.1 to 4 mm in diameter. Fibrous tissue, which may later become calcified, appears during the process of healing, leading to valvar dysfunction. Mitral and aortic incompetence, and less frequently stenosis, are the most common lesions. Echocardiographic evaluation is a useful non-invasive method for assessment of valvar dysfunction. Doppler examination should increase the sensitivity of early detection of valve disease. The presence of Libman-Sacks vegetations predisposes to bacterial endocarditis. Peripheral embolism is rare. The coronary arteries can be affected by an acute inflammatory arteritic process or, less frequently in childhood, by atherosclerosis. Coronary arteritis can lead to aneurysmal dilation of the arteries, thrombosis, and myocardial infarction. This is an uncommon cause of death. Disturbances of rhythm and conduction are common. Atrial fibrillation or flutter may be seen during acute pericarditis, whereas ventricular ectopic beats and first-degree atrioventricular block are seen in the course of active myocarditis. Complete heart block may result from

vasculitis of small vessels, and fibrosis of the conduction system has been described in adults. Systemic hypertension is very frequent. It is generally caused by lupus nephritis or by prolonged steroid therapy.

The revised criteria for the diagnosis of systemic lupus erythematosus require the presence of at least four of the following: malar rash; discoid rash; photosensitivity; oral ulcers; arthritis, pleuritis, or pericarditis; renal disorders such as proteinuria or cellular casts; neurological disorders such as seizures or psychosis; haematological disorders such as haemolytic anaemia, leucopenia, lymphopenia, or thrombocytopenia; immunological disorders such as positive lupus erythematosus cell preparations, antibodies against double-stranded DNA (anti-dsDNA) or Smith protein (anti-Sm), or antinuclear antibodies.³⁰² A revision to the immunological criteria was made in 1997 to include antiphospholipid and anticardiolipin antibodies.³⁰³

Long-term prognosis is variable. Boys seem to have a more severe form of the disease than girls. The most common causes of death are renal involvement and sepsis. Death from cardiac lesions is not frequent, but aggressive therapy is warranted when myocarditis is evident, as its course can be fulminant and lethal.³⁰⁴ Corticosteroids are the basis of treatment. Immunosuppressive therapy with azathioprine or cyclophosphamide can be used as a supplement where there is no response to high doses of steroids or when there is severe renal or central nervous system involvement. Apart from this systemic form of therapy, the management of specific lesions does not differ from the patient without lupus erythematosus.

Neonatal lupus erythematosus is a rare variety of the systemic disease. It is frequently associated with maternal lupus. It is characterised by cutaneous lesions with or without congenital complete heart block and systemic manifestations.³⁰⁵ Prolongation of the QT interval, sinus bradycardia, lower-grade heart block and dilated cardiomyopathy can also occur. Skin lesions develop within the first 3 months of life and occur mainly in areas exposed to light, thus suggesting photosensitivity. They consist of erythematous macules, papules or plaques that may exhibit the characteristics of discoid lupus, specifically, scaling, atrophy, follicular plugging, and telangiectasia. Later, they have residual hyper- or hypopigmentation and completely resolve within 12 months with minimal atrophy or scarring. Systemic manifestations include hepatosplenomegaly, anaemia, leucopenia and thrombocytopenia. They occur within the first weeks of life and tend to be self-limiting. Specific treatment is rarely necessary. Congenital complete heart block, unlike the cutaneous and systemic manifestations, is irreversible. There is a high correlation with the presence of anti-SS-A/Ro antibodies in maternal serum, these having been demonstrated in over three-quarters of patients.³⁰⁶ Approximately 5% of babies born to mothers with these antibodies will develop complete heart block.³⁰⁷ The autoantibodies are frequently found in patients with systemic lupus erythematosus and Sjögren's syndrome, but they are rarely encountered in the general population. Anti-SSA/Ro or anti-SSB/La antibodies are immunoglobulin G forms that reach the fetus by transplacental transfer. They can be detected in babies with congenital complete heart block before 3 months of age, but not after they are 6 months old. The underlying mechanism producing heart block is not clear, but it produces fibrosis of the atrial

component of the atrioventricular conduction axis. Pacing may be required in approximately two-thirds.³⁰⁸ Complete heart block in subsequent pregnancies of mothers with lupus is uncommon, affecting approximately one-sixth. Treatment, both for prevention of heart block and as a treatment for evident evolving heart block, has centered on fluorinated steroids. This remains controversial and has yet to be proven beneficial (see Chapter 16).³⁰⁹

HEART DISEASE INDUCED BY TOXIC MECHANISMS

Adverse reactions to drugs and other substances can affect the heart in different ways. These can be classified as hypersensitivity myocarditis, toxic myocarditis, cardiomyopathy, or endocardial fibrosis (Tables 57-3 through 57-5).

The list of drugs in which hypersensitivity myocarditis has been described is very long (see Table 57-3). The true incidence is unknown, since it is rarely recognised clinically and, therefore, tends to be a postmortem finding. Inappropriate sinus tachycardia, mild radiographic cardiomegaly, and ST segment and T wave changes on the electrocardiogram in the presence of other allergic reactions and hypereosinophilia should raise suspicion for clinical diagnosis. Diagnosis is important, since sudden death from heart block or ventricular tachycardia can occur.³¹⁰ Hypersensitivity myocarditis is not dose dependent and can occur at any time during administration of drugs. A delayed hypersensitivity reaction is the accepted mechanism. Histopathological examination reveals an interstitial inflammatory infiltrate with eosinophils, atypical lymphocytes, and plasma cells, which mainly affects the ventricles. Myocytic damage is seen, but necrosis is uncommon. Severe cases may exhibit a non-necrotizing vasculitis. These lesions are reversible upon stopping the

drug. Fibrosis, therefore, is not seen. Treatment is centered around discontinuing the offending drug, combined with use of corticosteroids or immunosuppressive therapy.

Many substances have been implicated in the production of toxic myocarditis (see [Table 57-4](#)). This is a dose-related condition in which the effects are cumulative. Clinical presentation is that of acute myocarditis. Extensive cellular necrosis occurs over a short period. Histopathological signs include myocardial damage, inflammatory infiltrate, and acute necrotizing vasculitis.³¹¹ Upon recovery, there can be multiple focal scars with residual myocardial dysfunction.

Drug-induced cardiomyopathies are most commonly attributed to alcohol, cobalt, and the anthracycline antibiotics. They produce a dilated cardiomyopathy with poor contractility, leading to congestive cardiac failure. Of these drugs, the anthracycline antibiotics, especially Adriamycin, are important in childhood. Chronic cardiotoxic effects of Adriamycin result in a dose-related cardiomyopathy, which generally appears at a cumulative dose exceeding 450 to 550 mg/m². There is great individual variation.³¹² Cardiac function should be continually monitored by echocardiography and/or radionuclide angiography. Pathological lesions are focal and disseminated throughout the left ventricular wall and ventricular septum. Myocytes exhibit vacuolar degeneration and/or myofibrillar loss, which may progress to necrosis and interstitial fibrosis. Inflammatory

infiltrates are not present. The formation of free radicals and the release of cardio- and vasoactive substances are the most accepted pathogenetic hypotheses. Multiple agents have been proposed to have a protective effect against the cardiotoxic effects of Adriamycin and doxorubicin, but these are still under investigation.^{313–315}

Cardiac irradiation during radiotherapy can produce a dose-related heart disease. This appears with doses greater than 4000 to 6000 rad, depending on the amount of cardiac surface exposed. The most common lesion is a delayed pericarditis, which generally appears within the first year of radiation therapy. It adopts the form of an acute pericarditis with fever, pleuritic chest pain, and a pericardial friction rub. Alternatively, it may produce a chronic, generally asymptomatic, pericardial effusion. Treatment is supportive and the disease tends to resolve spontaneously. Some patients develop tamponade requiring pericardiocentesis, and some progress to a chronic constrictive pericarditis necessitating pericardiectomy. Pancarditis is the most severe form of radiation-induced heart disease. There is pericardial and myocardial fibrosis with or without endocardial fibrosis. Patients present in intractable heart failure with the clinical and haemodynamic features of a restrictive cardiomyopathy. Irradiation and Adriamycin have additive cardiotoxic effects that appear at doses of each agent when both forms of therapy are used simultaneously or sequentially. Also, accelerated coronary arterial disease is seen in patients exposed to radiotherapy.³¹⁶

MISCELLANEOUS SYSTEMIC DISORDERS**Hutchinson-Gilford Progeria**

Progeria is a disease of premature aging frequently due to a mutation in the lamin A gene. The defective gene product undergoes abnormal post-translational processing and leads to abnormal morphology of the nuclear envelope, with thickening of the nuclear lamina, loss of peripheral heterochromatin, blebbing of the nuclear envelope, and clustering of nuclear pores.³¹⁷ How this leads to the clinical phenotype of accelerated aging remains to be elucidated. Affected children are normal during the first months of life, exhibiting evidence of the disease in the second year with failure to thrive, loss of subcutaneous fat, scleroderma, alopecia and development of a typical facies. This consists of a disproportionately large head for the face, a beaked nose, micrognathia, thin lips, and prominent eyes. Skeletal abnormalities include dystrophic clavicles, thoracic deformities, knock-knees, persistent patency of the fontanelle, and osteoarthritis. Intellectual development is normal.³¹⁸ The cardiovascular system is affected by premature atherosclerosis of the coronary arteries and the aorta. Most patients have ischaemic heart disease and suffer from myocardial infarctions at a mean age of 13 years. Some present with a dilated cardiomyopathy and cardiac failure with normal coronary arteries. Calcification of the mitral and aortic valves is common.³¹⁹ Function of the adrenal, thyroid, parathyroid, and pituitary glands is normal. There is, however, resistance to insulin and abnormal levels of lipids in the serum, with an increase in total lipids, pre-beta, and beta lipoproteins. Dietary treatment with reduction of the lipids to within the normal range does not seem to alter the course of the disease.

Arteriohepatic Dysplasia (Alagille Syndrome)

Arteriohepatic dysplasia is characterised by chronic cholestasis. It usually becomes apparent within the first 3 months of life with prolonged jaundice. Involved infants may present later with a heart murmur.³²⁰ The other features making up this syndrome are a typical facies, vertebral malformations, peripheral pulmonary stenosis, and ocular involvement. Delayed physical, mental, and sexual development have not been consistently reported.³²¹ The disease is sometimes associated with defects in the *Jagged1* gene, which encodes a ligand for the Notch transmembrane receptor.³²² This signalling mechanism is important for vascular development.³²³

The characteristic facial appearance consists of a prominent forehead, deep-set eyes with mild hypertelorism and a small pointed chin. Ophthalmological examination reveals chorioretinal atrophy and pigment clumping, which may be pathognomonic. Peripheral pulmonary stenosis is the typical cardiovascular anomaly. On physical examination, there is a prominent left parasternal impulse and an ejection systolic murmur at the upper left sternal border radiating to the back, where it may be heard extending into diastole. The electrocardiogram shows right ventricular hypertrophy. Cardiac size may be normal or increased on the chest radiograph, and the lung fields may appear normal or oligoemic. Cardiac catheterisation and angiography confirm the peripheral pulmonary stenosis, which may be single or multiple. The most frequent accompanying cardiovascular lesions are patency of the arterial duct, valvar pulmonary stenosis, and atrial and ventricular septal defects.

Many patients have anomalies of the vertebral arches, usually with a butterfly appearance of the dorsal vertebrae. Xanthomas of the palms, extensor surfaces, and skin creases of the hands are seen when hyperlipidaemia is present. Elevated lipids and cholesterol in the serum are controlled by the use of cholestyramine and by the addition of corn oil to the diet. Arteriohepatic dysplasia is confirmed by liver biopsy, which shows the bile ducts to be absent from most portal areas. Periportal fibrosis is absent or mild, and the extrahepatic system is patent. Additional laboratory findings include elevated 5'-nucleotidase, alkaline phosphatase, transaminases, and bilirubin. The peripheral pulmonary stenosis is not progressive, and it does not influence the long-term prognosis of the disease. Half the deaths are from hepatic or cardiac causes.

Sickle Cell Haemoglobinopathy

Sickle cell haemoglobinopathy is a chronic haemolytic anaemia that predominantly affects those of African descent. The underlying abnormality is the substitution of glutamic acid by valine in the sixth position of the β -chain of haemoglobin. This results in the formation of haemoglobin S. When tension of oxygen is reduced, the haemoglobin S molecules polymerise and produce a crescent, sickle-shaped deformity in the red cells. The pathophysiological consequences of this are vaso-occlusive phenomena and chronic haemolysis. Organs affected by this process are the kidneys, lungs, liver, spleen, central nervous system, and bones. There are a host of cardiovascular signs and symptoms in patients with sickle cell anaemia, but there is no

histopathological evidence of a specific sickle cell cardiomyopathy. Cardiac output is increased, with an increase in stroke volume. The most common symptoms are exertional dyspnoea and palpitations. Physical examination reveals signs of a hyperdynamic circulation.

Peripheral pulses are full, and the apex beat is prominent and displaced laterally. Heart sounds are loud. The second heart sound is widely split and the pulmonary component is often increased. Ejection systolic murmurs are usually present. A third heart sound may be heard, but its presence does not imply cardiac failure. Signs of congestive cardiac failure are rare. Peripheral oedema, pulmonary rales and hepatomegaly may be secondary to venous stasis, pulmonary disease and cholestasis, respectively, and this can confuse the issue.

The electrocardiogram is non-specific. Signs of left ventricular hypertrophy are usually present. First-degree atrioventricular block and ST segment and T wave changes are common. Right ventricular hypertrophy is usually secondary to pulmonary vaso-occlusive disease and is more frequent in older patients. Cardiac enlargement and increased pulmonary vascular markings resembling those seen with a left-to-right shunt are the most frequent radiographic signs. Pulmonary infiltrates produced by infarction and infection may also be present. Echocardiographic examination reveals left atrial and ventricular dilation as a result of the volume overload of chronic anaemia. Left ventricular contraction is very dynamic. Mitral and tricuspid valvar regurgitation are also seen commonly.³²⁴

Congestive cardiac failure is more common in adults than in children. It appears to be secondary to co-existing renal or cardiovascular disease. Myocardial dysfunction with an abnormal response to exercise has been demonstrated in children, particularly if they suffer from pulmonary hypertension.³²⁵ Approximately one-third suffer from pulmonary hypertension, and this risk probably increases with age.³²⁶ The pulmonary hypertension is multi-factorial, resulting from the effects of chronic vaso-occlusive disease, increased left ventricular filling pressures due to the left-sided chamber enlargement, and probably other as yet undefined effects of vascular dysfunction. The presence of pulmonary hypertension greatly increases long-term risk.³²⁷ Additionally, the risk of sudden death during acute pulmonary vaso-occlusive crises is increased in the presence of pulmonary hypertension, probably secondary to acute increases in the pulmonary vascular resistance related to the crisis.³²⁸ Left ventricular dilation has been shown to normalise following transfusion of packed red cells, further supporting the notion that cardiac abnormalities are related to chronic anaemia, and not specific to sickle cell anaemia.³²⁹ Of course, chronic transfusion can lead to deposition of iron, resulting in ventricular diastolic dysfunction, and it is unclear whether chelation therapy is effective at preventing this complication.³³⁰

Repair of congenital cardiac malformations is complicated by the presence of sickle cell disease, as cardiopulmonary bypass and hypothermic circulatory arrest can precipitate vaso-occlusive crises. Most recommend a partial or complete exchange transfusion prior to initiation of surgery, with optimisation of blood gases, rates of flow, and volumes. These practices are also often employed even in patients with sickle cell trait. Despite this common

practice, there are reports of successful cardiac surgery using cardiopulmonary bypass without the use of exchange transfusion.³³¹

Anorexia Nervosa

Anorexia nervosa is a life-threatening disorder in which affected individuals attempt to lose weight through starvation, use of laxatives, and exercise. It affects females more often than males, and typically begins in adolescence. Patients have a distorted body image and fear of weight gain, maintaining a weight less than five-sixths of their ideal weight. While this disorder affects all bodily systems, it carries a high mortality, in part due to its effects on the cardiovascular system. Common findings include sinus bradycardia, reduced volumes, and diminished ventricular mass and cardiac output.^{332,333} Despite these changes, left ventricular contractility often remains normal,³³⁴ though cardiomyopathy has been reported.³³⁵ QT prolongation is observed, and may be due to, or exacerbated by, hypokalemia associated with the dietary derangements. This may explain some cases of sudden death.³³⁶ The precise aetiology of reduction in left ventricular mass, volume, and output remains to be elucidated. It may be due to atrophy secondary to malnutrition, or to the effects of chronic loss of preload. Refeeding can normalise many of the cardiac derangements including sinus bradycardia, QT prolongation, and left ventricular changes.^{330,337,338} Refeeding by itself can lead to severe cardiopulmonary compromise and must be carried out judiciously.³³⁹

Systemic Hypertension

MANISH D. SINHA and CHRISTOPHER J.D. REID

Systemic hypertension is one of the commonest cardiovascular diseases in adults. Over the past decade, several advances have been made in evaluating the state of blood pressure in children. Paediatric hypertension, nonetheless, remains poorly recognised. Essential hypertension is the most common form of hypertension in adults, but it is becoming increasingly clear that the origin of this condition is in childhood. The prevalence of essential hypertension during childhood is increasing, in keeping with the increasing prevalence of obesity. Secondary hypertension is clinically much more important in children, and is commonly caused by renal disease. Early detection and control not only reduce the general morbidity of hypertension, but also protect the function of the already damaged kidney. Fortunately, recent pharmacological advances enable the blood pressure to be controlled in all patients, with a minimum of undesirable side effects. Consequently, the management of hypertension is particularly rewarding for the practising paediatrician.

EVALUATION OF BLOOD PRESSURE: MEASUREMENT, NORMAL VALUES, AND IMPORTANT INFLUENCES

Measurement of Systemic Blood Pressure

In this section, we discuss issues related to the measurement of blood pressure in the clinic or office, along with 24-hour ambulatory monitoring. Measurement of blood pressure in children is usually first performed at the time of their first presentation to a paediatric department, or as part of their first school physical examination. It is often omitted. Common reasons cited by clinicians include the practical difficulties in making measurements in infants and young children, changing normative limits throughout childhood, and the belief that hypertension is primarily an adult disease. There are several aspects to measurement that need consideration. These include the type of measuring machine, the type of cuff and bladder, the technique of measurement, and variables relating to the patient, the observer, and the environment in which the measurements are made.

Cuff and Bladder

The cuff is the inelastic covering that encases an inflatable rubber bladder. The cuff is usually made of cloth, using semisynthetic or any other material that will reliably and evenly transmit pressure over the artery once the bladder is inflated. A combination that allows removal of the bladder from the cuff so that the cuff can be washed at regular intervals is probably more desirable.¹

The inflatable bladder, rather than the cuff, needs to be of the correct size. Failure to select the correct size of

bladder remains the most common error in the measurement of blood pressure. Miscuffing refers to the inaccuracy introduced as a result of using a bladder that is too small and narrow, or too long relative to the circumference of the upper arm. It is advisable to choose a size of cuff in relation to the circumference of the arm as opposed to its length. Although debated, most researchers in this area agree that the width for children should be about two-fifths of the circumference of the upper arm.² This is because measurements made using circumference rather than length as the yardstick correlate best with intra-arterial readings. In both adults and children, use of cuffs which are too small in length, or too narrow in width, will overestimate the pressures measured by errors ranging from 3 over 2 to 12 over 8 mm Hg, with even greater ranges of error in obese individuals.³ This is sometimes referred to as cuff hypertension. Too large a cuff is increasingly being recognised as a cause of underestimation of pressure in both adults and children.⁴⁻⁷ Length of the bladder is much more important in children than adults, and also leads to overestimation of the measured pressure.⁸

The suggested solution to the problem of the size of the cuff is to have a range of sizes of bladder available. In the United Kingdom, cuffs and bladders measuring 4 cm in width and 13 cm in length, and then 8 by 18 cm, 12 by 18 cm, 12 by 26 cm, and 12 by 40 cm are available. These usually suffice for arms of all sizes across the paediatric age range, including lean and obese children. Other national societies recommend different sizes.⁵ The bladder should be centred over the brachial artery, and should encircle from four-fifths to all of the upper arm.^{5,8} In practice, the widest cuff should be used to permit auscultation of the antecubital fossa. The size used should be recorded so that sequential measurements can be compared in the same patient.

Instruments

The mercury sphygmomanometer combined with an inflated cuff and auscultation remains the gold standard for the measurement of blood pressure in children. Widely accepted centiles for normal pressures through childhood have been developed using such a standard mercury sphygmomanometer instrument.⁹ Recently, nonetheless, concerns have emerged regarding the safety of mercury for users in the clinical environment, for technicians who have to service the instrument, and for the environment itself.^{10,11}

An issue with any method using auscultation is the introduction of the phenomenon of terminal digit preference, and bias of the observer because of knowledge of previous measurements. Any instrument that eliminates or reduces these two is to be welcomed. This initially led to

the development of the random-zero sphygmomanometer, which was developed and shown to minimise or eliminate both these items.^{12,13} Unfortunately, these devices were shown subsequently significantly to underestimate blood pressure, and were therefore abandoned.^{14,15}

Automated oscillometric devices have similarly been developed. These improve on the shortcomings of the auscultatory method by eliminating both terminal digit preference and the bias of the observer. They work by the detection of pressure pulses in the cuff. These are generated as a result of the volume pulses of the artery. When blood starts flowing through the artery at the point of systolic pressure, a pressure pulse is generated. As pressure within the deflating cuff is reduced in a stepwise manner, a series of pressure pulses generate the pulse oscillogram. The pulse amplitudes of this oscillogram provide an envelope curve, with the maximal value on this curve equating to the mean arterial pressure. Systolic and diastolic pressures are calculated from preset algorithms in the instrument microchip, and are a function of the mean. The algorithms are specific to the instrument, and are not declared by the manufacturers.^{16,17} Although these automated devices are increasingly being used in primary care and paediatric departments, there are some particular concerns that need to be highlighted. The Dinamap devices are the most commonly studied automated oscillometric devices reported in paediatric series. An earlier version of this device, model 1846 SX, had been shown to have superior correlation with intra-arterial measurements.¹⁸ Other studies, however, reported higher mean systolic measurements using models 1846, 8100, and 845 when compared with the random-zero sphygmomanometer and mercury sphygmomanometer.^{19,20} Diastolic measurements had been reported to have better agreement.¹⁹ A more recent report using the Dinamap 8100 monitor highlighted the discrepancy between the two methods, with measurements using the device higher by a mean of 10 mm Hg for systolic and 5 mm Hg for diastolic blood pressure.²¹ Although normative limits have been proposed using the Dinamap 8100 instrument, caution needs to be proposed before applying these limits in clinical practice.²² Another particular practical observation with oscillometric devices is the phenomenon of measurements being higher by about 3 to 5 mm Hg on first measurement, despite control of factors involving the patient, the observer, and the environment.^{20,23} The second reading has been reported to be more accurate.

Automatically inflated cuffs have recently been introduced. These measure both systolic and diastolic pressures, recording the results at preset intervals by detecting oscillations in the pressure from the cuff. They are especially useful in the care of the critically ill child, saving nursing time and reducing disturbance to the patient. The calibration needs to be checked frequently if the result is to be regarded as accurate, but they are useful in detecting changes. Indeed, they will alarm automatically if preset parameters are exceeded.

Aneroid sphygmomanometers have also gained in popularity in clinical practice because of their portability and their reliance on techniques similar to the standard mercury sphygmomanometer. Because of this, however, they have no influence on the biases existing with the mercury sphygmomanometer. The devices have proven their accuracy when regular 6-month maintenance is in place to service the instruments.²⁴

The majority of devices in clinical use, nonetheless, have not been evaluated independently for accuracy using the two most widely accepted protocols for validation.^{25,26} These protocols have been proposed by the British Hypertension Society and the Association for the Advancement of Medical Instrumentation. Several updates of validation have been published, but the best method of finding up-to-date information is on the nonprofit Web site <http://www.dablededucational.com>.²⁷

Technique of Measurement

The child should be relaxed and quiet when blood pressure is recorded. Should this not be possible, but readings are made, then the conditions should be recorded. A simple description of the process of measurement to a child at a level appropriate for age will usually lead to a cooperative patient, thus allowing accurate recordings. Measuring pressures in infants who are crying is not useful. The standard position is the sitting position when children are older than 3 years, with the fully exposed arm supported or resting on a table at the level of the heart.²³ An arm higher than the heart will underestimate the pressure, while a lower position will produce overestimations.²⁸ In younger children and infants, pressure should be routinely measured when the patient is in the supine position. The sphygmomanometer should be placed at the level of the eye of the observer to eliminate error from parallax. The cuff should be inflated about 30 mm Hg above the point at which the radial pulse disappears. In some patients, there will be a silent gap between the systolic and diastolic pressures. Simply inflating the cuff until the sound disappears in such individuals may produce a serious underestimation of systolic pressure. Once inflated, the cuff should be deflated at a rate of 2 to 3 mm Hg per second while auscultating with the stethoscope. The sudden distension of the collapsed artery at the systolic pressure is associated with a clear tapping sound, defined as phase 1 of the Korotkoff sounds. The murmur of turbulent blood flowing through the partially occluded artery is phase 2. Phase 3 is a high-pitched sound produced when the artery, closed during diastole, opens in systole. When the artery no longer closes during diastole, the tapping sounds are low pitched and muffled and quieter. This is phase 4. Phase 5 is when the sounds disappear. This is variable, and may not occur in some children. The fourth phase, however, tends to overestimate the diastolic pressure, while the fifth phase underestimates it. Although the fifth sound is widely accepted as the optimal measurement of diastolic pressure amongst adolescents and adults, there has been considerable debate in the literature concerning its value in children younger than 13 years of age. For these younger children, the fourth sound had generally been preferred, and was recommended by the Task Force Reports on Blood Pressure Control in Children.^{29,30} An international committee, nonetheless, recommended the fifth sound,^{31,32} and the update of the Task Force Recommendations also advocates using this sound. It is preferred because of its easier identification by observers and the comparability it provides for measuring diastolic pressures across age groups. The two sounds are not equal in most children, and may vary considerably, by up to 10 mm Hg.³³

The measurement of blood pressure in infants, and in some older children, is sometimes difficult because the sounds are inaudible. The old flush technique is unreliable. It has now been superseded by the use of Doppler

ultrasound, using an ultrasonic beam to detect motion of the arterial wall when the cuff is deflated. This technique is remarkably reliable for measurement of the systolic pressure, and corresponds to the intra-arterial pressure better than any other method, including auscultation.³⁴ It is less reliable in the measurement of diastolic pressure, even when machines specifically designed for diastolic pressure are used.³⁵ All hospital paediatric departments, especially those specializing in paediatric cardiology, should have an ultrasonic machine for measurement of blood pressure. It is particularly useful in determining pressure in the legs in children with suspected aortic coarctation.³⁴ Recording of the systolic blood pressure by palpation of the radial artery underestimates the pressure by as much as 11 mm Hg.³⁴ The blood pressure measurement should be recorded immediately, without rounding off the measured value to the nearest preferred whole value.

The number of measurements to be obtained for each visit in order for the observer to be assured that the measured pressure is accurate is also important. In practical terms, an observer should attempt to take at least two or three measurements at each visit. The second measurement is a truer reflection of the pressure, the first being least accurate, especially when measured with an automated oscillometric instrument. Measurements over two, and preferably three, visits should be considered to provide a better reflection of a given blood pressure.^{9,20}

Ambulatory Measurement of Blood Pressure

Ambulatory monitoring using a small, portable, programmable monitor, and performed over a continuous 24-hour period, has become a well-accepted method for the diagnosis of hypertension and assessment of treatment in adults. It is now increasingly gaining recognition for its superior role in the diagnosis and evaluation of blood pressure in children. The monitors typically use an oscillometric technique. They can be programmed to record the blood pressure frequently, for example, every 30 minutes during the day and hourly at night. The readings are stored for later downloading, display and analysis by personal computer. The monitor can be worn on the belt or in the pocket, and the recording is made as the children carry on their normal daytime and night-time activities.

There are some inherent disadvantages of recording a single measurement of blood pressure, since pressure itself is a continuous variable. Additionally, there is the phenomenon of white coat hypertension, especially in children. We discuss this in more detail later. Measures made in the clinic also provide no information of pressures when the patient is asleep. Monitoring over a 24-hour period has several advantages over solitary measurements. It is a more accurate representation, being more physiological and detecting the circadian variation in pressure. Multiple measurements are made in the regular environment, including measurements when the patient is both awake and asleep. Measurements are automatically stored, removing observer error and bias. The technique has been shown to have higher reproducibility than measurements made in the clinic in adults.³⁶⁻³⁹ This has also been shown in children,⁴⁰⁻⁴⁴ although reproducing the nocturnal decline in pressure has not been observed as consistently.^{37,44} With improving technology, the instruments themselves have become smaller, and this has resulted in their improved tolerability by children,

even in infants and toddlers as young as 2 months of age,⁴⁵ although there are no normative limits for this population. As normative standards for ambulatory measurements exist only for children older than 5 years of age, we would not recommend such monitoring in younger children.

Increasing age, and higher mean arterial pressures, have previously been described as factors that improve the rate of success of ambulatory measurements made over 24 hours.^{46,47} Our own experience is that monitoring is well tolerated, with more successful measurements achieved when patients are asleep than when awake. This is primarily related to the normal unrestricted daytime activity of the child causing errors in measurement due to movement.⁴⁸

Accurate documentation of the waking and sleeping periods is important for correct interpretation of any study made over 24 hours. A number of studies in children have considered measurements only during a fixed waking period, between 08:00 to 20:00, or sleeping, from 24:00 to 06:00, in effect ignoring measurements made over 6 hours during the period of 24 hours. This method has been preferred by some as it improves accuracy in correctly classifying measurements made when the patient is awake and asleep. Our own practice has been to identify correctly the periods when awake or sleeping, using a diary that records such times. Unpublished data from our own series would suggest an error of up to one-tenth in misclassification of measurements made during waking and sleeping. No study has thus far shown the inaccuracy introduced, if any, in ambulatory measurements when ignoring one-quarter of recording time as described above.

Normative data for ambulatory monitoring has now been published.⁴⁹ A recent study from the same group using the least mean square method of analysis to account for the non-Gaussian distribution of the original cohort provides 90th and 95th percentiles for daytime and night-time values stratified according to sex and height.^{50,51} Our own preference is for the data using the least mean square method. The criteria for defining hypertension in children are different when using data derived from office measurements as opposed to ambulatory monitoring, with higher values for daytime levels using 24-hour monitoring of normotensive children compared to measurements made in the clinic.⁵² Findings in children with hypertension, however, are inconsistent.^{44,53-56} Ambulatory devices allow assessment of systolic and diastolic pressures, expressed as mean and standard deviation of values during the 24-hour period, including daytime and night-time. The pressure load and dipping state, described below, can also be assessed.

The pressure load as assessed over 24 hours expresses the percentage of measurements above the 95th percentile, but provides no information regarding the amplitude and duration of the pressures above the 95th percentile. In adults, this load has been shown to be more accurate than mean pressures^{57,58} in predicting damage to end organs. A recent review⁵⁹ suggested a load of less than one-quarter to be normal, and greater than half to be more closely related to damage to the end organs. Attempts have also been made⁶⁰ to determine the agreement between mean pressures greater than the 95th percentile and a load of 30% when diagnosing hypertension on the basis of ambulatory monitoring. This data,⁶⁰ and that from others,⁶¹⁻⁶³ suggests that mean pressures above the 95th percentile correlate better with a load in excess of 50%.⁶¹⁻⁶³

The physiological nocturnal dip in pressure, and the rise with waking, or the morning surge, has been well described in adults. The absence of any dip in adults is related to cardiovascular and cerebrovascular morbidity and mortality.^{64–66} This relationship has not been described in children. A state of non-dipping, however, has been observed in several groups of children with a variety of renal diseases, and after renal transplantation.^{67–70} Untreated children with secondary hypertension have been reported to develop nocturnal hypertension and the non-dipping state, as opposed to patients with primary hypertension who maintain their dipping state.⁷¹ The morning surge as described in adults,^{72,73} however, is not usually reported in children.

Normal Blood Pressure in Childhood

A large number of studies have been undertaken to establish the range of blood pressure found in normal children,^{74–76} with the results for boys summarised in Figure 58-1. As a general rule, a steady increase has been observed with age, with no significant difference between the sexes during childhood. Most studies, unfortunately, differ in some respect, for example, in the sizes of cuff used, with measurements taken with the patient sitting or supine, using different end-points for diastolic pressure, and so on.

Figure 58-1 The 95th centiles for systolic and diastolic blood pressure in boys taken from various sources. Data from the Rochester (Minnesota) study,²⁹ including data from the Muscatine study¹²⁵; a Scandinavian study⁷⁶; the Bogalusa study⁷⁹; the Zurich study⁷⁵; and the Londe study⁷⁴. The conditions and measurement parameters varied. Children were seated, except in the study of Londe, where they were supine.⁷⁴ The widths of the cuffs used were 9 and 13 cm (Scandinavian),⁷⁶ two-thirds of upper arm (Londe),⁷⁴ at least two-thirds of upper arm (Rochester),²⁹ mostly 10 and 12.5 cm (Bogalusa),⁷⁹ and the largest possible (Zurich).⁷⁵ Standard mercury sphygmomanometers were used except in the Zurich study, where random zero manometers were used. There is an overlap between use of phase 4, muffling of sounds, and phase 5, cessation of sounds. These differences in technique make it difficult to interpret apparent differences between ethnic groups. Adult black individuals have an increased prevalence of hypertension and damage to target organs when compared with whites.⁷⁷ Nigerian children were found to have higher pressures than black American children.⁷⁸ Higher values for black than white children might be expected in view of the higher prevalence of hypertension in black adults. These were reported by the Bogalusa study,⁷⁹ but similar,^{30,80–83} lower,^{84–86} and no difference in values⁸⁷ have also been reported. A significant increase in the proportion of hypertensive 18-year-old black adolescents has also been reported,^{88,89} albeit that another study⁹⁰ found no difference in the renin-angiotensin-aldosterone system when comparing black and white children and adolescents. It has been suggested⁹¹ that height rather than age is the appropriate standard to which blood pressure should be related. After controlling for height, the effect of age on blood pressure disappears. It is also suggested, therefore, that evaluation of blood pressure in an individual should be based on height and weight rather than age.⁸⁰ It is not clear whether sexual maturation has an effect, independent of body mass, on blood pressure.⁷⁴

Obesity poses special problems because of the essential requirement for an adequate cuff in making measurements. Where adequate sizes have been used, obese adolescents have been found to have a higher incidence of hypertension.^{86,92–94} Corrections have been made according to the circumference of the arm and the size of the cuff used in the measurement⁹⁵ (Table 58-1). Levels of cholesterol and triglyceride in the serum do not correlate well with blood pressure,⁷⁹ but levels of glucose in the plasma 1 hour after a glucose load were found to correlate with blood pressure independently of weight.⁹⁶ The deleterious influence of salt on blood pressure in children has become clearer, and is discussed briefly later in this chapter. No difference was apparent in blood pressure between bottle- and breast-fed infants.⁹⁷

Normal Values for Blood Pressure Measured in the Clinic

Pressures during childhood vary physiologically with gender, age and height. The practising clinician requires standards with which to compare the blood pressure of

individual patients. The most recent Fourth Report from the working group of the National High Blood Pressure Education Program in the United States now provides 50th, 90th, 95th, and 99th centiles for pressures obtained by auscultation in formats specific for gender, age, and height, and is widely accepted as the reference standard for normative values.⁹ It provides data over and above that from the previous reports of the Task Force on Blood Pressure Control in Children,^{30,32} giving comprehensive values for seven different centiles for height at each age from 1 to 17 years, as shown in [Table 58-2](#) for boys, and [Table 58-3](#) for girls. Despite this addition of new data, there is minimal change in the levels for gender, age, and height for the 90th and 95th percentiles from the last report. Additionally, the new data describes stages of hypertension, defining normotension as below the 90th percentile, pre-hypertension as between the 90th and 95th percentiles, the first stage of hypertension as between the 95th and 99th percentiles plus 5 mm Hg, and the second stage of hypertension as greater than the 99th percentile plus 5 mm Hg, similar to the seventh report of the joint national committee.⁹⁸ It provides guidance on the speed at which evaluation, treatment, and referral should be made in a child with elevated blood pressure. The age and gender specific centiles for blood pressure in boys and girls from birth to 12 months of age are shown in [Figures 58-2 and 58-3](#).

Normal Values for Ambulatory Monitoring of Blood Pressure

Data on 24-hour ambulatory monitoring in normal children and adolescents has now been published by several authors.^{49,52,83,99–102} These publications contain detailed tables and graphs of mean and standard deviation for systolic and diastolic blood pressure, for day and night, and by sex, height and age. The normative data from a mid-European cohort⁴⁹ is most widely accepted. As already discussed, our own preference is to use the data provided by the same group using the least mean square method of analysis.^{50,51} There are some common findings in all these series. An important observation is that, in normal children and adolescents, there is a physiological nocturnal dip relative to daytime values as described in adults, with an average fall of one-eighth for systolic, and just over one-fifth for diastolic, pressures.^{49,101,102}

As also discussed, the criterions for defining hypertension in children are different when using values obtained in the office as opposed to ambulatory monitoring. Mean values obtained by ambulatory monitoring for both systolic and diastolic pressures are higher during the daytime than those obtained in the clinic for children of the same age and height, probably secondary to the unrestricted physical activity during monitoring over 24 hours. Consequently, normal values based on measurements made in the clinic, such as the Fourth Report described above, should not be used for assessment of readings obtained by ambulatory monitoring. Again, as already emphasised, one study showed higher values in daytime when using 24-hour values for normotensive children,⁵² but findings in children with hypertension are inconsistent.^{44,53–56} Some^{101,102} have also found no differences in pressures between the sexes for ages ranging from 6 to 14 years, while others⁸³ found higher values for boys at all ages from 10 to 18 years, and

still others⁴⁹ found higher values for boys when compared to girls at all heights.

Higher values are reported for black teenagers when sleeping compared with white teenagers, though there was no difference during daytime.⁸³ These observations have been demonstrated both in adults and in younger children, and are shown to persist longitudinally over time.^{103–106} It is suggested¹⁰⁷ that this reduced nocturnal fall in black children may represent an increased load, which might contribute to the excess morbidity and mortality from essential hypertension seen in African Americans. Interactions between both genetic and environmental factors are thought to contribute to the ethnic differences in patterns noted with ambulatory monitoring, although much of the variations in levels and patterns remain poorly understood.¹⁰⁸

White Coat Hypertension and Masked Hypertension

If ambulatory measurements are interpreted in conjunction with those made in the clinic, two further categories are recognised over and above true normotension and true hypertension. White coat hypertension is defined as high measurements made in the clinic but normal values when obtained by self-measurement or using daytime ambulatory monitoring. This phenomenon was first described in children when it was observed that almost half of patients with raised values in the clinic had normal values when assessed using ambulatory monitoring.¹⁰⁹ The observation has since been confirmed in several other studies, albeit with differences in prevalence depending on population studied and the diagnostic criterions.^{54,110–112} There is some evidence that such white coat hypertension is potentially a pre-hypertensive state.¹¹³ As opposed to a previous study,¹¹⁴ those suggesting the pre-hypertensive state reported white coat hypertension in just over half their cohort, with exaggerated values found after exercise, and an increase in the left ventricular mass index in one-tenth of those with white coat hypertension in this predominantly overweight cohort based in a tertiary centre.

Masked hypertension is defined as the finding of normal values in the clinic, but with either systolic or diastolic values obtained during daytime using ambulatory monitoring that are greater than or equal to the 95th centile for sex and height.⁴⁹ Such findings¹¹⁵ were observed in one-tenth of a cohort of normotensive patients aged from 6 to 25 years, with males more commonly affected than females. Similar prevalences were subsequently reported in a series of patients referred because of elevated pressures.¹¹⁴ Others¹¹² studied a large cohort of children aged from 6 to 18 years undergoing routine health checks, discovering masked hypertension in almost one-tenth. After follow up of three-quarters of these patients, almost half were shown to be normotensive using ambulatory monitoring, while 13 had persistent masked hypertension, and 3 had sustained hypertension. Those with masked hypertension had higher heart rates over 24 hours and more likelihood of parental hypertension. A small proportion of patients with either white coat or masked hypertension, therefore, may progress to develop sustained hypertension.

When faced with such patients, clinicians should look for co-morbid features, such as diabetes mellitus, obesity, family history of cardiovascular disease, and damage to end

organs. If none is found, then further follow-up is recommended, making repeated measurements both in the clinic and using ambulatory monitoring, and suggesting changes in lifestyle as for pre-hypertensive patients.⁹

Variability of Blood Pressure

Serial determinations of blood pressure are necessary before concluding that a child is hypertensive, as variability of blood pressure exists even if differences in the devices used for measurement are taken in to account.^{88,116,117} There is a general tendency for initially high pressures to regress towards the mean. This tendency is greatest in those with the highest pressures. It is not clear whether the initial recording or the later basal record is the better predictor of hypertensive disease.¹¹⁸ It is important to recognise that most people have highly labile pressures,¹¹⁹ with one study reporting that only one-fifth of those identified as having a labile blood pressure when young had definite hypertension in later life.¹²⁰

Most epidemiologic studies in children reporting on the prevalence of hypertension define elevated blood pressure on the basis of at least three measurements done at the time of a single visit, acknowledging the variability of blood pressure. It seems reasonable, at least in children,

only to follow up those whose pressures are persistently raised. General advice in relation to weight, smoking, and other risk factors should be given to those adolescents who are persistently borderline.

Tracking

The tendency of the blood pressure of an individual to rise with time along the centile of the initial determination is known as tracking. Such tracking was established by following the blood pressure of two cohorts from South Wales over a period of 8 to 10 years.¹²¹ The rise noted was significantly related to mean pressure at first determination, but only indirectly related to age, conclusions confirmed in a larger study extending over 30 years.¹²² The evidence from tracking, therefore, indicates that the blood pressure of an individual is determined from an early age. Any rise that occurs becomes steeper with time and is related to the initial starting pressure. Blood pressure does not rise with age in everyone. Indeed, in some populations it does not rise at all.¹²³ This emphasises the pathological nature of a raised blood pressure, and of tracking. The importance of tracking in children is firstly, whether it occurs, and if it does, at what age; and secondly, whether tracking enables individuals at risk of

development of hypertensive disease to be identified with reasonable reliability early in life.

A number of studies have demonstrated tracking in childhood.^{74,124–129} The phenomenon is not so marked as in adults, but the relation between initial and later pressures increases significantly as the population passes through adolescence. In one study,¹²⁸ two-thirds of children with systolic blood pressures more than one standard deviation above the mean at the initial evaluation were above the mean at follow-up. In the Muscatine study, using random zero sphygmomanometer devices,¹²⁵ the correlation coefficient for systolic pressures measured 6 years apart was 0.30. In a later report, these investigators reported that pressures in adults correlated with those present during childhood, and change in ponderosity from childhood to adult life. Tracking of blood pressure was more evident for teenagers than for younger children, and for systolic more than for diastolic pressures.¹³⁰ The correlation in adults is about 0.7, and this is achieved by about 18 years of age.¹²⁸ Others have demonstrated tracking from 5 years of age,¹³¹ or as starting between 1 and 5 years of age.¹³² By 4 years, the correlation in repeated measurements was 0.47. A recent retrospective analysis from the Bogalusa Heart Study research group, a community-based investigation of the evolution of cardiovascular disease risk beginning in childhood, has added to the evidence of tracking of blood pressure through childhood to adulthood.¹³³

It is becoming increasingly evident, therefore, that increased childhood weight and measurements greater than the 90th centile during early childhood predict

with higher accuracy individuals who will be at risk from hypertension, exacerbated by obesity and development of the metabolic syndrome, when they become adults. The realisation that the rise in blood pressure with age is not inevitable, and that individuals at risk might be identified early, so that appropriate avoidance of risk factors might ameliorate their future morbidity, is of considerable potential importance. Further research is required to identify the risk factors to show that their avoidance alters prognosis and to demonstrate the reliability of early identification of a raised blood pressure in predicting future disease.

Familial Clustering

The tendency for parents and children and siblings to have similar blood pressures is well recognised amongst adults. This clustering is also apparent in children, with a correlation between siblings of 0.33 at the age of 2 to 14 years.¹³⁴ Significant, though less strong, correlations have been found between mothers and infants as young as 1 week.¹³⁵ Studies on adopted children, compared with other members of the family, including non-adopted siblings, have shown no correlation between the blood pressure of adopted children and other members of the family. The blood pressure of the parents and the non-adopted children, in contrast, correlated significantly.¹³⁵ This implies that, at least in children, inheritance is more important than environment in determining blood pressure. Environment is not without influence, however, and the duration

of adoption rather than age at adoption, as well as resemblance in body weight, was linked to the small positive aggregation of blood pressure observed in adoptees living in the same home.^{135,136}

Exercise, Traction, and Hypertension

Isometric rather than dynamic exercise is associated with a greater rise in diastolic pressure.¹³⁷ The Task Force Group²⁹ expressed doubt concerning the advisability of isometric exercise, such as weight lifting, body building, and so on, in hypertensive children. No dangerous rise in either diastolic or systolic pressure was demonstrated, however, during either dynamic or isometric exercise in hypertensive adolescents,¹³⁸ with some¹³⁹ concluding that maximal exercise testing was safe in hypertensive adolescents. Although the exercise performance of this cohort was normal, systolic and diastolic pressures were higher than in children with labile hypertension. This finding might indicate caution in allowing full participation in physical activity such as competitive sports. With this caveat, exercise is recommended for hypertension because it is associated with a useful reduction in peripheral vascular resistance and blood pressure.¹⁴⁰ Children undergoing orthopaedic immobilisation with plaster casts, and those in traction, have a fourfold greater incidence of hypertension.¹⁴¹ The rise in blood pressure, averaging 33 mm Hg in one study, was maximal on the fourth day of treatment, but resolved when the treatment was stopped.¹⁴² The cause is not known, but it has been related to increased sympathetic activity from stretching of the sciatic nerve, to retention of salt and water from immobilisation, and to increased production of catecholamines causing increased output of renin from the kidney.¹⁴²

Obesity and Hypertension

The dramatic increase in childhood obesity and overweight state in most developed countries has been an alarming phenomenon over the past two to three decades.^{143–146} This phenomenon has been reported worldwide, with recognition that these trends are likely to have major consequence for public health.¹⁴⁷ One major consequence is the development of the metabolic syndrome, this being the association of obesity, hypertension, dyslipidaemia, and diabetes mellitus. Population-based studies have shown that obese and overweight children have much higher rates of hypertension than those who are not overweight.^{146,148–151} As we have discussed, levels of blood pressure track from childhood to adulthood. Hypertension, along with other components of the metabolic syndrome, has been shown to lead to the development of early atherosclerosis.^{152,153} Lean mass and total body fat mass independently and positively correlate with increased pressures.¹⁵⁴ A positive correlation with blood pressure in this latter cohort was observed across a range of bodily habituses, and not just for overweight or obese children. Others¹⁵⁵ have suggested that loss of weight would help reduce risks of developing hypertension in later life. When evaluating patients with high blood pressure, therefore, note should be taken of the presence of co-morbid features, such as overweight, obesity, and dyslipidaemia. Measures to lose weight should remain an

active part of the plan for management of an overweight or obese child with hypertension.

HYPERTENSION

Definition

The precise level defining hypertension during childhood has been debated for some time. Population-based studies have provided some understanding of the physiological changes in blood pressure during childhood. Blood pressure is influenced by gender and age, but the predominant influence of height over age on blood pressure variability, accounting for almost two-fifths of change, has been well demonstrated by the Bogalusa Heart Study.¹⁵⁶ At a given age, taller children have higher pressures. This relationship of increasing blood pressure with body size, therefore, is physiological.

It is possible, nonetheless, to define the statistical likelihood of a pathological event occurring at a given level of blood pressure. If the generally observed rise in blood pressure with advancing age in adult life is itself pathological, then the appropriate cut-off point might be the mean plus 2 standard deviations for a young adult, equating to 140/90 mm Hg. Alternatively, an even lower value of 125/75 mm Hg might be taken, since this represents the mean. Extending this statistical definition in children, the normal can also be defined in relation to the population. Values above the 95th centile are then regarded as being more likely to represent abnormality. This approach necessarily defines 5% of the population as being hypertensive.

The most appropriate definition, therefore, is one that defines values beyond which there is an associated significant risk of developing increased morbidity and mortality in the future. For example, men aged from 40 to 69 years with a blood pressure of 160/100 mm Hg are four times more likely to die than those with a blood pressure of 120/80 mm Hg.¹⁵⁷ A man with a blood pressure of 150/100 mm Hg at the age of 45 years can expect to live 11 years less than a man with a blood pressure of 120/80 mm Hg.¹⁵⁸ No such data exists in children. There is some evidence from the Bogalusa Heart Study that values above the 90th centile will lead to hypertension in adulthood in one-third of patients.¹⁵⁹

The Fourth Report now provides 50th, 90th, 95th, and 99th centile values obtained by auscultation in gender, age, and height specific format for a large number of children.⁹ This guideline has pooled data from several epidemiologic studies, some of whom have measurements made only once. Keeping in mind some of the issues we have already discussed, this is bound to introduce some inaccuracies, with the possibility that some patients may be misclassified.²⁰ The Fourth Report on measurements of blood pressure, nonetheless, provides the most widely accepted reference standards for normative values.

Which measurement is more important—systolic or diastolic? In children, as in adults, systolic hypertension seems to be more important than diastolic hypertension.¹⁶⁰ Systolic hypertension is more common than diastolic hypertension, and correlates better to left ventricular mass index across a wide range of values.^{161–165} Systolic hypertension, when present in combination with normal diastolic blood pressure in a patient, needs to be evaluated and treated.

Another useful definition of hypertension would be values above which treatment was associated with a reduction

in morbidity and mortality. Although such values have been established for adults, the lack of damage to end organs, and/or absence of cerebrovascular and cardiovascular endpoints with values during childhood, make it impossible to assign a risk above certain levels. The most common surrogate marker during childhood of hypertensive damage to end organs is the presence of an increased indexed left ventricular mass and/or the presence of left ventricular hypertrophy. Studies of normal and hypertensive children have found that systolic blood pressure and the mass index are positively associated across a wide range of values, with no clear threshold to predict a pathologically increased index.^{161–165} It should also be noted that, as blood pressure is a continuous variable within a population, to regard a certain level as pathological is to some extent arbitrary.¹⁶⁶

Classification

Primary, or essential, hypertension is a term used to describe hypertension for which no obvious cause is apparent. This is the most common type of mild hypertension found in children. Secondary hypertension is hypertension for which an underlying cause can be identified. Such a cause is found in up to nine-tenths of children presenting with severe hypertension, with renal disease being the underlying abnormality in the majority. With the increasing prevalence of childhood obesity, and of the metabolic syndrome as discussed above, changes are occurring in this distribution of primary and secondary hypertension. It is helpful clinically to categorise secondary hypertension as being acute and transient, or chronic and sustained.¹⁶⁷ There is considerable overlap, nonetheless, between children falling into these two groups, and one form may progress to the other.¹⁶⁷

Patients may show systolic or diastolic hypertension, or both. Isolated systolic hypertension, with a wide pulse pressure, may be a feature of hyperthyroidism, aortic valvar incompetence, patency of the arterial duct, or an arteriovenous shunt. Stress may cause a rise in both systolic and diastolic pressure, or in systolic pressure alone. As we have also discussed, the white coat and masked variants are further diagnostic categories that have been introduced in the field of childhood hypertension.

The severity of the vascular changes observed on retinal examination permits grading of hypertension in childhood. Long-standing hypertension is known to be associated with retinal arteriolar narrowing.^{168,169} So-called grade I changes occur with mild venous narrowing at the site of arterial crossing, with slight thickening of the arterial wall. In the changes graded at the second level, there is obvious arteriolar thickening producing the copper wire appearance. Changes of the third grade exist when the arteriolar wall is so thick that no column of blood is visible, this giving the silver wire appearance, with marked venous compression. Grade IV changes are described when the arterioles are thin fibrous cords, with no distal flow. Retinal haemorrhages and exudates are additionally present in changes of the third grade, while papilloedema is a feature of the fourth grade, also considered to be malignant hypertension. Severe retinal changes are less common in children, although papilloedema is observed in hypertensive encephalopathy with headache, drowsiness, and convulsions.¹⁷⁰ Retinal arterioles, as opposed to retinal venules,

show better correlation with increasing pressures in both normotensive and hypertensive children. Retinal examination, however, is often difficult in children, who may not be able to tolerate a detailed retinal examination.

Prevalence

The overall prevalence of mild hypertension must be about 5% because this is determined by the definition. The definition, however, requires that the raised blood pressure be persistent. This will tend to lower the prevalence, whereas the inclusion of systolic or diastolic pressure within the definition will tend to raise it.

It is well established that elevated levels can normalise after several measurements are performed over time, with one study,¹⁷¹ after repeated screening of adolescents, identifying 1.2% of the cohort as having mild systolic, and 2.4% having mild diastolic hypertension. Results from another review¹⁷² showed the range of prevalence dropping from 2% to 13% at initial screening to about 1% showing persistent mild hypertension after repeated measurements. This remains true even now with significant reduction of prevalence of hypertension.^{173,174}

Several recent population-based studies from both the developed and the developing world, nonetheless, when using the criteria suggested in the Fourth Report, have found prevalences between 4.5% and 23%.^{9,146,148,149,175} Those conducting these studies measured pressures one to three times at one single visit using a mercury sphygmomanometer or an oscillometric device.

The prevalence of severe hypertension is difficult to ascertain. It can only be determined from surveys of populations. Detailed diagnoses are not always provided in such studies. Prevalence for secondary hypertension varied between zero and 0.2% in various surveys.¹⁷² These surveys vary according to their design, and the selection and referral to hospital for investigations. Some studies of normal populations covering thousands of children have revealed no cases of severe secondary hypertension.^{172,176} In the Muscatine study,¹¹⁶ 0.1% had secondary hypertension. Results obtained from other surveys produced figures of 0.07%,¹⁷⁷ 0.11%,¹⁷⁸ and 0.17%.¹⁷⁹

Causes

Many conditions can be associated with hypertension (Table 58-4), and even this lengthy list is not exhaustive. In Table 58-5, we show the final diagnosis of 100 children referred with severe hypertension to a specialised centre. More recently, an increased incidence of essential hypertension has been associated with overweight and obesity. In practice, if the primary condition is not obvious, coarctation is excluded, and if the hypertension is severe rather than mild or borderline, then renal disease accounts for the vast majority of cases.

In Table 58-5, we show the distribution of ages for the different causes identified. Aortic coarctation, renovascular hypertension, mainly due to thrombosis of the renal artery following umbilical arterial catheterisation, and intracranial haemorrhage are common causes in neonates and infants. In the preschool child, aortic coarctation, renovascular causes, congenital renal abnormalities, tumours, and haemolytic uraemic syndrome predominate. In the older

	Raised intracranial pressure
	Guillain-Barré syndrome, dysautonomia
Miscellaneous	Essential

child, chronic nephritis, reflux nephropathy, and end-stage renal disease are more common.

Clinical Features and Complications

The presenting symptoms of hypertension vary according to the severity of the causative disease, the severity of the hypertension, and the age of the child. Raised blood pressure may be an unexpected cause of a common childhood symptom, such as recurrent abdominal pain or headache. It may be an incidental and apparently unconnected finding on physical examination in a child with another complaint. In Table 58-6, we summarise the major clinical symptoms in a cohort of infants and children reviewed from the literature.¹⁷² Inspection of this list emphasises the need to exclude hypertension in any sick child, and should reinforce the importance of routine measurement in the assessment of children.

Severe hypertension may cause congestive cardiac failure with fluid overload, cardiac dilation with impaired ventricular function and mitral incompetence, and pulmonary oedema. This combination is life-threatening and requires intensive care with positive pressure ventilation, diuretic therapy, inotropic support, and sometimes haemofiltration. Paediatric nephrologists, cardiologists, and often paediatric intensivists are usually involved in the investigation and management of severe life-threatening hypertension.

About one-tenth of children with hypertension have neurological symptoms and complications,^{180,181} which are frequently the presenting feature. Convulsions were the most frequently encountered complication in one review, occurring in over nine-tenths of the children.¹⁸² Facial palsy and an altered level of consciousness were each encountered in 4%. Visual disturbances may be caused by retinal involvement, vitreous haemorrhage, and infarction of the anterior visual pathways.¹⁸³ Cortical blindness is associated with cerebral oedema, which usually resolves, leaving no residual impairment. The posterior leucoencephalopathy syndrome involves oedematous lesions, particularly of the posterior parietal and occipital lobes, and may spread to the basal ganglia, the brainstem, and the cerebellum.¹⁸⁴ It is characterised by headache, nausea and vomiting, seizures, visual disturbances, altered sensory experiences, and occasionally a focal neurological deficit. Whilst there is usually no change seen on computerised tomographic scans, magnetic resonance imaging reveals increased signals predominantly involving the posterior regions of the cerebral hemispheres.

In spite of the relatively good prognosis in survivors, hypertensive encephalopathy is potentially fatal and requires urgent treatment, which we will discuss below. At the other end of the spectrum of severity, mild hypertension, which is usually diagnosed incidentally, may produce no obvious clinical manifestations. Essential hypertension is often mild, and is most commonly seen in the overweight adolescent with a family history of hypertension.

Diagnosis

At diagnosis, it is necessary to establish the severity of the effects of the hypertension, and its cause. A complete family history is important. Essential hypertension is often familial. Some types of renal disease that cause hypertension are inherited, for example, autosomal dominant polycystic

Syndrome	Percentage (%)
Infants	
Congestive cardiac failure	56
Respiratory distress	36
Failure to thrive, vomiting	29
Irritability	20
Convulsions	11
Children	
Headache	30
Nausea, vomiting	13
Hypertensive encephalopathy	10.6
Polydipsia, polyuria	7.4
Visual problems	5.2
Tiredness, irritability	4.5
Cardiac failure	4.5
Facial palsy	3.4
Epistaxis	3.0
Growth retardation, weight loss	2.7
Cardiac murmur	2.7
Abdominal pain	1.8
Enuresis	1.2

Data from 645 infants and children.

From Leuman EP: Blood pressure and hypertension in childhood and adolescence. In Frick P, von Harneck GA, Martini GA, et al, eds: *Advances in Internal Medicine and Pediatrics*. Berlin: Springer, 1979, pp. 109–183.

kidney disease, autosomal recessive polycystic kidney disease, and neurofibromatosis type 1. The blood pressure of the parents should be measured. The neonatal history may reveal perinatal asphyxia with low Apgar scores, a risk factor for renal venous thrombosis. Insertion of umbilical arterial and venous catheters in the newborn may lead to reno-vascular thrombosis or embolisation that may be associated with hypertension. A past history of recurrent infections of the urinary tract suggests pyelonephritic

scarring as a possible cause. Enquiry should be made for specific symptoms associated with hypertension, such as headaches, epistaxis, or blurred vision. Intermittent episodes of headache, sweating, palpitations and pallor, and rarely flushing may suggest a pheochromocytoma. A thorough history of potential ingestion of medications should be obtained, and adolescent patients should be asked about use of recreational drugs, such as Ecstasy and cocaine.¹⁸⁵ Maternal use of cocaine may also lead to sustained postnatal hypertension in the newborn.¹⁸⁶

The physical examination aims to look for signs of the underlying cause of hypertension, and for evidence of damage to end organs. The height and weight should be measured, and the body mass index calculated. Long-standing undiagnosed hypertension may cause poor growth.¹⁸⁷ Initial inspection of the patient may suggest syndromes known to be associated with hypertension, including Cushing's syndrome, Williams syndrome,^{188,189} and Turner's syndrome.¹⁹⁰ Peripheral pulses should be assessed, in particular simultaneous palpation of the right brachial and the femoral pulse to exclude brachio-femoral delay as a sign of aortic coarctation. Blood pressure should be measured in the right arm with the patient both lying and standing, and measured in the legs to determine if there is any difference between the upper and lower limbs, a feature again suggestive of coarctation. Close inspection of the skin may reveal the café-au-lait patches and neurofibromas of neurofibromatosis type 1. Palpable kidneys suggest enlarged polycystic kidneys, especially autosomal recessive polycystic kidney disease. Fundoscopy may show changes suggesting long-standing hypertension, such as narrowing or sclerosis of retinal arteries, and changes of arteriovenous crossing. Severe hypertension is associated with retinal haemorrhages and papilloedema.

A strong indication of the cause of the hypertension is often present from the history and examination. As a general rule, essential hypertension is usually mild, while secondary hypertension is severe. Unless the hypertension

is mild, the initial investigation and control require admission to hospital. The proportion of children with secondary hypertension caused by aortic coarctation, up to one-third, should be identified clinically. Renal disease, or renal arterial stenosis, is the commonest cause of secondary hypertension in childhood, and this will usually be apparent as the cause after initial routine investigations. The approach to investigation and assessment of neonatal and childhood hypertension have recently been reviewed.^{9,191} Routine investigations, and those designed to establish the severity of the hypertension, will include a full blood count, plasma urea, electrolytes, creatinine, and uric acid. A hypokalaemic alkalosis suggests excess activity of aldosterone, either from a mineralocorticoid syndrome or secondary to hyper-reninism. Further blood tests may include measurements of renin, aldosterone, and catecholamines in the plasma. We will discuss such measurements further, but the use of antihypertensive drugs prior to investigation frequently invalidates these assays. The urine should be examined for blood, protein, cells, and casts as markers of renal disease, and should be cultured if urinalysis is abnormal. Unless the cause is obvious, measurements are usually made of vanillylmandelic acid in the urine to exclude either a pheochromocytoma or hypertension caused by neuroblastoma. A chest radiograph, an electrocardiogram, and an echocardiogram, looking for left ventricular hypertrophy, should be performed,^{9,192,193} and ultrasonic investigation made of the kidneys, looking for obvious renal asymmetry, scarring, cysts, or dilation. In addition, a scan using ^{99m}Tc-dimercaptosuccinic acid is usually performed,¹⁹⁴ this test having a high sensitivity for renal scarring that may not be detected by ultrasonic investigation. As we will discuss, renal arteriography and other specific investigations may be required. As already indicated, the control of the hypertension with drugs may invalidate the determination of renin, aldosterone, and catecholamines in the plasma, as well as the latter agents in the urine,^{195,196} so that samples of blood and urine for these investigations, whenever possible, should always be taken prior to initiation of therapy.

Screening

Controversy still exists as to whether normal children should be screened for hypertension. The Fourth Report recommends measurement of blood pressure in all children older than 3 years when seen by a health professional.⁹ For children younger than 3 years, measurement of blood pressure has been recommended in specific groups.⁹

Due to some of the inherent problems with measurement of blood pressure discussed previously, the usefulness of routine measurement in children has been questioned.^{20,197} As discussed, levels of pressure in children are very variable, and the correlation between initial and follow-up measurements is not sufficiently strong to allow predictions of future values to be made from initial recordings.¹⁹⁸ It has also been suggested that the rate of identification of severe hypertension is too low to justify the expense.³⁰

For mild hypertension, the dilemma is considerable, because a large number of such children would be identified by a screening programme. To label an apparently well child as hypertensive could, and probably would, cause great harm. To treat mild hypertension is expensive, and

may even be dangerous, but to leave hypertensive children undiagnosed, to become hypertensive adults, may also be undesirable.¹⁹⁹ The issues with severe hypertension are clearer. Early diagnosis allows effective treatment, prevents complications, and improves life expectancy.

In practice, we recommend that children with pressures higher than the 90th centile for age and height should be recalled for further measurement. If found to be normal, no further follow-up is required, though general advice concerning reduction of weight, diet, and so on should be given. The child with severe hypertension should be investigated immediately. As we will discuss, the child with mild hypertension should be followed up. Ambulatory monitoring will help to establish whether such children discovered during visits to the clinic have mild but sustained hypertension at home or at school, or whether they have white coat hypertension.

Hypertension in Infants

The diagnosis of hypertension in infancy requires knowledge of the normal limits for blood pressure. An increasing amount of data is available providing values for premature and term neonates, and in infants in the first year of life.^{200–207} A simple guide is that repeated measurements of systolic pressure above 90 mm Hg in neonates at term, and above 80 mm Hg in preterm neonates, are indicative of hypertension.²⁰⁸ Systemic hypertension in the newborn that is not related to aortic coarctation appears to be increasing. Thromboembolic occlusions of the renal vasculature are commonly related to indwelling umbilical arterial and venous catheters, with four-fifths of cases of renal arterial thrombosis reported in one series associated with indwelling umbilical arterial catheters.²⁰⁹ Aortic thrombosis has been demonstrated in up to one-third of neonates with indwelling catheters.²¹⁰ It is important to check that the tip of the catheter is left below the level of the renal artery, which is between the ninth thoracic and first lumbar vertebrae, and immediately to withdraw it below this level if it is found to be incorrectly positioned. The diagnosis of renal vascular involvement may be made by ultrasonic investigation, although computerised tomography or magnetic resonance angiography may give clearer imaging. In some patients, an aortogram and selective renal arteriography may be necessary. Direct dissolution of clot with recombinant human tissue plasminogen activator can also be achieved using the catheter used for the diagnostic study. Infants who suffer an intravascular thrombosis should be screened for inherited thrombophilic disorders.²¹¹

A relatively common cause of neonatal hypertension is bronchopulmonary dysplasia.²¹² Other rarer causes of neonatal hypertension include congenital renal arterial stenosis,²¹³ renal venous thrombosis, structural renal disorders, raised intracranial pressure from space-occupying lesions, pheochromocytoma, congenital adrenal hyperplasia, and autosomal recessive polycystic kidney disease. In one study,²¹⁴ all infants reviewed with this last diagnosis had established hypertension by 3 months of age. Infants requiring extracorporeal membrane oxygenation are also at risk of hypertension.²¹⁵

Neonates with hypertension are often severely ill, with tachypnoea, cyanosis and congestive cardiac failure. Neurological symptoms are common, with lethargy, apnoea,

fits, and focal neurological defects. These symptoms may be related to intracranial bleeding or to hypertensive encephalopathy. One-quarter of affected infants, however, may be asymptomatic.²⁰⁹ Renal enlargement is uncommon except with renal venous thrombosis. Haematuria and proteinuria occur in about half the infants, but can be present without hypertension. Raised levels of urea or creatinine are common. A consumptive coagulopathy with a microangiopathic haemolytic anaemia may be present, with thrombocytopenia, fragmented red cells and prolonged prothrombin and partial thromboplastin times. Activity of renin is usually raised in the plasma.

Control of the hypertension is vital. Prazosin, in doses up to 500 µg/kg per day, hydralazine up to 10 mg/kg per day, and propranolol up to 2 mg/kg per day are usually successful, though a diuretic may also be required. More potent vasodilator agents, such as minoxidil or captopril, an inhibitor of angiotensin-converting enzyme, may be required. Acute control of severe hypertension can usually be obtained with an intravenous infusion of labetalol, given at 1 to 3 mg/kg per hour, or nitroprusside at 2.5 to 5 µg/kg per minute.

The prognosis for hypertensive neonates and infants is largely determined by the underlying cause. Most studies describe an overall good outcome for neonates. Hypertension is transient in many infants. In one small series,²⁰⁹ it was possible to discontinue medication in more than three-quarters of hypertensive infants, and at follow-up all but one had normalised their pressures, remaining free from medication. Other investigators²¹⁶ followed up a similar series of hypertensive babies discharged from a neonatal intensive care unit. Of the three-quarters requiring drug treatment, all had discontinued medication by the age of 24 months. Similar favourable outcomes were reported for neonates with aortic thrombosis and neonatal renovascular hypertension²¹⁷ and for those who developed renal venous thrombosis.²¹⁸ Of the latter group, two infants who developed hypertension responded to removal of the abnormal kidney.

Essential, or Primary, Hypertension

The essential form accounts for about nine-tenths of hypertension in adults. It may be defined as a rise in blood pressure of unknown cause that increases risk for cerebral, cardiac, and renal events. In developed countries, the risk of becoming hypertensive during a lifetime, defined for adults as pressures greater than 140/90 mm Hg, exceeds 90%.²¹⁹ Essential hypertension is commonly associated with other cardiovascular risk factors such as ageing, being overweight, insulin resistance, diabetes, and hyperlipidaemia. There is a strong genetic component in essential hypertension. Studies in animals have shown an association with excessive ingestion of salt.²²⁰ People with essential hypertension also excrete a salt load more rapidly than do normal subjects, and this abnormality is present in normotensive young relatives.²²¹ These observations suggest that a renal abnormality may precede the development of essential hypertension in susceptible people. The genetic nature and self-perpetuation of essential hypertension are perhaps the two most recognised characteristics of the condition. As we will discuss, there are well-described monogenic forms of hypertension, but essential hypertension is likely to involve the complex interplay of many genes.²²²

The impact of essential hypertension in adults has led to increasing interest in the early characteristics seen during childhood that are associated with the subsequent development of hypertension. Events during early life^{126,130,152} and diet during fetal development, infancy, and childhood probably influence the eventual levels of blood pressure.^{133,151,223} Findings relating low weight at birth to an increased risk of death from cardiovascular events in later adult life²²⁴ have led to further studies exploring this relationship.²²⁵ Some²²⁶ have suggested that the link is a deficiency of nephrons at birth in babies born with low weight. Such a deficiency of nephrons may then progress, through hyperfiltration injury in the remaining nephrons, to further glomerulosclerosis and hypertension.²²⁷ Babies born at term with low weight have been shown to have significantly higher blood pressures by the age of 6 years than those born with normal weight.²²⁸ At birth, however, the initial pressures have been found to be significantly lower, and heart rates significantly higher, in those born weighing less than 2500 g.²²⁹ The smaller babies then showed a significantly faster rise in pressure during the first post-natal month, and through the remainder of the first year maintained their pressures at the same levels as the bigger babies, thereby sustaining a higher pressure per kilogram of body weight. Premature birth has also been associated with significantly increased risk of hypertension.²³⁰ A role has been suggested for elevated levels of uric acid, contributing to endothelial dysfunction and leading to microvascular and inflammatory injury to the kidney,²³¹ this notion being supported by the finding that levels of uric acid correlated with systolic blood pressures.²³²

There is broad recognition that much of the hypertension found in adults relates to dietary intake of salt. The relation between the prevalence of hypertension in a population and the cultural preference for salt in the diet is well established.²³³ Processed food accounts for four-fifths of the salt in the average Western diet, and it is argued that the manufacturers of this processed food should reduce this content.²³⁴ A meta-analysis²³⁵ of 10 trials looking at the effect of reducing intake of salt on pressures in infants, children, and adolescents showed that a modest reduction led to an immediate and significant fall in blood pressure.

Investigation and Diagnosis

The majority of children with essential hypertension have only mild elevations of blood pressure, with no clinical signs of hypertension. Only 2 of 74 children reported in one study²³⁶ had left ventricular hypertrophy. Severe hypertension can result from essential hypertension, with almost one-tenth of one cohort²³⁷ having diastolic pressures greater than 122 mm Hg.

Adults with essential hypertension have been classified according to the activity of renin in the plasma,²³⁸ though the significance of this is not established.²³⁹ Low levels of renin are common in blacks with hypertension, and there is some evidence that cardiovascular complications, such as cerebrovascular accidents or myocardial infarcts, are rarer if the activity is low. Activity of renin, however, is usually normal in children with essential hypertension.^{74,236,240} Occasional instances of low levels have been reported in children with essential hypertension.²⁴¹

The diagnosis of essential hypertension depends on the exclusion of all known causes of secondary hypertension (see Table 58-4). Cardiovascular causes are usually excluded

during the clinical history and examination. Similarly, the problems produced by the central nervous system, and hypertension related to drugs or metabolic causes, do not pose diagnostic difficulties. Renal disease may be apparent from the clinical evaluation, from the examination of urine, or from the measurement of electrolytes in the plasma. A hypokalaemic alkalosis, which suggests either primary or secondary excess of mineralocorticoids, should be excluded in all cases. Activity of renin in the plasma should be carefully determined, and would be expected to be normal in essential hypertension. Ultrasonic and nuclear scans of the kidneys are usually appropriate to exclude major structural abnormalities and to identify parenchymal scarring. If the clinical history and examination, full blood count, plasma electrolytes, examination of urine, urinary excretion of catecholamine metabolites, thyroid function, ultrasonic and nuclear scans, activity of renin in the plasma, and urinary excretion of steroids are all normal, and the hypertension is not severe, then a diagnosis of essential hypertension is usually appropriate. Severe hypertension, particularly with a raised activity of renin in the plasma, will necessitate a careful search for a renal or renovascular cause. This will involve a renal arteriogram, usually with selective sampling from the renal vein to measure levels of renin in the plasma.

Management

There is no question about the desirability of treating children with severe hypertension. We discuss appropriate treatment in our section devoted to this topic. Some common considerations need discussing here, however, as they are of general importance in the management of hypertension in all children, and also because some are of unique significance to children.

The decision to attempt to lower the blood pressure in children must depend, to some extent, on the assessment by the physician of the circumstances of each child. The psychosocial effects on an adolescent of forcing a confrontation with the implications of long-term management for hypertension may exacerbate the problem, as well as causing undesirable alterations in behaviour and growth. Compliance, particularly with medication, may be unsatisfactory.

General dietary and health advice should initially be given. The avoidance of risk factors, such as smoking, should be encouraged. Obesity should be treated with caloric reduction, and regular exercise encouraged. A reduced intake of salt, to 50 mmol per day, with no salt added to cooking or at the table, is important. Some have suggested combining this with a diet high in potassium.²⁴² A high ratio of polyunsaturated to saturated fats should be encouraged, while foods rich in cholesterol should be avoided, refined carbohydrate reduced, and the content of dietary fibre increased. Such advice may seem a counsel of perfection, but much can usually be achieved by a minimum of intervention, and without generating excessive anxiety or food fads. Compounds known to exacerbate hypertension, such as liquorice, sympathomimetics, and corticosteroids should be avoided. Oral contraceptives must be used with careful monitoring.

Such measures are probably all that is required initially, together with a relaxed but reliable follow-up to check the blood pressure. If the pressure remains obviously unacceptably raised, at more than 99th centile, or continues to be mildly raised over a period of 1 to 2 years, then antihypertensive treatment may be required. We will discuss this in depth below.

Caution regarding treatment of mild hypertension is advisable, notwithstanding the reports of successful intervention.^{243,244} This is because some studies have failed to demonstrate a significant difference in morbidity from coronary arterial disease between a control group and a group undergoing treatment that involved the reduction in known risk factors and the treatment of hypertension.²⁴⁵ A reasonable interpretation of available evidence would allow advice concerning smoking, hypercholesterolaemia, obesity, and exercise.²⁴⁶ The creation of undue anxiety should always be avoided. Treatment with drugs to reduce blood pressure seems reasonable, as indicated above, as long as careful follow-up is guaranteed.

Hypertension induced by oral contraceptives is common, with an incidence of 7.5%. Furthermore, oral contraceptives will exacerbate hypertension in a similar proportion of individuals.²⁴⁷ The mechanism is thought to involve stimulation of the release of renin and aldosterone, a direct effect of oestrogen on retention of salt and water, and sensitisation of smooth muscle to vasoconstriction produced by angiotensin II. Cardiac output may also increase. Decisions regarding individual patients will need to take account of individual factors, not least the assessment of the risk of pregnancy. It would seem advisable, however, to discontinue oral contraception if hypertension occurs, but not to preclude its use in the presence of preexisting mild hypertension. A formulation containing low levels of oestrogen should be used. A further rise in blood pressure would then be an indication for stopping treatment.

Up to half of the adults receiving antihypertensive therapy become non-compliant. This is probably equally common in children, especially adolescents.²⁴⁸ The quality of the relationship between doctor and patient, the degree of knowledge of the patient and of participation, and the ease of consultation are important factors. The ease of administration of the medication, including a reduction in the number of drugs and frequency of ingestion, is important. Long-acting formulations requiring once-daily dosage are preferred. Alterations in life style, including diet, must be introduced slowly. Changing habits is often resisted and may also lead to non-compliance in other areas.

Renal Hypertension

Pathophysiology

Renin is a proteolytic enzyme that is produced by the juxtaglomerular cells and stored in the afferent arteriole. After release into the blood, it reacts with angiotensinogen, a substrate in the plasma produced by the liver, to form the decapeptide, angiotensin I. This agent is then further acted upon by converting enzyme in the lung to produce the octapeptide, angiotensin II, which raises blood pressure by direct vasoconstriction and by its indirect effects on the nervous system. It stimulates secretion of aldosterone, promotes retention of sodium by the kidney, and stimulates thirst and the release of catecholamines and vasopressin.²⁴⁹ Baroreceptors located in the afferent arteriole control the release of renin. This is also affected by other factors, including delivery of sodium in the distal tubule to the macula densa, sympathetic activity, catecholamines, and hypokalaemia. Activity of the renin-angiotensin system is intrinsically related to the balance of sodium and the volume of extracellular fluid.

The importance of renal ischaemia in the generation of hypertension has been appreciated since classic canine experiments.²⁵⁰ The detailed mechanisms, nonetheless, remain controversial.²⁴⁹ Unilateral renal arterial constriction in the rat will produce hypertension. If the constriction is removed within a few weeks, the hypertension subsides. If the clip is left for longer, and then removed, the hypertension often persists. Removal of the non-clipped kidney, but not the previously clipped kidney, will often result in a fall in blood pressure. Concentrations of angiotensin II rise in the plasma with the initial unilateral constriction, and this is probably responsible for the initial rise in blood pressure. Thereafter, the concentration slowly decreases, even though the hypertension persists. It is likely that the renin-angiotensin system is still responsible for the hypertension at this stage. This is partly through its vasoconstrictive action, and partly because of retention of salt.²⁴⁹ Later, after months or years, removal of the abnormal kidney in humans fails to reduce blood pressure. It is likely that renin is not involved in the maintenance of the hypertension. The mechanism by which retention of salt causes hypertension is not certain. It would be expected that a rise in arterial pressure would lead to a pressure natriuresis. If hypertension is maintained without depletion of sodium, therefore, the relation between blood pressure and renal excretion of salt must be reset at a higher level.²⁵¹ This is perhaps a result of the effect of angiotensin II in reducing renal perfusion and increasing retention of sodium by the kidney, both directly and by release of aldosterone.²⁴⁹ The persistence of hypertension after the removal of the initial cause in experimental animals has its clinical counterpart in pheochromocytoma, Cushing's syndrome, Conn's syndrome and aortic coarctation. In these instances, the blood pressure does not always return to normal after removal of the cause.

The persistent hypertension may be related to damage to the renal vasculature of the non-experimental kidney. This can, in some way which is not yet clear, cause retention of sodium. The mechanism may be similar to that involved in the later stages of essential hypertension, and to the increased peripheral vascular resistance caused by medial and intimal hypertrophy of peripheral arterioles.²⁵² The complexities of experimental renal hypertension are such that it can cause no surprise that the amelioration of renal ischaemia in the human does not always lead to a reduction in hypertension.²⁵³ Fortunately, in children, perhaps because the period of hypertension is shorter, the results of surgery for renovascular hypertension are more predictable.

Renovascular Hypertension

Renovascular hypertension can be defined as hypertension resulting from obstruction to flow of blood in the renal artery or its branches. The obstruction may be caused by intrinsic disease of the artery, or by compression on the artery from outside. Renovascular lesions account for up to one-tenth of cases of children referred with hypertension,^{254–256} and are the third commonest cause of significant hypertension in children after renal scarring and glomerular disease. Fibromuscular dysplasia, or fibromuscular non-atherosclerotic stenosis of the renal vessels, is the main vascular abnormality, and is classified according to the arterial layer in which the lesions predominate.^{257,258} Intimal fibroplasia is a rare cause in adults, but occurs primarily in children.

Fibromuscular dysplasia, or hyperplasia of the media, is more common, and predominates in adolescents and adults. Overall, the condition is most common in middle-aged females.¹⁷² The lesion in adults is commonly situated in the middle or distal part of the renal artery, whereas stenosis occurs more frequently at the origin of the vessel in children. The aetiology of the condition is unknown, but a cellular reaction to altered dynamics of pressure and flow in the artery has been proposed.²⁵⁷ Genetic factors may play a role, with the condition being commoner in first-degree relatives of those with involvement of the renal arteries,²⁵⁹ and in those carrying the ACE-1 allele for the angiotensin-converting-enzyme.²⁶⁰ It is important to recognise that the condition may be progressive,²⁶¹ and may also involve arteries other than the renal vessels.^{258,262} A careful search for the involvement of other arteries is mandatory, with particular note taken of absent peripheral pulses or the presence of bruits, especially over the carotids.

A number of cases are associated with neurofibromatosis type 1.^{255,263} A careful family history, and clinical examination for other features of the condition, is important. The renal arterial stenosis in neurofibromatosis type 1 is usually caused by intimal proliferation or neurofibromatotic proliferation in the arterial wall.¹⁷² Associated coarctation of the abdominal aorta is common. Occasionally, compression on the artery from outside by a neurofibroma or ganglion neuroma is responsible for hypertension. Other space-occupying lesions that may involve compression of the renal artery include tumours, fibrous bands, haematomas and pheochromocytomas. Acquired narrowing of the abdominal aorta has been observed following radiotherapy for intra-abdominal malignant disease.²⁶⁴ Coarctation of the abdominal aorta without neurofibromatosis is often accompanied by renal arterial stenosis.²⁶⁵ Other vessels originating from the abdominal aorta are usually involved.

Takayasu's arteritis is an important cause of renovascular hypertension in non-white children.²⁶⁶ The arteritis affects the aorta, the proximal portions of its major branches, and the pulmonary arteries. The onset of the vasculitis is associated with an acute systemic illness, which usually subsides after a few weeks but may recur. The aetiology is unknown, though a link with tuberculosis has been suggested.^{267,268} A raised erythrocytic sedimentation rate, and elevated levels of immunoglobulin, indicate active disease. Diagnostic imaging includes Doppler ultrasound and arteriography. More recently, three-dimensional magnetic resonance angiography and positron emission tomography have been shown to reveal early changes in the process of the disease, avoiding the need for intravenous contrast or ionising radiation.^{269,270} Therapy of the arteritis is based on the use of corticosteroids,²⁷¹ and in some patients the addition of other immunosuppressive drugs such as methotrexate or azathioprine.²⁷² Following this, management is mainly concerned with control of the hypertension. The prognosis is, to some extent, dependent on the severity of the vasculitis and the resultant damage.

Other miscellaneous causes may be found. Renal arterial stenosis can be present in some cases of infantile hypercalcaemia syndrome.²⁷³ As already discussed, thrombosis or embolism of the renal artery is an important cause of hypertension in infants. Stenosis of arterial branches within the kidney may lead to severe hypertension, and

is difficult to diagnose.²⁷⁴ Diffuse renal arteriolar stenotic lesions can occur in polyarteritis nodosa, haemolytic uraemic syndrome, and following renal irradiation.²⁷⁵ Renal venous thrombosis in infancy can lead to the development of hypertension.^{218,276} Hypertension is common after renal transplantation, but only rarely is caused by renal arterial stenosis. Renal hypertension can occur after traumatic injury to the kidney, causing renal arterial thrombosis or intrarenal vascular damage, or from perinephric inflammation causing constriction on the kidney.¹⁷² Arterio-venous fistulas, either congenital or acquired, following trauma, surgery, or renal biopsy, can all cause hypertension.

A bruit over the renal artery is a useful diagnostic sign, albeit often absent in children with renovascular hypertension. Hypokalaemic alkalosis suggests underlying secondary hyperaldosteronism, which is a consistent feature of renovascular hypertension. Doppler ultrasound has limited sensitivity for detecting renal arterial stenosis.^{277,278} Computed duplex sonography is able to measure blood flow velocities as a guide to the presence of stenosis.²⁷⁹ Overall sensitivity and specificity for Doppler assessment is excellent.²⁸⁰ Renal scintigraphy may show asymmetry of function and size, with reduced uptake on the side of the stenosed renal artery, but paediatric renovascular disease is often bilateral,²⁵⁵ and these investigations may not be helpful. Performing the scan before, and then after, a dose of an inhibitor of angiotensin-converting enzyme, such as captopril, may reveal a significant reduction in function of the affected kidney on the second scan. This technique has been found to have sensitivity and specificity of around 90% in adults.²⁸¹ A study in children gave comparable findings when compared with renal arteriography.²⁸²

Direct evidence of renal ischaemia with stimulation of the renin-angiotensin system is derived from the differential

determination of renal venous renin. A ratio of 1.5 or more between the affected and the non-affected kidney may predict unilateral renal ischaemia and an anticipated positive response to surgery.^{283–285} Using this ratio to predict unilateral disease, however, does not always correlate with the arteriographic findings²⁵⁵ and in no way removes the need for arteriography. The level of renin in the renal vein of the non-affected kidney is usually suppressed to the level of the systemic concentrations. A ratio of less than 1.5 suggests either bilateral disease, or non-renovascular hypertension, though renovascular hypertension and successful surgery have been reported in some patients.²⁸⁶ A normal renal arteriogram, with similar activities of renin in both renal veins, will certainly exclude a renal cause for hypertension in most, if not all, cases.

The gold standard investigation for renal arterial stenosis is selective renal arteriography and estimation of renal venous renin. The procedure is usually performed under sedation or general anaesthesia, with access to the renal artery and vein from puncture of the femoral vessels. If the hypertension is mild and easily controlled, and if the other investigations do not suggest renovascular hypertension, it is reasonable not to recommend arteriography, though careful follow-up is essential. The blood pressure should be carefully controlled before attempting arteriography. Adequate hydration should be maintained, and the blood pressure monitored throughout the procedure. Newer techniques include magnetic resonance angiography^{287–289} and computed tomographic and spiral angiography.²⁹⁰ These have the advantage of being less invasive, and can normally be performed without general anaesthesia in children and adolescents.

Interventional treatments of renovascular hypertension include percutaneous transluminal angioplasty (Fig. 58-4)

Figure 58-4 This series of images show the steps of treatment for a 9-year-old boy with renovascular hypertension. The areas of interest in each panel are indicated by arrows. A magnetic resonance angiogram (Panel A) demonstrates bilateral renal arterial stenosis, combined with the middle aortic syndrome. Panel B shows an enhanced image.

Figure 58-4 Cont'd Panel C is a percutaneous renal arteriogram showing severe stenosis of the left proximal renal artery, a normal right renal artery, and stenosis of the middle part of the aorta. Panel D shows complete correction of the left renal arterial stenosis subsequent to balloon angioplasty. Panels E and F show the diameter of the aorta before (E) and after (F) balloon angioplasty, performed because of persistent hypertension. The patient now has normal blood pressure on a low dose of a single antihypertensive agent 6 months after the aortic balloon angioplasty.

and open surgery. In general, angioplasty is the preferred approach for discrete non-ostial stenoses, whilst open surgery is often needed for ostial, multiple, and extensive stenoses.²⁹¹ The rate of cure for surgery in renovascular hypertension in children is high.^{172,283,292} It varied between 85% and 100% in various series of properly selected patients, with no operative deaths in one large series.²⁹² The operative techniques vary according to the nature of

the disease. They include renal arterial reconstruction and reimplantation, autotransplantation of the kidney, and venous grafting or prosthetic bypass of the stenosis.^{292–295} Decisions regarding treatment where there is abdominal aortic narrowing associated with renal artery stenosis are challenging, because surgical correction of the renal arterial stenosis by vascular shunts from above the coarctation may compromise flow to other organs. Successful outcomes

have been reported in the majority of children undergoing surgery for renovascular hypertension associated with abdominal aortic narrowing.^{292,294}

Percutaneous transluminal angioplasty is the preferred approach for discrete non-ostial stenoses. The technique is less successful with ostial stenosis, the presence of intrarenal stenoses and abnormalities in other vascular beds, or the long segment renal arterial stenosis often seen in neurofibromatosis type 1. Several published series show an overall favourable outcome, including a number of cases with neurofibromatosis type 1.^{253,263,296–301} Restenosis is relatively common, occurring in up to one-quarter of cases³⁰² and is commoner if a stent has been placed in the vessel. There is relatively little experience of stenting stenosed arteries in children.^{301,303} Stenosis may develop in the previously normal renal artery on the unaffected side.³⁰⁴ The progressive nature of fibromuscular dysplasia in children suggests that every attempt should be made to preserve renal function. Nephrectomy should be performed only if the kidney is small or scarred and has very poor function, accounting for less than one-fifth of total function.

Renal Parenchymal Disease

The renal disease causing hypertension is usually evident from the initial clinical and laboratory evaluation (see Table 58-5). Chronic pyelonephritis with renal scarring is a major cause of childhood hypertension.^{180,305,306} Some tertiary centres have reported the development of hypertension in up to one-quarter of patients with severe reflux nephropathy, although other centres have reported a much lower prevalence.³⁰⁷ A careful search for renal scarring must always be performed using scintigraphic techniques, since renal ultrasound used in isolation may fail to identify renal scarring.³⁰⁸ If scarring is demonstrated, a contrast micturating cystourethrogram, or indirect radioisotope cystogram, should be considered. Treatment of hypertension is usually medical, as the damage is often bilateral and affects more than one segment of the kidney. Where investigations indicate that the cause of hypertension is a small, scarred and poorly functioning kidney, with a normal unscarred kidney on the other side, then removal of the damaged kidney may cure the hypertension and remove the need for antihypertensive therapy. Occasionally, partial nephrectomy may be indicated for focal scarring where the remainder of the kidney is undamaged; in these cases, sampling of renin in the renal vein is usually required to confirm isolated hyperreninaemia arising from the scarred segment. Obstruction at the pelviureteric junction is occasionally associated with hypertension, which can be cured in some instances by a pyeloplasty.^{309–311}

Hypertension is common in acute nephritic syndrome. Indeed, this diagnosis has to be considered in any child with unexplained acute hypertension. Plasma renin is low because of the retention of sodium.^{312,313} Hypertension is also common in chronic glomerulonephritis (see Table 58-5), and is almost invariable when renal function declines. Diseases associated with widespread arteriolar damage, such as haemolytic uraemic syndrome, systemic lupus erythematosus, and polyarteritis nodosa, are often accompanied by hypertension. Polycystic kidneys are an important cause of hypertension. The raised pressures are seen early in the autosomal recessive form of the condition encountered in childhood.³¹⁴ Hypertension may also develop in childhood in the more common autosomal dominant

variant.³¹⁵ Hypertension is less common with primary interstitial tubular diseases, such as the Fanconi syndrome or juvenile nephronophthisis, and with the diseases associated with salt wasting, such as renal dysplasia or obstructive uropathy in infancy. When renal insufficiency supervenes, however, even children with these conditions may develop hypertension.

Primary Hyper-reninism

Severe hypertension is uncommon in children with nephroblastoma, also known as Wilms' tumour. It can occur when renal ischaemia is present, or after haemorrhage into the tumour. Occasionally, production of renin by the tumour has been described.³¹⁶ Tumours of the juxtaglomerular cells, or haemangiopericytomas, are extremely rare. With these tumours, the activity of renin is elevated in the plasma, and there is often evidence of secondary hyperaldosteronism. The tumours are single, benign and small, measuring from 0.8 to 4 cm.¹⁷² They should be suspected when a raised level of renin is found in the renal vein in association with a normal intravenous urogram. They may be apparent as a translucent area seen during the nephrographic phase of a selective renal arteriogram.³¹⁷ Computed tomography may assist in the diagnosis of these lesions.³¹⁸ Surgical removal of the tumour is indicated.

Aortic Coarctation

Aortic coarctation is one of the most important causes, after renal disease, of severe hypertension in children.^{172,305} The cause of the hypertension in patients with coarctation is complex and not fully explained. The main hypotheses include mechanical obstruction,³¹⁹ the neural theory of altered autonomic and baroreceptor function,^{320–322} and activation of the renin-angiotensin system.^{323,324} Despite apparently successful surgical correction of the aortic narrowing, ongoing or recurrent hypertension is well recognised and common. It may be considered a long-term condition even after surgical correction.³²⁵ In this respect, it is of interest that only 6% of patients with coarctation aged between 1 and 5 years of age had residual hypertension, whereas three-tenths of those undergoing surgery between 6 and 18 years, and almost half of those between 19 and 40 years, had hypertension following surgery.³²⁶ Older age at surgery is also associated with higher risk of subsequent hypertension and cardiovascular morbidity.³²⁷ The pathogenesis of post-operative hypertension is likely to be multifactorial, and involve alterations in the systems described above. The diagnosis and treatment of aortic coarctation is discussed at length in Chapter 46.

Endocrine Disorders

Adrenocortical Hypertension

The adrenal gland synthesises mineralocorticoids, glucocorticoids, and sex hormones from cholesterol. Plasma cortisol feeds back to the pituitary to control the output of adrenocorticotrophic hormone, which stimulates the rate of conversion of cholesterol to pregnenolone. This is an intermediate in the production of all three classes of adrenocortical hormone. Any failure of the control of normal feedback by cortisol will produce an increase in adrenocorticotrophic hormone, giving rise to congenital adrenal hyperplasia. The most useful investigations in the

diagnosis of adrenocortical hypertension are a determination of renin in the plasma, which is usually suppressed, along with aldosterone, the exclusion of a hypokalaemic alkalosis, and a careful analysis of the urinary excretion of steroids.

11 β -Hydroxylase Deficiency

11-Hydroxylation is the final step in the production of cortisol, also known as compound F, from its immediate precursor corticosterone, or compound S. It is also an essential step in the production of aldosterone from deoxycorticosteroid. Adrenal hyperplasia results from the decreased production of cortisol with an increase in levels of compound S and its urinary metabolites in the plasma. Virilisation is a prominent clinical feature, and hypertension is present in many patients. This is in contrast to the more common variety of congenital adrenal hyperplasia associated with a deficiency in 21-hydroxylase. Hypertension is thought to be caused by an excess of deoxycorticosteroid, which has mineralocorticoid effects. There is evidence of hyperaldosteronism, with a hypokalaemic alkalosis and a low concentration of renin in the plasma.

17 α -Hydroxylase Deficiency

17-Hydroxylation is required for the conversion of pregnenolone to 17-hydroxypregnenolone in the production of cortisol and sex hormones. A defect in this process, therefore, results in the diminished secretion of all glucocorticoids and sex hormones, with an increased secretion of mineralocorticoids, leading to hypertension and hypokalaemia. Clinical features include hypogonadism, amenorrhoea, and male pseudohermaphroditism. The production of 17-deoxysteroids, including deoxycorticosteroid and compound B, is increased, but secretion of aldosterone is low, perhaps because of the low levels of renin in the plasma, which is required for the synthesis of aldosterone. It is suppressed by the high concentration of deoxycorticosteroid.³²⁸ The hypertension in both varieties of congenital adrenal hyperplasia resolves with treatment with a glucocorticoid.

Cushing's Syndrome

Cushing's syndrome may be caused by excessive production of adrenocorticotrophic hormone, either pituitary or ectopic, leading to adrenal hyperplasia, by an adrenal tumour such as an adenoma or carcinoma, by primary adrenocortical hyperplasia, or by exogenous administration of glucocorticoids.³²⁹ Hypertension occurs in half of affected children and adolescents.³³⁰ Clinical features include obesity, short stature, hirsutism, and acne. The cause of the hypertension is multi-factorial, and includes the aldosterone-like action of glucocorticoids, activation of the renin-angiotensin system,³³¹ suppression of various vasodilatory systems including nitric oxide,³³² and enhanced response to pressor effects of vasoactive substances, including catecholamines and angiotensin II.³³³ Hypertension may persist after treatment of the underlying cause.

Hyperaldosteronism and Low-renin Hypertension

Concentration of aldosterone in the plasma is high in infancy, decreasing to adult values by 5 years of age.^{334,335} Urinary excretion is related to excretion of sodium.³²⁸ The cardinal features of hyperaldosteronism are retention of sodium, hypokalaemia, hypertension, and suppressed activity of renin in the plasma. These changes are seen in a variety of hypertensive syndromes, which share the

common feature of low activity of renin in the plasma, but some conditions have high levels of aldosterone and others have low levels (Table 58-7). Several of these syndromes are inherited as single mendelian traits, including dexamethasone-suppressible hypertension and Liddle syndrome, which are autosomally dominant, and apparent mineralocorticoid excess, which is autosomally recessive. The molecular defect has been established for each of these conditions, enabling genetic diagnosis. In addition, the profiles of steroids in the urine for these conditions are characteristic and can aid in diagnosis.³³⁶

Primary Hyperaldosteronism

Primary hyperaldosteronism is extremely rare in children. It is usually related to nodular hyperplasia rather than to Conn's syndrome, where there is an aldosterone-producing tumour. Hypertension may be severe, and is associated with a low concentration of renin in the plasma and hypokalaemia. Oedema is either absent or minimal. Surgery is recommended for adrenal adenomas. Hypertension frequently recurs after operative treatment for nodular hyperplasia, which may, therefore, respond more satisfactorily to long-term treatment with the antagonist of aldosterone, spironolactone.

Dexamethasone-suppressible Hyperaldosteronism

The hypertension in dexamethasone-suppressible hyperaldosteronism, a dominantly inherited condition that is also known as glucocorticoid-remediable aldosteronism or familial hyperaldosteronism type I, is variable. It is resistant to normal medication, albeit responding to treatment with dexamethasone. Activity of renin is profoundly low in the plasma, and levels of aldosterone are usually, but not always, raised in the serum. The genetic defect is an unequal cross-over event between genes encoding 11 β -hydroxylase and aldosterone synthase. This results in a chimeric duplication containing the regulatory elements of 11 β -hydroxylase and the coding sequence of aldosterone synthase.³³⁷ Consequently, aldosterone is ectopically synthesised in the adrenal fasciculate zone under the regulation of adrenocorticotrophin hormone, rather than its usual secretagogue, angiotensin II. This chimeric gene product converts cortisol to its 18-oxo and 18-hydroxy metabolites, leading to a pathognomonic profile of urinary steroids, with a raised ratio of 18-oxotetrahydrocortisol to tetrahydroaldosterone.³³⁸ Treatment with dexamethasone leads to suppression of adrenocorticotrophic hormone, and hence suppression of the ectopically produced aldosterone. Direct antagonists of aldosterone, such as spironolactone, have also been used successfully, and may avoid the side effects of dexamethasone.³³⁹

Liddle's Syndrome

Liddle's syndrome is an autosomal dominant condition with a clinical presentation typical of primary hyperaldosteronism, and yet levels of aldosterone in the serum and urine, as well as activity of renin in the plasma, are suppressed.^{340,341} Patients have constitutive activation of the amiloride-sensitive distal renal epithelial sodium channel as a result of mutations in the β - or γ -subunit of the epithelial sodium channel.³⁴²⁻³⁴⁴ Analysis of urinary steroids reveals negligible aldosterone. Treatment with triamterine or amiloride is successful.

Apparent Mineralocorticoid Excess

A number of children have been observed with hypertension associated with suppressed activity of renin in the plasma, subnormal levels of aldosterone, hypokalaemia with

TABLE 58-7

SYNDROMES OF LOW-RENIN HYPERTENSION

Condition	Inheritance	Aldosterone Level	Potassium Level	Mechanism
11 β -Hydroxylase deficiency	Autosomal recessive	Decreased	Low	11 β -Hydroxylase deficiency
17 α -Hydroxylase deficiency	Autosomal recessive	Decreased	Low	17 α -Hydroxylase deficiency
Primary hyperaldosteronism	Sporadic	Increased	Low	Adrenocortical hyperplasia or tumour
Dexamethasone-suppressible hyperaldosteronism	Autosomal dominant	Increased	Low	11 β -Hydroxylase/aldosterone synthase hyperaldosteronism chimeric gene duplication
Liddle syndrome	Autosomal dominant	Decreased	Low	Mutations in β/γ -subunits of epithelial sodium channel conferring increased activity
Apparent mineralocorticoid	Autosomal recessive	Decreased	Low	11 β -Hydroxysteroid dehydrogenase excess deficiency with impaired conversion of cortisol to cortisone
Gordon's syndrome	Autosomal dominant	Decreased	High	Increased distal proximal tubular NaCl reabsorption; WNK gene mutations

alkalosis, and a reduced excretion of all known steroids.^{328,336} Deficiency of 11 β -hydroxysteroid dehydrogenase is the primary defect.^{345,346} In this autosomal recessive condition, these mutations cause increased intracellular cortisol that activates the mineralocorticoid receptor.³⁴⁷ In addition, the cortisol leads to suppression of adrenocorticotrophic hormone, and hence reduced excretion of other corticosteroids. The condition responds to treatment with spironolactone, an antagonist of the mineralocorticoid receptor.

Gordon's Syndrome

Gordon's syndrome is an autosomal dominant condition that is also known as pseudohypoaldosteronism type II. It is characterised by hypertension with low plasma renin activity, hyperkalaemia, metabolic acidosis, and normal glomerular filtration rates.³⁴⁸ Mutations in the *with-no-lysine kinase 4* gene, or WNK4, are associated with this condition.³⁴⁹ The gene normally inhibits the thiazide-sensitive sodium-chloride co-transporter in the distal convoluted tubule. Mutated genes fail to inhibit this co-transporter, leading to enhanced reabsorption of sodium chloride and water, with resultant expansion of volume, suppression of renin, and hypertension.³⁵⁰ The condition responds to restriction of sodium and therapy with thiazide diuretics.

Phaeochromocytoma

Benign phaeochromocytomas, and the malignant phaeochromoblastomas, develop from chromaffin tissue in the adrenal gland or sympathetic ganglions. These tumours produce excessive amounts of catecholamines, and lead to an increase in the excretion of their metabolites in the urine. Abnormal production of catecholamines is also observed with neuroblastomas, and occasionally with ganglion neuromas. Adrenaline and noradrenaline are the principal biologically active catecholamines. Noradrenaline is synthesised from tyrosine via dihydroxyphenylalanine and dopamine. It is then methylated to produce adrenaline, this being the main hormone of the adrenal medulla. Noradrenaline is principally produced by postganglionic sympathetic nerves. Noradrenaline acts mainly on sympathetic α -adrenoceptors, while adrenaline stimulates both α - and β -adrenoceptors. The catecholamines are metabolised to metadrenaline, also called metanephrine, and normetadrenaline, also called

normetanephrine, and then oxidised to the principle urinary metabolite 3-methoxy-4-hydroxymandelic acid, also called vanillylmandelic acid. The urine also contains homovanillic acid, produced from dopamine, as well as adrenaline and noradrenaline. Malignant tumours excrete dopamine and homovanillic acid.

Because of the practical difficulties in obtaining accurately timed collections of urine over 24 hours in small children, spot samples may be used, expressing the excretion of vanillylmandelic acid relative to urinary creatinine.³⁵¹ Excretion is usually raised in children with phaeochromocytomas, especially if the urine is collected when the patient is hypertensive. Collections over 24 hours may be necessary if the hypertension is episodic. Levels of adrenaline and noradrenaline in the plasma should also be measured. Typically, adrenal tumours produce a rise predominantly in adrenaline, while extra-adrenal tumours lead to raised noradrenaline levels. We show the normal values for excretion of catecholamines in the urine in Table 58-8. Recent publications suggest that measurement of the levels of metanephrine and normetanephrine in the urine and plasma may be the most sensitive and specific assays for the confirmation of phaeochromocytoma.^{195,196,352} Whilst catecholamines may be secreted episodically, plasma free metanephrines are produced continuously by the metabolism of catecholamines within phaeochromocytoma tumour cells.³⁵²

Bananas, and drugs and foods containing vanilla, should be eliminated from the diet before urine is collected. Methyl dopa, clofibrate, and inhibitors of monoamine oxidase will reduce excretion of catecholamines. β -Blockers, and blockers of the calcium channels, may increase the levels of catecholamines in the plasma. Labetalol may also interfere with assays. Ideally, the patient should not be receiving these drugs when samples are collected for investigation for phaeochromocytoma. Stress may also lead to increased release of catecholamines, and so collection of blood should be done via a previously inserted cannula, when the child has been resting.

The hypertension is usually ascribed to the increased secretion of noradrenaline. Thus, administration of phenolamine, which blocks α -adrenoceptors, will lower the

blood pressure by more than 20 mm Hg. A starting dose of 0.01 mg/kg body weight is increased to 0.1 mg/kg if no effect is observed. False-positive results are common. The majority of children also have high concentrations of renin in the plasma with secondary aldosteronism. This has been ascribed to depletion of fluid volume, direct stimulation of secretion of renin by adrenaline, compression on the renal artery by the tumour, and associated renal arterial disease in those with neurofibromatosis.¹⁷²

The adrenal medulla is the common site for the tumours, which vary in size from 1 to 10 cm. They are more common on the right, and are bilateral in one-fifth of patients. In one-third, tumours are situated in both the adrenal and extra-adrenal areas, or only in an extra-adrenal site. Boys are affected twice as often as girls, and the incidence is highest between the ages of 11 and 15 years. The most common extra-adrenal site is the aortic bifurcation, or the vicinity of the renal hilum. Bladder tumours are described, which cause paroxysmal hypertension during micturition and, sometimes, haematuria.³⁵³ A dominant mode of inheritance is apparent in some families, and more than half of

the patients have multiple tumours. Pheochromocytoma is frequently associated with other conditions, such as neurofibromatosis and von Hippel-Lindau disease, and with the autosomally dominant multiple endocrine neoplasia syndrome, which includes medullary thyroid carcinoma, islet cell adenoma, and hyperparathyroidism.³⁵⁴ Hypertension is less common with other neurogenic tumours and only affects about one-tenth of children with neuroblastomas. An increase in urinary dopamine, and its metabolite homovanillic acid, is a characteristic of neuroblastomas.

Clinical features relate to the hypertension, which is sustained in almost nine-tenths of cases, and include headaches, sweating, nausea and vomiting, visual disturbances, abdominal pain, polyuria and polydipsia, convulsions, pallor, and acrocyanosis.

The location of the tumour or tumours can be established with a variety of imaging techniques including ultrasound, scintigraphy, computed tomography, and magnetic resonance imaging.³⁵⁵ More invasive techniques involve sampling of blood at different levels from the inferior caval vein for determination of levels of catecholamines

in the plasma, and arteriography.³⁵⁶ Invasive investigations should be performed only after full α - and β -adrenoceptor blockade to control the hypertension, and after correction of hypovolaemia. The latter is essential in any case before surgery. Safe anaesthesia and surgery require careful pre-operative preparation. Phenoxybenzamine, at 1 mg/kg per day, is used to block α -adrenoceptors, and propranolol, also at 1 mg/kg per day, is used for blockade of β -adrenoceptors. Monitoring of arterial and central venous pressures is required during surgery.³⁵⁷ Intravenous adrenergic blocking agents such as phentolamine and esmolol should be readily available. Surgical removal of the tumour or tumours results in cure, but the frequency of multiple tumours suggests that long-term follow-up is indicated.

Miscellaneous Endocrine Causes

Primary hyperthyroidism is a rare cause of hypertension in children.³⁵⁸ Hypertension is also rare in children with primary hyperparathyroidism and is probably related to nephrocalcinosis³⁵⁹ and to hypercalcaemia which, as we discuss briefly below, raises peripheral vascular resistance.

Neurological Disorders

Severe hypertension can occur in a variety of acute neurological disorders, for example Guillain-Barré syndrome,³⁶⁰ poliomyelitis, intracranial lesions such as tumours, trauma, asphyxia, and encephalitis.³⁶¹ Autonomic dysfunction with overactivity of the sympathetic system is thought to be involved in the pathogenesis in these disorders and in the Riley-Day syndrome of familial dysautonomia,³⁶² though raised intracranial pressure may be a particular precipitating factor.

Miscellaneous Causes of Hypertension

Drugs

Oral contraceptives have already been discussed. Glucocorticoids and mineralocorticoids are potent causes of hypertension, particularly in children with pre-existing renal disease. Sympathomimetic agents can raise the blood pressure even when used as topical preparations³⁶³ or in nose drops. Mercury poisoning causing acrodynia, or pink disease, is associated with hypertension. Poisoning with heavy metals, such as cadmium and lead, overdosage of reserpine, methyl dopa and phenylcyclidine, and cough syrup containing ephedrine have all caused hypertension.¹⁷²

Burns

Systemic hypertension occurs in one-third of children with severe burns.³⁶⁴ Excessive production of catecholamines, increased renin-angiotensin stimulation, expansion of volume, and hypercalcaemia have been considered in the pathogenesis.¹⁷²

Hypercalcaemia

Hypercalcaemia is associated with hypertension, probably because of a rise in peripheral vascular resistance.³⁶⁵ The syndrome of infantile hypercalcaemia²⁷³ may be associated with renal arterial stenosis and hypertension.

Other Causes

Hypertension occurs in acute intermittent porphyria.³⁶⁶ It can be associated with Turner's syndrome, even in the absence of aortic coarctation,^{190,367} and with Marfan syndrome.³⁶⁸ It has been described in pseudoxanthoma elasticum,³⁶⁹ Stevens-Johnson syndrome,³⁷⁰ and acrodermatitis enteropathica.³⁷¹ It also occurs during sickle

cell crisis.³⁷² Ingestion of liquorice, which contains a substance with a mineralocorticoid effect, may cause hypertension that is similar to the hypertension induced by deoxycorticosteroid.³⁷³

MEDICAL THERAPY

The importance of non-pharmacological interventions in the management of hypertension has already been discussed, as have the indications for treatment and for surgery. Here we concentrate on pharmacological treatment.

Maintenance Therapy of Chronic Hypertension

Maintenance therapy for chronic hypertension is intended to control the blood pressure at the 90th centile or less for height, age, and sex (Table 58-9). Reference should, therefore, be made to the available tables showing centiles for blood pressure during childhood so that a clear target range for treatment is identified.⁹ Compliance is promoted by using the fewest drugs at the lowest dose and frequency. Long-acting formulations requiring once-daily dosing are available for a range of drugs, and liquid or dispersible preparations of most important antihypertensive drugs are also available for use in infants and younger children. If more than one drug is required, the additional drug or drugs should act through a different, and hence complementary, mechanism.

The availability of long-acting inhibitors of angiotensin-converting enzyme, blockers of the calcium channels, and β -blockers provides the majority of hypertensive children with effective and simple treatment that is relatively free of serious side effects. Information on the use of some of the available antihypertensive drugs, however, is limited.

Inhibitors of Angiotensin-converting Enzyme

The inhibitors of angiotensin-converting enzyme are effective antihypertensive agents,³⁷⁴⁻³⁷⁶ particularly in renin-mediated hypertension. They also have other benefits in specific situations, such as proteinuric renal impairment and diabetes mellitus.^{377,378} The hypotensive effect is not usually seen until some nine-tenths of the enzymic activity has been inhibited. Consequently, there may not be a graded response to the given dose. Captopril is useful initial treatment as the half-life is short, at 2 hours, allowing fairly rapid modification of dose until control is achieved. The recommended dose by body weight for neonates and infants is smaller, as the potency is greater in this group. It is recommended that a small initial test dose be given while the patient is closely observed, as some have shown a profound fall in blood pressure with postural hypotension after a single dose. Enalapril, lisinopril, and ramipril have a long half-life, from 12 to 24 hours, enabling once-daily dosing, which helps compliance in long-term therapy. The reduction in production of aldosterone associated with these drugs may lead to an increase in the levels of potassium, especially with pre-existing renal impairment. Rash, neutropenia, loss of taste, and cough are rare side effects. This class of drugs is relatively contraindicated in renal arterial stenosis, as they inhibit the angiotensin II-mediated compensatory efferent arteriolar vasoconstriction, with the risk of a precipitous fall in rates of glomerular filtration.³⁷⁹ More recently, drugs blocking the receptors to angiotensin II have been

TABLE 58-9

ANTIHYPERTENSIVE DRUGS FOR ORAL USE

Drug	Major Side Effects	Precautions	Dose
Angiotensin II–converting Enzyme Inhibitors			
Captopril	Hypotension, rash, cough, agranulocytosis	Avoid in renal artery stenosis	Children: 0.1–0.5 mg/kg (maximum 2 mg/kg) three times a day Neonates: 0.01–0.05 mg/kg three times a day
Enalapril	Hypotension, cough	Avoid in renal artery stenosis	0.1 mg/kg (maximum 1.0 mg/kg) once daily (enalapril has been substituted for captopril as 1 mg enalapril per 7.5 mg captopril)
Calcium Channel Blockers			
Nifedipine	Flushing, tachycardia, headache	—	Capsule: 5–10 mg three times a day Modified release tablets: 10–20 mg twice a day Slow release tablets: 30–60 mg once a day
Amlodipine	Flushing, tachycardia, abdominal pain	—	0.1–0.2 mg/kg once a day; increase to a maximum of 10 mg
Diuretics			
Chlorothiazide	Hypokalaemia, hyperuricaemia	Renal insufficiency	10 mg/kg (maximum 40 mg/kg) per day
Furosemide	Hypokalaemia	Renal insufficiency	1–4 mg/kg once or twice a day
Spironolactone	Hyperkalaemia, gynaecomastia	Renal insufficiency	1 mg/kg twice or three times a day
β-Adrenoceptor Blockers			
Propranolol	Reduced cardiac output, bradycardia	Cardiac failure, asthma	0.2–2.0 mg/kg three times a day
Atenolol	As propranolol	As propranolol	1–2 mg/kg (maximum 8 mg/kg) once a day
α-Adrenoceptor Blockers			
Prazosin	Hypotension after first dose, dizziness	First dose reaction	0.01 mg/kg three times a day; increase to a maximum of 0.5 mg/kg three times a day
Mixed α- and β-Adrenoceptor Blockers			
Labetalol	Rash, dry eyes, dizziness	Cardiac failure, asthma	1–2 mg/kg three or four times a day
Vasodilators			
Minoxidil	Fluid retention, tachycardia, hirsutism	—	0.1 mg/kg twice daily; increase by 0.1 mg/kg per dose every 3 days to a maximum of 0.5 mg/kg twice a day
Hydralazine	Flushing, tachycardia, lupus syndrome	—	0.2–1.0 mg/kg

used in children, often in combination with inhibitors of angiotensin-converting enzyme, to produce a combined effect on both hypertension and proteinuria.^{380–383}

Blockers of Calcium Channels

These blockers are most effective in low-renin, volume-dependent hypertension. They interfere with the inward displacement of calcium ions through voltage-dependent slow channels in the cell membrane, and reduce blood pressure by causing vasodilation. Nifedipine has been widely used, both in its short-acting form for the rapid lowering of blood pressure in urgent situations, and in its slow-release forms for maintenance treatment of chronic hypertension. These drugs are usually well tolerated. Side effects are mainly related to vasodilatation, and include tachycardia and flushing. Amlodipine is a newer agent that requires only a single daily dose. It has been used successfully for children.^{384,385}

Diuretics

These agents are particularly useful in patients with renal disease. They are often required as a second agent to control the retention of fluid associated with long-term use of vasodilators. Thiazide diuretics are effective if the rate

of glomerular filtration is over half of normal, but a loop diuretic, such as furosemide, will be needed for more severe degrees of renal impairment. In refractory oedema, especially when associated with congestive cardiac failure, the addition of metolazone to furosemide is usually effective.^{386,387} Side effects include hypokalaemia with both groups of diuretics, and ototoxicity when using loop diuretics. The mineralocorticoid antagonist spironolactone is useful in conditions of mineralocorticoid excess. It may also be used in addition to a loop or thiazide diuretic for its potassium sparing effect. Triamterene and amiloride are used specifically for Liddle syndrome.

Blockers of β-Adrenoceptors

The β-blockers have been used as first line therapy for a long time, and are effective in many patients. Cardiac output is reduced, peripheral release of noradrenaline is impaired, release of renin is inhibited, and there is centrally mediated reduction in peripheral sympathetic activity. There is a relatively poor correlation between the antihypertensive effect of the drug and the level of drug in the plasma. Side effects are numerous, and include exacerbation of asthma and cardiac failure, depressed mood, nightmares, and disturbed

metabolism of lipids and glucose. Propranolol is useful for initial introduction of β -blockade during in-patient management, where four-times-daily dosing is feasible, and when the shorter half-life makes dose adjustment easier. For long-term treatment, atenolol has a long half-life and need only be given once daily.

Blockers of α -Adrenoceptors

Prazosin is an α -adrenoceptor blocker. It has few serious side effects in children. The antihypertensive effect is through vasodilation. Caution should be observed with the first dose, as it may cause marked postural hypotension. This class of drug is useful in treating catecholamine-induced hypertension. Recently, a long-acting α -adrenoceptor blocker, doxazosin, has been available for once daily dosage. It is not officially licensed for use in children.

Blockers of Both α - and β -Adrenoceptors

Labetalol³⁸⁸ is a non-selective β -blocker, with less potent α -adrenoceptor blocking properties. Its main use is as an intravenous infusion in the treatment of hypertensive emergencies.^{255,389,390}

Vasodilating Agents

The vasodilators are a group of pharmacologically diverse drugs that have vasodilation as their common effect. Some drugs with this effect have already been described above. Hydralazine and minoxidil act directly on the vascular smooth muscle to reduce peripheral vascular resistance. Hydralazine is most often used as an intravenous bolus for rapid control of severe hypertension. Minoxidil

is a powerful vasodilator and is usually used as an added agent in resistant hypertension. It causes marked hirsutism. As mentioned above, long-term use of vasodilating drugs is often associated with retention of salt and water, and a diuretic may, therefore, need to be used in addition.

Hypertensive Crisis

The rapid but controlled lowering of blood pressure is essential in children who present with clinically severe hypertension. Clinical features necessitating emergency treatment of hypertension include visual disturbance with retinal haemorrhages and papilloedema; encephalopathy with headache, vomiting, hyper-reflexia, obtunded neurological state, or seizures; and cardiac failure with a dilating heart. Similarly, severely elevated blood pressure that has not yet led to symptomatic damage to target organs should be urgently controlled before an adverse event occurs. It is important initially to assess clinically the extracellular fluid volume. If there is evidence of overload with increased jugular venous pressure or pulmonary oedema, then removal of fluid by a furosemide-induced diuresis or by dialysis is required. The hypertension of acute nephritic syndrome often settles rapidly if an adequate diuresis can be obtained.

Sudden large falls in blood pressure have to be avoided if neurological complications are to be prevented.²⁵⁵ These complications are more likely if the hypertension has been long standing, though the chronicity of hypertension may not be apparent at initial clinical assessment

TABLE 58-10

DRUGS FOR TREATMENT OF HYPERTENSIVE EMERGENCIES

Drug	Onset of Action	Dose and Route	Mode of Action	Comment
Labetalol	Minutes	1–3 mg/kg per hr as intravenous infusion	Vasodilator	Titrate rate of constant infusion against change in blood pressure
Sodium nitroprusside	Seconds	0.5 μ g/kg per min intravenously; increase by 0.2 μ g/kg per min to a maximum of 8 μ g/kg per min	Vasodilator	1. Titrate rate of constant infusion against change in blood pressure 2. Stop treatment if blood thiocyanate exceeds 100 μ g/ml
Hydralazine	Minutes	1. 0.3–0.5 mg/kg as intravenous slow bolus dose; maximum 4-hourly 2. 0.025–0.05 mg/kg per hr intravenously to maximum of 3 mg/kg in 24 hr	Vasodilator	Titrate rate of constant infusion against change in blood pressure
Nifedipine (capsules)	Minutes	0.25–0.5 mg/kg orally	Vasodilator	1. Effect is less controllable than with intravenous infusion 2. Child must bite and swallow capsule, or liquid contents should be removed via a needle and syringe and then swallowed
Minoxidil	Minutes	0.1–0.2 mg/kg orally	Vasodilator	See (1) for nifedipine
Furosemide	Minutes	2–5 mg/kg intravenously over 20 min	Loop diuretic	For severe intravascular volume expansion states Rapid administration of large doses may be ototoxic

of a child presenting with hypertensive crisis. Some children with malignant hypertension are depleted for salt and fluid and have intense vasoconstriction. They may be especially sensitive to vasodilation and require considerable quantities of saline to maintain and control the blood pressure; therefore, an intravenous line should always be established. Patients should be managed on an intensive care unit or high-dependency unit by staff experienced in treating severe hypertension with intravenous drugs. Clinical improvement is often seen with a relatively small reduction of blood pressure, and the initial aim should not be rapid reduction of blood pressure to normal levels. Rather, as a guide, the eventual target blood pressure should be defined, the total reduction in systolic blood pressure calculated, and then the blood pressure reduced by one-third of this total in the first 6 hours, two-thirds of the total by the next 24 to 36 hours, and the total reduction achieved over a subsequent 48 to 72 hours.

A selection of drugs for use in hypertensive emergencies is shown in Table 58-10. Labetalol is an effective first choice. If it proves insufficient, then sodium nitroprusside may be added. The latter is especially useful because of its very short duration of action. Constant monitoring of the rate of infusion and blood pressure is required during its use. Thiocyanate toxicity can occur with long-term therapy or with renal insufficiency. Although nitroprusside has been used without ill effects for up to 10 days,³⁹¹ levels of thiocyanate should be monitored in the blood after 48 hours, and treatment discontinued if the concentration exceeds 100 µg/mL. The solution must be protected from light by shielding the syringe and infusion lines.

Less severe hypertensive crisis is often managed successfully with oral nifedipine in rapid-acting capsule form. Children should be instructed to bite the capsule, as most absorption occurs after swallowing the contained liquid. In young children, a liquid preparation is available, or the contents of a capsule may be aspirated by syringe and fine needle and then administered orally. Intravenous hydralazine may also be used as a rapid acting vasodilator. These agents, however, give less precise control over the rate of fall of blood pressure, and intravenous infusion treatment is preferred where there is symptomatic severe hypertension.

Cardiovascular Risk Factors in Infancy and Childhood

MARIETTA CHARAKIDA, JULIAN P. HALCOX, STAVROS P. LOUKOGEORGAKIS, and JOHN E. DEANFIELD

Although the clinical complications of atherosclerosis do not usually occur until adulthood, it is now appreciated that the underlying arterial pathology begins much earlier. Over the last two decades, there have been substantial advances in the understanding of the disturbed vascular biology involved in the initiation and progression of atherosclerosis and its late sequels, with identification of several risk factors on the causal pathway.

In developed countries, better treatment of adults with clinical cardiovascular disease, including reduction of risk factors, has resulted in substantial decrease in morbidity and mortality. This downward trend is slowing, and in developing countries there has been a huge increase in the burden and consequences of atherosclerosis, largely due to a deterioration in the levels of risk factors in the population.^{1,2} This has led to increasing interest in the understanding and treatment of the adverse influences promoting atherosclerosis during its long preclinical stage, rather than merely attempting to reverse long-standing atherosclerosis by complex and often expensive interventions which do not fully reverse risk.

The need for identification and treatment of risk factors from childhood is supported by a number of key observations:

- In autopsy studies, atheroma is prevalent in children and young adults who died of non-cardiac causes, from the first decade of life. This has recently been confirmed using intravascular ultrasound, with almost one-fifth of teenagers in the United States being found to have early lesions in their coronary arteries (Fig. 59-1).^{3,4}
- The interaction between risk factors and the vessel wall in early life has a strong influence on later cardiovascular outcome. In a recent reanalysis of the Framingham cohort, the risk factor profile at 50 years was associated with a tenfold variation in later event rates.⁵
- Risk factors in early years, such as blood pressure and adiposity, track into adulthood and predict higher rates of events produced by coronary arterial disease.⁵
- Reduction of risk factors in the young, by modification of lifestyle and/or medication, can improve dysfunctional vascular biology, such as endothelial function, and reverse structural changes in the arterial wall, such as the thickness of the carotid intimal and medial layers.⁶
- Early intervention to reduce risk factors is likely to produce greatly leveraged gains in cardiovascular outcome, so that duration of exposure is crucial. In the

ARIC study, a genetically determined 28% reduction in lifetime levels of low-density lipoprotein cholesterol levels in subjects with a polymorphism of the PCSK9 gene was associated with a reduction of almost nine-tenths in cardiovascular events.⁷

The study of arterial disease in childhood has been greatly facilitated by the development of non-invasive tests of vascular function and structure using ultrasound, and more recently magnetic resonance. In this chapter, we will review the range of factors which can interact with the arterial wall from early in life, discussing the evidence for a causal role and the opportunity for intervention. This approach to prevention is relevant, not only for the management of children who are at high risk, but also as a population-based strategy to reduce morbidity and mortality from atherosclerosis in later life.

CLASSICAL RISK FACTORS

Classical risk factors identified from adult studies, including hypercholesterolemia, hypertension, cigarette smoking, diabetes, and family history, all have adverse effects on the arterial wall from childhood. Originally it was thought that this occurred only in selected groups with high cardiovascular risk, such as those with familial hypercholesterolaemia, diabetes mellitus types 1 and 2, chronic renal disease, or chronic inflammatory conditions. Large epidemiological studies, however, such as the Bogalusa Heart Study, the Muscatine study, and the Cardiovascular Risk in Young Finns Study in childhood and adolescence, have demonstrated the impact of risk factors even in the general paediatric population. Furthermore, these risk factors tend to track into adulthood.⁸⁻¹³

Dyslipidaemia

Cholesterol is absorbed from the intestine, transported to the liver, and taken up by low-density lipoprotein-related proteins.¹⁴ Hepatic cholesterol enters the circulation as very low density lipoprotein, and is metabolised to remnant lipoproteins. Reverse transport of cholesterol from peripheral tissues to the liver is mediated by high-density lipoproteins.¹⁵⁻¹⁷ Cholesterol is recycled to low-density lipoproteins and very low density lipoproteins by cholesteryl-ester transport proteins, or is taken up in the liver by hepatic lipase.¹⁴ Defects in this pathway translate into a range of disordered lipid profiles.

Cholesterol was first postulated to be related to atherosclerosis because it is the major component of advanced atherosclerotic lesions. The causal relationship between

Figure 59-1 The images provide the evidence that atherosclerosis begins in childhood. Coronary atherosclerotic plaques were found in young American soldiers in their teens and early 20s who died in action in the Korean war.³ The arrow in panel A highlights the presence of significant plaque. The intravascular ultrasonic image of the coronary artery of a 17-year-old boy shown in panel B, who died of non-cardiac causes, shows the distinct mural thickening of the coronary artery (arrow).⁴ (A, Reproduced with permission from Enos WF, Holms RH, Beyer J: Coronary disease among United States soldiers killed in action in Korea; preliminary report. *JAMA* 1953;152:1090–1093. Copyright © 1953 Massachusetts Medical Society. All rights reserved. B, Reproduced with permission from Tuzcu EM, Kapadia SR, Tutar E, et al: High prevalence of coronary atherosclerosis in asymptomatic teenagers and young adults: Evidence from intravascular ultrasound. *Circulation* 2001;103:2705–2710.)

cholesterol and the formation of atherosclerotic plaques is now well established, and the impact of cholesterol both in initiation and progression of arterial disease is understood.^{18,19} Once lipid subfractions are retained in the intimal layers of the arterial walls, they undergo oxidative modification, and acquire pro-inflammatory actions.²⁰ Oxidised low-density lipoprotein stimulates the expression of adhesion molecules, such as vascular cell adhesion molecule-1, on endothelial cells, increasing the expression of monocyte chemotactic protein-1 by vascular cells. This promotes infiltration of myocytes into the vascular wall, and proliferation of macrophages. Apart from these initial steps in atherogenesis, oxidised low-density lipoproteins are involved in the progression of atherosclerosis.²⁰ They promote proliferation of macrophages and smooth muscle cells, as well as the expression and secretion of a variety of growth factors and cytokines from vascular cells. The resulting injury, apoptosis, and necrosis of vascular cells leads to the formation of the lipid core seen in established atherosclerotic lesions.¹⁹

The association between levels of cholesterol and cardiovascular risk is strong, continuous, and dependent on concentration, even at low levels of cholesterol, from childhood onwards. It is amenable to reversion.²¹ Large randomised trials in adults, predominantly using statins, have shown that significant reductions in levels of cholesterol are associated with a tremendous decrease in clinical events.^{22–24} A drop of no more than 1% in the level of cholesterol in the serum reduces the risk for coronary arterial disease by 2%.²⁵

In children, extreme elevations in the levels of lipids are usually encountered as a result of genetic hyperlipidaemias,

whereas modest increases are seen in relation to dietary habits and a sedentary type of life.²⁶ Reference values for the total concentrations of cholesterol in the serum are available for both sexes from the first few months of life up to 1 year of age, and every 2 years afterwards up to 18 years. At birth, levels of cholesterol are low. They then rise over the first year of life to the level for the rest of childhood before puberty. These normal values in Western societies, even in childhood, are markedly higher than in countries with healthier diets and lifestyles. They may not be therefore healthy and appropriate for prevention of atheroma (Fig. 59-2).^{27,28}

Strategies for screening children to establish levels of cholesterol have been reviewed recently in the light of the increasing evidence for the risk in the population, and to identify subjects with familial hypercholesterolaemia. Recent guidelines produced by the National Cholesterol Educational Program, designed to increase sensitivity and specificity of screening programmes, are outlined in Table 59-1.²⁶ Implementation of national strategies for cascade screening of families, once an index case has been identified, should greatly improve the rate of detection and lead to early and more active treatment from childhood. Family education is important, as eating habits in childhood influence behaviour in later life. The use of drugs, usually statins, in children remains controversial. According to the guidelines, they are not usually advocated until after the first decade of life, and only in children with hyperlipidaemia and two or more other cardiovascular risk factors. Over the past few years, however, a number of randomised controlled trials have demonstrated that treatment with statins is effective and safe in children, albeit with the short-term follow up²⁹ (see Fig. 59-2). For example, it was shown

Figure 59-2 Dyslipidaemia in childhood. Panel A shows that higher levels of low-density lipoprotein (LDL) cholesterol, even within normal limits, were associated with reduced arterial distensibility in healthy British children aged from 9 to 11 years.²⁷ Panel B shows that treatment over 2 years with pravastatin was associated with a reduction in carotid intimal and medial thickness in children with familial hypercholesterolaemia.²⁸ CA, carotid artery; CCA, common carotid artery; IMT, intima media thickness. (A, Reproduced with permission from Leeson CP, Whincup PH, Cook DG, et al: Cholesterol and arterial distensibility in the first decade of life: A population-based study. *Circulation* 2000;101:1533–1538.)

TABLE 59-1

RECOMMENDATIONS FOR THERAPEUTIC MANAGEMENT OF HIGH-RISK HYPERLIPIDAEMIA IN CHILDREN AND ADOLESCENTS

Original Recommendations of the National Cholesterol Education Program Expert Panel

1. Consider drug therapy in children ≥ 10 years of age (usually wait until menarche for females) and after a 6- to 12-month trial of fat- and cholesterol-restricted dietary management
2. Consider drug therapy if
 - Low-density lipoprotein level remains 4.90 mmol/L (190 mg/dL), or
 - Low-density lipoprotein level remains > 4.10 mmol/L (160 mg/dL) and there is a positive family history of premature cardiovascular disease
 - Two other risk factors are present in the child or adolescent after vigorous attempts to control these risk factors
3. Referral to specialized lipid centre may be appropriate
4. Treatment goal
 - Minimal low-density lipoprotein < 3.35 mmol/L (130 mg/dL)
 - Ideal low-density lipoprotein < 2.85 mmol/L (110 mg/dL)

2007 Modifications to National Cholesterol Educational Program recommendations

1. In addition to family history, overweight and obesity should trigger screening with a fasting lipid profile
2. Overweight and obese children with lipid abnormalities should be screened for other aspects of the metabolic syndrome (i.e., insulin resistance and type 2 diabetes, hypertension, and central adiposity)
3. For children meeting criteria for starting lipid-lowering drug therapy, a statin drug is recommended as first-line treatment
4. For children with high-risk lipid abnormalities, the presence of additional risk factors or high-risk conditions may also lower the recommended cutpoint low-density lipoprotein cholesterol level for initiation of drug therapy, lower the desired target low-density lipoprotein cholesterol level, and in selected cases, may prompt consideration for initiation below the age of 10 years
These risk factors and high-risk conditions may include
 - Male gender
 - Strong family history of premature cardiovascular disease or events
 - Presence of associated low high-density lipoproteins, high triglycerides, small, dense low-density lipoproteins
 - Presence of overweight or obesity and aspects of the metabolic syndrome
 - Presence of other medical conditions associated with an increased atherosclerotic risk such as diabetes, human immunodeficiency virus infection, systemic lupus erythematosus, organ transplantation, survival of childhood cancer
 - Presence of hypertension
 - Current smoking and passive smoke exposure
 - Presence of novel and emerging risk factors and markers, e.g., elevated lipoprotein(a), homocysteine, C-reactive protein
5. Ongoing research of drug therapy of high-risk lipid abnormalities in children is needed, particularly with regard to long-term efficacy and safety, and impact on the atherosclerotic disease process

Adapted from McCrindle BW, Urbina EM, Dennison BA, et al: Drug therapy of high-risk lipid abnormalities in children and adolescents: A scientific statement from the American Heart Association Atherosclerosis, Hypertension, and Obesity in Youth Committee, Council of Cardiovascular Disease in the Young, with the Council on Cardiovascular Nursing. *Circulation* 2007;115:1948–1967.

that, in children with familial hypercholesterolaemia, early treatment from the age of 8 years was associated with delay in progression of carotid intimal and medial thickness in adolescents and young adults.³⁰ As far as combined hyperlipidaemias are concerned, no specific guidelines exist for children with persisting hypertriglyceridaemia or low levels of high-density lipoproteins. In such cases, a diet restricted in terms of fat and cholesterol is important, and extra caution is needed in the setting of extreme elevations of triglycerides so as to prevent pancreatitis.²⁶

Hypertension

Hypertension is the most common risk factor for clinical cardiovascular disease in both men and women, irrespective of age. Both diastolic and systolic levels of pressure have been associated in a continuous and dose-dependent manner with incidence of stroke, coronary arterial, and peripheral vascular events.³¹ The pathophysiology that contributes to cardiovascular risk involves changes in resistance vessels, conduit arteries, and the heart, with alterations in shear stress in the arterial wall, endothelial dysfunction, a procoagulant state, increased oxidative stress, and inflammation.

Recent population studies emphasise the continuous relationship between blood pressure and cardiovascular outcome at levels previously considered safe and effective. This has been termed prehypertension by some, and an excessive response in the levels of blood pressure to exercise has also been shown to predict future cardiovascular events, further broadening the hypertensive phenotype. A wealth of clinical studies have shown that reduction in blood pressure by lifestyle or antihypertensive medication results in substantial fall in cardiovascular complications.

Measurement of blood pressure in childhood is important, as levels from as early as the first year of life track into adulthood. Essential, or idiopathic, hypertension is rare in childhood. It should only be diagnosed when secondary causes have been excluded. In these cases, it is usual to find a strong family history of hypertension. The commonest cause of secondary childhood hypertension is renal disease, but other aetiologies include coarctation of the aorta, endocrine disease, such as pheochromocytoma or hyperthyroidism, and adverse consequences of therapeutic regimes, such as oral contraceptives, sympathomimetics, and so on.³² Recent reports have shown an association between blood pressure and the index of body mass (see below).^{32,33}

According to recommendations made by the National High Blood Pressure Education Program, children older than 3 years should have their blood pressure measured when visiting the doctor. The risk for hypertension, however, cannot be estimated by a single measurement.³⁴ Blood pressure varies during the day and is influenced by factors of measurement, including the size of cuff, as well as by other less well-controlled factors, such as anxiety and stress. Accurate measurement in childhood requires use of a cuff that is appropriate to the size of the child's right upper arm, with an inflatable bladder having a width that is equal or greater than two-fifths of the circumference of the arm at a point midway between the olecranon and the acromion. The length of the bladder within the cuff should be sufficient to cover at least four-fifths of the circumference of the arm. An oversized cuff can underestimate pressure, whereas an undersized cuff can

overestimate the measurement. Before labelling a child as hypertensive, serial measurements should be performed and evaluated according to age, sex, and height-specific percentile plots.^{32,34}

The management of childhood hypertension is directed at identifying a cause and any predisposing factors. Changes in lifestyle, and pharmacologic interventions, are recommended based on criteria established according to the age of the child, the degree of hypertension, and the response to treatment. In children whose serial measurements lie between 90th and 95th percentiles, modifications of lifestyle are advocated to achieve decreased caloric intake and increased activity.³⁴ A reduction in the intake of salt, and increased intake of potassium and calcium, consumption of fresh fruits and vegetables and low-fat dairy products, as well as regular physical exercise and loss of weight, may assist in lowering the blood pressure in children. In adolescents, diets high in polyunsaturated fatty acids are reported to lower both systolic and diastolic measurements. For those found to have measurements lying between the 95th and 99th percentiles plus 5 mm Hg, re-evaluation should occur within 1 or 2 weeks. If this finding is confirmed, pharmacological therapy should be initiated.³⁴ Antihypertensive medication should also be initiated if there is evidence of damage to end-organs.³⁴ A number of classes of drugs can be used to lower blood pressure in the young. Blockers of the renin-angiotensin system have been used, particularly in children with co-existing pathology such as diabetes or proteinuria, while β -adrenergic and calcium channel blockers have been successfully administered in children with migraines.³⁴

Cigarette Smoking

Cigarette smoking is the most important preventable cause of premature death in Western societies. A strong epidemiological link between cigarette smoking and atherosclerosis has been confirmed in many studies. In young individuals who would otherwise be at very low risk of developing cardiovascular disease,³⁵ cigarette smoking may cause as many as three-quarters of the events related to atherosclerosis. The longer a person smokes, the higher the risk for coronary arterial disease. In most European countries, 3% of 11-year-olds, 10% of 13-year-olds, and up to one-third of 15-year-olds, are daily smokers, according to the British Medical Association Tobacco Control Resource Centre. There is also evidence that those who begin smoking before the age of 20 years have the highest incidence, and earliest onset, of coronary arterial disease and hypertension.

Tobacco smoke contains hundreds of potential toxic compounds that may accelerate atherogenesis and increase the risk of complications. Endothelial dysfunction occurs early in both active and passive smokers, with a decrease in the bioavailability of nitric oxide.³⁶ Cigarette smoking also increases pro-inflammatory cytokines and adhesion molecules, and disturbs the coagulation system.³⁷ Smoking is also associated with other abnormal risk factors, including blood pressure and lipid profile. Cigarette smoking has recently been targeted by many countries, with legislation introduced to ban smoking in public places. Early evidence has shown an impressive rapid reduction in acute coronary arterial events.³⁸ A major initiative in the young, which includes education in schools on smoking, is a further

prerequisite for a successful strategy for reduction of smoking in the population.

Genetics/Family History

The important contribution of genetic make-up in the atherosclerotic process has long been recognised.³⁹ Identification of single gene disorders, such as familial hypercholesterolaemia, has been important in establishing causal relations between risk factors and disease, and has enormously increased our understanding of atherogenesis.⁴⁰ In the absence of overt conventional risk factors, a clear association between family history of premature coronary arterial disease and endothelial dysfunction has been reported, further supporting the importance of the genetic background.^{41,42} There has been an explosion of new information from genome-wide association studies, linking a range of genetic polymorphisms to cardiovascular risk in adults.^{43,44} This has led to identification of new locuses, which will stimulate research into novel pathways contributing to vascular disease. Large studies of children will be required to determine whether the genetic variations associated with risk in adults operate from an early age to promote atherogenesis or, alternatively, are involved in destabilising established lesions to produce clinical complications.

NOVEL RISK FACTORS

A number of classical risk factors have clearly been linked to the evolution of the preclinical phase of atherosclerosis from childhood. High levels of these individual risk factors, such as cholesterol or hypertension, nonetheless, are uncommon in the absence of specific genetic conditions, such as familial hypercholesterolaemia and other diseases. It is likely, therefore, that a number of previously unrecognised factors, which are more prevalent in the population, may also contribute to initiation and progression of atherosclerosis.

Infection and Inflammation

Atherosclerosis has long been recognised as an inflammatory disorder, and the pathways involved in disturbed vascular biology have been described.⁴⁵ Recently, it has become clear that extrinsic inflammatory stimuluses may be involved in vascular inflammation and atherosclerosis. Infection is the commonest inflammatory condition in the young. The first evidence for a causal link with vascular disease came from animal studies in chickens with herpesvirus.⁴⁶ Data from human cross sectional epidemiological studies have subsequently implicated a number of viral and bacterial infections. This has led to the concept of the total pathogen burden influencing atherosclerosis, rather than isolated specific agents.⁴⁷ Several mechanisms have been proposed. The first is a direct effect of pathogens in the arterial wall, with systemic inflammatory activation leading to secondary arterial mural changes.⁴⁸ Most of the clinical studies, including numerous trials using antibiotics, have been performed in adults. They have produced conflicting results and are mostly disappointing.⁴⁹ This may be the result of confounding by the burden of other risk factors or, alternatively, because the role of infection may be greatest earlier in the evolution of arterial disease. The latter concept is supported by both animal studies and recent work using surrogate markers of

early arterial disease in children and young adults. For example, a reversible effect of even mild infection of the upper respiratory tract on endothelium-dependent flow-mediated dilation has been shown in prepubertal children,⁵⁰ and young men who are seropositive for *Chlamydia pneumoniae* have increased thickness of the carotid intimal and medial layers.⁵¹ In addition, other chronic infections, including the human immunodeficiency virus, have been linked with functional and structural arterial abnormalities from childhood and adverse cardiovascular outcome.^{52,53} The vascular consequences of childhood infection are likely to depend on a number of factors, including the burden, frequency, and chronicity of infection, the susceptibility of the host, and the presence of other coexisting risk factors for atherosclerosis. Currently, there is no evidence to support a therapeutic strategy against infection for prevention of vascular events in the young, except perhaps in situations of high risk. After transplantation of the heart in children, cytomegalovirus, in particular, has been linked to systemic coronary endothelial dysfunction, and recently to progression of coronary arteriopathy.⁵⁴ It may, therefore, become an interesting target for specific treatment in these patients.

Children with chronic inflammatory conditions, such as systemic lupus erythematosus and rheumatoid arthritis, have evidence for abnormalities for arterial structure and function, including reduced flow-mediated dilation and increased thickness of the carotid intimal and medial layers, which are likely to represent accelerated atherosclerosis.⁵⁵ Similar abnormalities in the same measures have been associated with increased cardiovascular morbidity and mortality in adults. Childhood vasculitis, including Kawasaki disease, may result in both acute and sustained arterial mural abnormalities, even in the absence of acute coronary arterial complications.⁵⁶ Long-term and careful follow-up of these children is important to determine the potential interaction with later acquired risk factors, and the indications for more active preclinical treatment.

Recently, evidence has emerged that chronic periodontal inflammation, which is prevalent in both children and adults, may have adverse effects on the arterial wall. In a randomised controlled trial, reduction in this inflammatory stimulus by periodontal treatment led to recovery of endothelial function, providing evidence for a causal link and a potential new opportunity for population-based reduction of cardiovascular risk.⁵⁷

Early Life Programming

For more than a century, it has been recognised that critical windows in early development may affect permanently later outcome and disease. It was the impact of early nutrition in animal studies that promoted the use of the term programming to describe the potential impact of early influences on later outcome.⁵⁸ An association between birth weight and weight at 1 year, and later cardiovascular risk, led to the development of the hypothesis of fetal origins for cardiovascular disease (Fig. 59-3).⁵⁹⁻⁶¹ This concept proposed that low birth weight was a surrogate for adverse events that had occurred in intra-uterine life. Blood pressure is the most commonly reported end point in large epidemiological studies examining the developmental origins of cardiovascular disease, since it can be measured easily and non-invasively in different age groups. More than

Figure 59-3 Early life programming. Panel A shows that low weight at birth was associated with increased cardiovascular mortality in a prospective cohort. There was a continuous relationship between weight at birth and outcome up to the top decile in men and women.⁵⁹ Panel B shows that weight at birth had a significant graded positive association with flow-mediated dilation (FMD) in a cohort of British children aged from 9 to 11 years when excluding the highest quintile.⁶⁰ Panel C shows flow-mediated endothelial dependent dilation in adolescence according to quarters of weight change in the initial 2 postnatal weeks. Flow mediated dilation was 4% lower in adolescents who were born prior to term, with the highest compared with the lowest rate of weight gain, in the first 2 weeks after birth. This evidence supports the catch up growth hypothesis.⁶¹ (B, Reproduced with permission from Leeson CP, Whincup PH, Cook DG, et al: Flow-mediated dilation in 9- to 11-year-old children: The influence of intrauterine and childhood factors. *Circulation* 1997;96:2233-2238. C, Reproduced with permission from Singhal A, Cole TJ, Fewtrell M, et al: Is slower early growth beneficial for long-term cardiovascular health? *Circulation* 2004;109:1108-1113.)

50 studies have shown an inverse association between birth weight and blood pressure in adulthood, at the rate of 1 to 2 mm Hg per kilogram.⁶² This association is seen in both males and females, and for both systolic and diastolic levels of blood pressure. The causal relationship, however, between adverse fetal environment, intra-uterine retardation of growth, and later cardiovascular disease, has been controversial. As a result of a series of randomised controlled trials, it has been suggested that the postnatal acceleration of growth is the important adverse influence, rather than events occurring antenatally. This has been termed the catch up growth hypothesis.^{63,64} The critical postnatal window which affects long-term development may vary from a few weeks to few months (see Fig. 59-3).⁵⁹⁻⁶¹ Despite strong evidence for early life programming, both antenatally and postnatally, the mechanisms by which later arterial phenotype and cardiovascular outcome are influenced remain

speculative. They may include effects on the growth and development of organs such as the liver or kidney, neurohormonal homeostasis, and levels of cardiovascular risk factors, as well as direct effects on the arterial wall. Evidence for programming has been demonstrated for blood pressure, cholesterol, and insulin resistance, as well as for endothelial function and arterial distensibility.^{63,65}

The catch up growth hypothesis has significant implications for science and public health, as postnatal factors, particularly nutrition, are amenable to intervention. The effects of early nutrition may be substantial. For example, the reduction of 3 mm Hg in diastolic blood pressure seen in infants fed a low-nutrient diet is greater than that for all other strategies for reducing blood pressure in the young, including weight loss, restriction of salt, and exercise.^{66,67} Feeding strategies for preterm and term infants, including weight gain targets and composition of milk formulas,

need to consider not only the short-term effects on health, but also the long-term impact on cardiovascular outcome. Further research should address the relationship between early growth, later growth trajectories, and profiles of cardiovascular risk factors.

Obesity

Over the last two decades, in parallel with advances in reduction of several classical risk factors, there has been an alarming increase in the occurrence of obesity, accompanied by upward shift in the distributions of body fat in the population, especially in the young.⁶⁸ This has been a worldwide trend. There is now strong evidence that obesity in adults is associated with coronary arterial disease and cardiovascular events, in association with a high-risk cardiometabolic profile and type 2 diabetes.⁶⁹ In the West, the current social distribution of obesity, which is more prevalent in lower socioeconomic groups, suggests that its impact could further exacerbate social inequalities in cardiovascular morbidity and mortality.⁷⁰ In developing countries, where obesity is rising in parallel with changes in risk factors associated with urbanisation, the cardiovascular consequences of obesity could be further amplified.⁷¹

The prevalence of obesity is rising rapidly in children. Specific nomograms which are age and gender specific based on the body mass index are now used for childhood stratification (Table 59-2A).⁷² Cut points have been defined. Normal weight is considered to represent those falling between the 5th and 85th percentiles. Those at risk for becoming overweight are those between the 85th and 95th percentiles, while those already overweight are above the 95th percentile. Using this classification, recent data indicates that the prevalence of overweight among children in the United States of America has risen from around one-twentieth in the 1980s to almost one-sixth during the last few years.⁷³

The epidemic of childhood obesity is likely to have a substantial impact on the future burden of cardiovascular disease within the population for several reasons. Firstly, obesity in childhood tracks to adulthood.⁷⁴ Overweight adolescents may be as much as 20 times more likely than their leaner peers to be obese in early adulthood. This has been confirmed in a number of longitudinal studies, including the Muscatine and the Bogalusa heart studies and the Cardiovascular Risk in Young Finns study.^{75,76} Of note, the likelihood that an obese child will become an obese adult increases with age and the severity of obesity.⁷⁷ Secondly, obesity results in a deranged metabolic profile, which includes dyslipidaemia, hypertension, and insulin resistance (Fig. 59-4).^{78,79} The extrapolation of criteria established for adults with the metabolic syndrome to children has been controversial. The International Diabetes Federation has developed a consensus to define metabolic syndrome in children, with thresholds of abnormality being determined according to age. The disturbed metabolic profile seen in obese children is associated with accelerated development of type 2 diabetes.⁷⁹ After adjusting for subsequent weight gain, female adolescents aged 18 with an index of body mass of greater than 30 kg/m² were 10 times more likely to develop diabetes than those with an index of less than 22 kg/m².⁷⁹ Thirdly, the cardiovascular effects of obesity are likely to be cumulative, so that both degree and duration of obesity may be important.

TABLE 59-2

A. MANAGEMENT OF WEIGHT AND GOALS OF TREATMENT, BASED ON PERCENTILES FOR THE INDEX OF BODY MASS AND STATE OF HEALTH

Index of Body Mass	Classification	Goal of Treatment
<85th percentile	Normal weight for height	Maintain percentile to prevent obesity
85th–95th percentile	At risk for overweight	Maintain index with aging to reduce to <85th percentile; if index > 25 kg/m ² , maintenance of weight
≥95th percentile	Overweight	Maintenance of weight in younger children, or gradual loss in adolescents, to reduce percentile within the index
≥30 kg/m ²	Adult obesity cut point	Gradual loss of weight by 1–2 kg per month to achieve healthier index
>95th percentile, comorbidity present	Overweight with comorbidity	Gradual loss of weight by 1–2 kg per month to achieve healthier index; assess need for additional treatment of associated conditions

B. GUIDING PRINCIPLES FOR TREATMENT OF OVERWEIGHT CHILDREN

1. Establish individual goals and approaches based on age, degree of overweight, and presence of comorbidities
2. Involve the family or major caregivers in the treatment
3. Provide assessment and monitor frequently
4. Consider behavioural, psychological, and social correlates of weight gain in the plan devised for treatment
5. Provide recommendations for dietary changes and increases in physical activity that can be implemented within the family environment and that foster optimal health, growth, and development

Adapted from Daniels SR, Arnett DK, Eckel RH, et al: Overweight in children and adolescents: Pathophysiology, consequences, prevention and treatment. *Circulation* 2005;111:1999–2012.

At least four studies have demonstrated that adolescents who are overweight suffer high overall mortality.^{80,81} It is likely that the adverse impact of obesity on the population will not be avoided merely by management of its associated risk factors such as hypertension and dyslipidaemia.

A focus on prevention of obesity in childhood rather than in adulthood is more logical, both because it is likely to be more effective and also because it will have a greater benefit for the long-term health of the population. Indeed, children have greater adaptability than adults, and preventing the initial gain in weight is far easier than attempting weight loss once obese. There is little evidence, nevertheless, that current approaches to reduction of weight in the young result in long-term benefits, in terms of either loss of weight or morbidity. Most trials have been short term, and many aspects of adiposity in the young remain unclear. These include the pattern of distribution of fat at different ages and in different ethnic groups, as well as the mechanisms which link adiposity and early vascular mural changes. Understanding these mechanisms is important, as, even if preventative measures to reverse obesity were to be implemented rapidly, at least

Figure 59-4 Obesity and metabolic syndrome in children and adolescents aged from 4 to 20 years. In children and adolescents in the United States, levels of insulin, blood pressure (BP), and low-density lipoprotein (LDL) cholesterol showed a significant increase with increasing levels of obesity, whereas high-density lipoprotein (HDL) cholesterol showed a graded decrease.⁷⁹ MO, moderately obese; N, not obese; O, obese; SO, severely obese. (Reproduced with permission from Weiss R, Dziura J, Burgert TS, et al: Obesity and the metabolic syndrome in children and adolescents. *N Engl J Med* 2004;350:2362–2374. Copyright © 2004 Massachusetts Medical Society. All rights reserved.)

one generation will end up in adult life with a high prevalence of obesity from childhood. A successful approach to deal with obesity in the young will require concerted political and societal action to alter the obesogenic environment in which children are growing up. There appear to be key windows of opportunity for intervention against obesity, which include pregnancy, the perinatal period to influence programming, infancy, puberty, and adolescence. Current approaches for treatment of obesity in the young include diets, modifications of lifestyle, drugs, and bariatric surgery for the morbidly obese (see [Table 59-2B](#)). A better understanding of mechanisms may lead to novel strategies to uncouple obesity and cardiovascular damage.

Diabetes

Although type 1 diabetes was the commonest form of diabetes in childhood, the epidemic of obesity is driving a rapid rise in the early presentation of type 2 diabetes. This is particularly prevalent in Asian, Afro-Caribbean, and Hispanic children, and is a worldwide phenomenon.⁸²

The risk for later atherosclerosis and premature cardiovascular death is markedly increased. The pathophysiology of atherosclerosis in diabetes is complex. It involves endothelial activation, inflammation, oxidative stress, and disturbed endogenous vascular repair.⁸³ In type 2 diabetes, the vascular impact is related to resistance to insulin, and the commonly associated risk profile of hypertension, dyslipidaemia, and disturbed metabolism of fat cells.⁸⁴

The optimal approach to the treatment of children and adolescents with type 1 diabetes, in addition to glycaemic control to retard cardiovascular disease, is uncertain.⁵⁵ Trials of statins and the antagonists of the renin-angiotensin system, which have proven benefit in adults, are in progress. In children with type 2 diabetes, modifications in lifestyle to achieve sustained loss of weight are crucial,

but difficult to achieve.^{55,85} Treatment to restore insulin sensitivity with metformin and thiazolidinediones may be required.⁸⁵ Evidence is accumulating for the benefit of reduction of other associated cardiovascular risk factors, including blood pressure and dyslipidaemia, in these high-risk subjects. As a result, more active treatment with statins and antihypertensive agents is likely to be extended to younger subjects, with the aim of lifetime reduction in cardiovascular risk.

SUMMARY

The assessment and management of cardiovascular risk factors from childhood has emerged as a crucial strategy for reduction of the risk from atherosclerosis over the lifetime.⁵⁵ Understanding of the evolution of early atherosclerosis, and the impact of interventions at a young age, has been facilitated by the development of non-invasive tests of early changes in arterial function and structure, which are on the causal pathway for later clinical disease. Using this approach, reduction of a range of risk factors in childhood has been shown to be associated with reversibility of early vascular abnormalities. New risk factors are emerging at an early age because of the deterioration in the lifestyle and behaviour of the population. Poor diet and less physical exercise have led to an epidemic of childhood obesity. Paediatricians need to be involved in the characterisation and management of cardiovascular risk factors from childhood, in both high-risk individuals and the general population. The medical profession, in addition, should engage actively with families, teachers, providers of health care, and politicians to promote understanding of the importance of lifetime investment in the reduction of risk factors. Without this, the gains achieved from better management of clinical cardiovascular disease are likely to be overwhelmed by an epidemic driven by deterioration of the profile of risk factors in the next generation of patients.

This article highlights the potential consequences of childhood obesity on cardiovascular health in adult life. It also suggests that targeting the associated risk factors is unlikely to be sufficient, and that obesity itself should be managed.

Management of Congenital Heart Disease in Pregnancy

CANDICE K. SILVERSIDES, SAMUEL C. SIU, MATHEW SERMER, and JACK M. COLMAN

The successes of paediatric cardiology and cardiac surgery have enabled a new cohort of women, born with congenitally malformed hearts, to reach adulthood. Many of these women differ both anatomically and physiologically from any who have considered pregnancy in the past. Most women in this new cohort can anticipate safe and successful pregnancies. Pregnancy, however, imparts additional haemodynamic loads, changes in mechanisms of clotting, and increased propensity to arrhythmias, all of which increase the risk of adverse maternal cardiac events during pregnancy. In addition, there may be risks for adverse fetal and neonatal events. The recognition and appropriate management of such risks, when present, should optimise outcomes, while the recognition in other cases that a woman with a congenitally malformed heart is not at high risk allows reassurance.

IMPACT OF PREGNANCY ON THE CARDIOVASCULAR SYSTEM

Haemodynamic Changes during Pregnancy

The maternal volume of blood increases by approximately 50%, beginning during the first trimester, and peaking in the third trimester.^{1,2} There is also an increase of up to 40% in the mass of erythrocytes.³ The average heart rate increases by 10 to 20 beats per minute. Beginning early in the first trimester, the systemic vascular resistance and systemic arterial pressure begin to decrease owing to the low-resistance circuit in the uterus and to the effects of endogenous vasodilators. The systemic vascular resistance decreases until mid pregnancy, plateaus, and then rises toward the levels existing prior to pregnancy.^{4,5} Systemic arterial pressure also begins to return toward pre-pregnancy levels in the third trimester. The changes in blood volume, vascular resistance, and heart rate all contribute to an increase in cardiac output, which begins early in the first trimester, continues to increase until approximately the end of the second trimester, rising to between one-third and one-half of the levels existing prior to pregnancy,^{4,6–11} and then plateaus until term. Cardiac output is affected by position, and is highest when the mother is lying on her left side. The supine gravid uterus can compress the inferior caval vein, which limits venous return, and may lead to a substantial reduction in cardiac output. Women with cardiac disease have been shown to have lower cardiac output during pregnancy when compared to women without such disease.¹² The increased blood volume and systemic vasodilation also affect the flow of blood to other organs, including the skin, uterus, and kidneys. In the kidney, the result is an increase in the effective renal flow of plasma, and a 50% increase in the rate of glomerular filtration.¹³

Labour is associated with a further increase by approximately 10% in basal cardiac output, augmented by an additional surge of up to one-sixth with each uterine contraction.¹⁴ Anxiety, pain, tachycardia, and hypertension or hypotension also contribute to cardiac complications at the time of labour and delivery. Following delivery, there is a further increase in cardiac output due to relief of compression on the inferior caval vein, and auto-transfusion from the now fully contracted uterus. Rapid mobilisation of interstitial fluid in the immediate period following pregnancy may have a significant negative impact on a woman with already compromised cardiac function. Although many of the described changes regress within the first few days after delivery, complete resolution of pregnancy-induced effects on cardiac function may not occur until 6 months after delivery.¹⁵

Cardiac Symptoms and Signs in Normal Pregnancy

During pregnancy, women often experience fatigue, dyspnea, tachypnoea, palpitations, presyncope, and decreased exercise tolerance. Such symptoms can be identical to those of cardiac decompensation, and clinicians must be careful to differentiate this possibility. Blood pressure decreases during the first part of pregnancy, and then during the last 6 weeks reaches or exceeds pre-pregnancy levels. Blood pressure should be taken when the mother is sitting or lying on her left side to avoid a falsely low reading caused by supine caval venous compression limiting venous return. The diastolic blood pressure falls more than the systolic pressure, resulting in a wide pulse pressure. The heart rate increases. Warm, erythematous hands and feet, nasal congestion, and breast engorgement are due to increased blood flow. Peripheral oedema may be noted. There may be a laterally displaced apical impulse due to modest increase in cardiac size, as well as upward displacement of the heart by the gravid uterus. There is often prominence of the jugular venous pulsation. There may be wide splitting of the first and second heart sounds. The continuous murmur of a venous hum in the right supraclavicular fossa, or a mammary souffle over an engorged breast, can become apparent during pregnancy. A systolic flow murmur is common, secondary to the hyperdynamic circulation, and is best heard at the left lower sternal border.

IMPACT OF PREGNANCY ON COMMON CARDIAC DIAGNOSTIC TESTS

The surface electrocardiogram may show a sinus tachycardia. Because of the change in position of the heart, the electrocardiogram may show a shift in the frontal plane

axis, or inversion of the T waves in the inferior leads. The chest radiograph may show a more horizontal cardiac shadow because of elevation of the diaphragm, and an enlarged cardiac silhouette. The pulmonary vascular markings may become more prominent due to increased blood flow, simulating the vascularity produced by a systemic-to-pulmonary shunt. Echocardiographically, the increase in blood volume manifests as mild increases in the dimensions of the atriums and ventricles. The left ventricular mass increases.^{7,15,16} The increased cardiac output is associated with increases in velocities of flow across all cardiac valves. Mitral regurgitation may either improve or worsen, according to the relative impact of the fall in systemic vascular resistance versus the change in geometry of the mitral valvar apparatus associated with increasing chamber size. Mild depression of left ventricular contractility has been demonstrated,¹¹ but left ventricular systolic performance is thought generally to be preserved.^{8,10,11}

PRECONCEPTION COUNSELING AND CONTRACEPTION

All women with congenitally malformed hearts should have age-appropriate counseling prior to potential conception, beginning in adolescence.¹⁷ This responsibility often falls to the specialist in congenital cardiac disease caring for the woman at the time, and his or her team, as the patient will often not have access to any others qualified to offer knowledgeable advice. Counseling should address:

- The diagnosis and long-term prognosis for the mother
- The maternal risk of pregnancy
- The risk to the fetus and neonate, including the risk of transmission of congenital cardiac disease to offspring
- Safe and unsafe options for contraception
- The need for high-risk obstetrical and multi-disciplinary care during pregnancy, if appropriate

It is common that information regarding diagnosis, previous procedures, and prognosis are not known to, or are misunderstood by, the patient. Clarification of diagnosis and functional capacity are fundamental to effective preconception counseling. The specialist in congenital cardiac disease is well suited to this task and also to ensuring that this information is provided to, and understood by, other caregivers involved in the management of the pregnancy. Discussion of long-term prognosis of the mother may be straightforward, or very complex and sensitive, depending on the underlying cardiac lesion, the types of surgical interventions, the residual lesions, and co-morbid medical conditions. Because maternal cardiac status can change over time, women with congenitally malformed hearts should be advised to ensure regular follow-up, and in particular to obtain a contemporaneous updated assessment prior to finalizing a decision to pursue pregnancy.¹⁷ We discuss general and lesion-specific maternal and fetal risks associated with pregnancy in the later sections of this chapter.

Family planning needs are often poorly addressed in women with congenitally malformed hearts.¹⁸ The safety and efficacy of various types of contraception need to be considered, but this has not been studied in women with congenitally malformed hearts. Recommendations regarding proper use of contraceptives have been extrapolated

from studies in women without cardiac disease, and are based on expert opinion.^{19–22} Options include:

- Barrier methods
- Combined oral contraceptives containing oestrogen and progestin
- Oral contraception with progestin alone
- Intra-uterine devices
- Sterilisation
- Emergency contraception

Barrier methods do not pose a health risk to the mother, but are associated with high rates of failure. Up to one-third of women using this technique will have an unintended pregnancy within the first year of use. Barrier methods, therefore, should not be recommended to women in whom there is a significant maternal risk of pregnancy.

Combined oral contraceptives have good efficacy, but the oestrogen component is associated with a risk of both arterial^{23,24} and venous²⁵ thrombosis, which limits their use in women with cyanotic cardiac disease, the Fontan circulation, significant systemic ventricular dysfunction, sustained arrhythmias, mechanical valves, or prior thromboembolic events (Table 60-1). Other forms of combined contraception such as skin patches containing ethinyl estradiol and norelgestromin, and vaginal rings containing ethinyl estradiol and etonogestrel, are also associated with a thrombotic risk. The risk of stroke in association with combined oral contraceptives is further increased if a woman has a history of hypertension, diabetes, obesity, smoking, or migraine headaches.²⁴ Both oestrogens and progestins can interfere with the metabolism of warfarin, and international normalised ratios need to be monitored more closely in women using these forms of contraception.

Oral contraception using progestin alone is not associated with a risk of arterial or venous thrombosis,²⁶ but those using these agents suffer higher rates of failure compared to those using combined oestrogens and progestin. Such higher rates of failure are particularly seen with older pills containing only progestin, the so-called mini-pills, which should not be used in women with cardiac disease who face substantial risk of pregnancy.²⁰ A newer form of pill containing desogestrel is associated with lower rates of failure.²⁷ Pills containing only progesterone are associated with higher rates of vaginal breakthrough bleeding, and may thus be unacceptable to some patients. Bosentan can reduce the efficacy of pills containing exclusively progestin, so these should not be used alone in patients with pulmonary arterial hypertension undergoing medication with bosentan, in whom the maternal risk associated with pregnancy is substantial. Other forms of contraception using progestin alone include injectable medroxyprogesterone acetate, subcutaneous implants containing etonogestrel, and intra-uterine systems impregnated with levonorgestrel. Depo-Provera, the injectable form of medroxyprogesterone, is given by deep intramuscular injection, and can result in haematomas, a problem for women taking anticoagulants. Implanon, containing etonogestrel, is a subdermal implant that carries less risk of producing haematomas than is seen with intramuscular injection.

Insertion of intra-uterine devices can be associated with bacteraemia. As a result, such devices are contra-indicated in women at high risk for endocarditis, such as those who have suffered previous endocarditis, or those with mechanical heart valves. In approximately one-twentieth

TABLE 60-1

COMBINED HORMONAL CONTRACEPTIVES IN WOMEN WITH CARDIAC DISEASE

Class 1: Always Usable	Class 2: Broadly Usable	Class 3: Caution in Use		Class 4: Do Not Use	
Minor valve lesions: mitral valve prolapse with trivial mitral regurgitation, bicuspid aortic valve with normal function, mild pulmonary stenosis	Tissue prosthetic valve lacking any class 3 or 4 features Mild native mitral and aortic valve disease Most arrhythmias other than atrial fibrillation or flutter Hypertrophic cardiomyopathy lacking any class 3 or 4 features	Thrombotic risk, even on warfarin Risk of paradoxical embolism	Mechanical valves: bileaflet valves Previous thromboembolism Atrial arrhythmias, dilated left atrium >4 cm Potential reversal of left to right shunt: unoperated atrial septal defects	Thrombotic risk, even on warfarin Risk of paradoxical embolism	Mechanical valves: Starr Edwards valve, Björk Shiley valve, any tricuspid valve Ischemic heart disease Pulmonary hypertension of any cause Dilated cardiomyopathy and left ventricular dysfunction of any cause (left ventricular ejection fraction <30%) Fontan circulation Previous arteritis involving coronary arteries, e.g., Kawasaki disease Cyanotic heart disease, pulmonary arteriovenous malformation
Repaired coarctation with no hypertension or aneurysm	Fully recovered past cardiomyopathy including peripartum cardiomyopathy				
Simple congenital lesions successfully repaired in childhood with no sequels	Uncomplicated Marfan syndrome Congenital heart disease lacking any class 3 or 4 features Small left-to-right shunt not reversible with physiological manoeuvres, e.g., small ventricular septal defects				

From Thorne S, MacGregor A, Nelson-Piercy C: Risks of contraception and pregnancy in heart disease. *Heart* 2006;92:1520–1525.

of women, a vasovagal reaction will occur when the cervix is instrumented for placement of a device. This can be particularly hazardous in women with pulmonary hypertension and those with the Fontan circulation.

Sterilisation should be considered for women in whom pregnancy carries a very high risk. This process has a number of limitations, including late rates of failure estimated as high as 1 in 200,²⁸ though bilateral fimbriectomy is associated with a much lower rate of failure. Further limitations are the associated maternal risks of general anaesthetics or abdominal insufflation with carbon dioxide, poorly tolerated in women with the Fontan circulation, for example, and the psychological impact on the patient. A new alternative utilises hysteroscopic insertion of intratubal stents under oral analgesia.²⁹ This method may prove useful for women at high risk with other techniques of sterilisation. Vasectomy may not be an ideal solution because a male partner may outlive his spouse and may wish to father children with a new partner.

Emergency contraception, the so-called morning-after pill, available in forms containing oestrogen and progestin, or progestin only, is safe for women with congenitally malformed hearts, and its availability should be made known.^{19,30} Termination may be the most appropriate response to pregnancy in infrequent cases, and the possibility should be explored when indicated.

When pregnancy is actively considered, or when the woman presents in a gravid condition, the assessment must incorporate advice about the proper level of obstetric and multi-disciplinary care during pregnancy. Most women with congenitally malformed hearts will benefit

from an initial cardiac and high-risk obstetrical consultation. Those with minor lesions and their caregivers can be reassured regarding the low risk of adverse events and the appropriateness of standard obstetrical care. Women at higher risk can be referred appropriately to high-risk obstetrical units, where they will have access to specialists with experience in managing complex cardiac disease through pregnancy.³¹

GLOBAL AND LESION SPECIFIC RISKS AND OUTCOMES

Global Assessment of Maternal and Fetal or Neonatal Risks

Maternal cardiac disease is a risk factor for adverse maternal and fetal events. When evaluating pregnant women with cardiac disease, a global assessment is made of the risk of adverse maternal cardiac events, with fetal and neonatal risks considered separately. This should be supplemented with weighing of lesion-specific risks when these are known.

A Canadian consortium prospectively developed and validated a global risk index for pregnant women with heart disease. A poor functional state defined as New York Heart Association functional class three or four, or cyanosis, systemic ventricular systolic dysfunction, obstruction in the left heart, and history of prior cardiac events such as arrhythmia, stroke, and cardiac failure, were all predictors of adverse maternal cardiac events during pregnancy.³² A point-score system assigned one point to each of these predictors. Patients with no predictors were at low risk, having a chance of adverse events in only one-twentieth

TABLE 60-2

RISK FACTORS FOR MATERNAL CARDIAC AND NEONATAL ADVERSE EVENTS DURING PREGNANCY IN WOMEN WITH HEART DISEASE

1.1 Adverse Event	1.2 Risk Factor	1.3 Adverse Event	1.4 Risk Factor
Maternal cardiac adverse event*	<i>General risks</i> 1. Poor functional class (NYHA class III or IV) or cyanosis 2. Systemic ventricular ejection fraction <40% 3. Left heart obstruction (mitral valve area <2 cm², aortic valve area <1.5 cm², or peak left ventricular outflow tract gradient >30 mm Hg) 4. Cardiac event (arrhythmia, stroke, pulmonary oedema) prior to pregnancy <i>Lesion specific risks (see text)</i>	Neonatal adverse event†	1. Poor maternal functional class (NYHA class III or IV) or cyanosis 2. Maternal left heart obstruction (defined above) 3. Maternal age <20 or >35 years 4. Obstetric risk factors‡ 5. Multiple gestation 6. Smoking during pregnancy 7. Anti-coagulant therapy

*Maternal cardiac adverse events include: pulmonary oedema, arrhythmia, stroke and death. The general risk factors can be used to constitute a risk index: the risk of a maternal cardiac adverse event with no risk factors present is <5%, with one risk factor present is 25%, and with more than one risk factor present is 75%. Data from Siu SC, Sermer M, Colman JM, et al: Prospective multicenter study of pregnancy outcomes in women with heart disease. *Circulation* 2001;104:515–521.

†Neonatal adverse event include premature birth, small-for-gestational age birth weight, respiratory distress syndrome, intraventricular haemorrhage, and fetal or neonatal death. Data from Siu SC, Sermer M, Colman JM, et al: Prospective multicenter study of pregnancy outcomes in women with heart disease. *Circulation* 2001;104:515–521.

‡History of premature delivery or rupture of membranes, incompetent cervix, or caesarean section; or intra-uterine growth retardation, antepartum bleeding >12 weeks of gestation, febrile illness, or uterine/placental abnormalities during present pregnancy.

of pregnancies, whereas those with one predictor were at intermediate risk, adverse effects being anticipated in one-quarter of pregnancies, and those with more than one predictor were at very high risk, with adverse events anticipated in three-quarters of pregnancies (Table 60-2 and Fig. 60-1). When applying the global score for risk, it should be borne in mind that patients previously known to be at high risk, such as those with Eisenmenger's syndrome, pulmonary hypertension, the Fontan circulation, or Marfan syndrome with a dilated aortic root, were not represented or else under-represented in the populations studied. These previously known markers of high risk, therefore, are not reflected in the global score, and must be separately considered through application of a parallel lesion-specific evaluation of risk. In a recent study, dysfunction of the subpulmonary ventricle and severe pulmonary regurgitation were shown to be additional predictors for adverse maternal cardiac events.³³ Other factors that increase maternal cardiac risk during pregnancy include

prosthetic valves, anticoagulant therapy, and co-morbid medical conditions such as diabetes and hypertension.

A British working group has also created a classification of risk for women with cardiac conditions undergoing pregnancy. This categorises the risk during pregnancy using global and lesion-specific elements¹⁹ (Table 60-3). According to these recommendations, pregnancy is contraindicated in women with cardiac lesions associated with extremely high risks of maternal morbidity and mortality. These lesions include systemic ventricular dysfunction producing New York Heart Association functional class, three or four symptoms, an ejection fraction of less than 30%, peripartum cardiomyopathy with any residual left ventricular dysfunction, severe obstruction of the left ventricular outflow tract, Marfan syndrome with an aortic root diameter of greater than 40 mm, and pulmonary arterial hypertension.

General and lesion-specific recommendations for evaluation and management of pregnancy have also been published by the European Society of Cardiology³⁴ and the Canadian Cardiovascular Society.^{35–37} In addition, there are excellent texts available devoted to pregnancy in women with cardiac disease.^{38–40}

Although the risks of adverse maternal events during pregnancy and the early peripartur period are reasonably well described, little data is available concerning late maternal outcomes in women with congenitally malformed hearts.^{41,42}

Women with cardiac disease also have an increased risk of adverse fetal and neonatal events. In a prospective study,⁴³ we showed that the risk of neonatal complications, such as premature birth, weight at birth small for gestational age, respiratory distress syndrome, intraventricular haemorrhage, and fetal or neonatal death, is higher in women with cardiac disease, amplified by specific maternal cardiac risk factors, and further amplified by concomitant maternal non-cardiac risk factors for adverse fetal and neonatal outcomes (Fig. 60-2; see also Table 60-2).

Figure 60-1 Maternal cardiac risk during pregnancy, showing data from the CARPREG Study. (Data from Siu SC, Sermer M, Colman JM, et al: Prospective multicenter study of pregnancy outcomes in women with heart disease. *Circulation* 2001;104:515–521.)

TABLE 60-3

PREGNANCY RISK FOR WOMEN WITH CARDIAC DISEASE

Class 1: No Risk	Class 2: Small Increased Risk	Class 2–3: Depending on the Individual	Class 3: Significant Risk	Class 4: Pregnancy Contra-indicated
Uncomplicated, small, or mild pulmonic stenosis, ventricular septal defect or patent ductus arteriosus, mitral valve prolapse with no more than trivial mitral regurgitation	Unoperated atrial septal defect Repaired tetralogy of Fallot Most arrhythmias	Mild left ventricular impairment Hypertrophic cardiomyopathy Native or tissue valvular heart disease not considered class 4 Marfan syndrome without dilated aortic root Heart transplant	Mechanical valve Systemic right ventricle (e.g., congenitally corrected transposition, complete transposition post-Mustard or post-Senning repair) Post-Fontan operation Cyanotic heart disease Other complex congenital lesions	Pulmonary arterial hypertension of any cause Severe systemic ventricular dysfunction associated with New York Heart Association functional class III–IV or left ventricular ejection fraction <30%* Previous peripartum cardiomyopathy with any residual impairment of left ventricular function Severe left heart obstruction Marfan syndrome with dilated aorta >40 mm
Successfully repaired simple lesions, e.g., atrial septal defect, ventricular septal defect, patent ductus arteriosus, or anomalous pulmonary venous connection Isolated atrial or ventricular extrasystoles				

*Risk assessment should be individualized for patients with more complex cardiac anatomy.

Modified from Thorne S, MacGregor A, Nelson-Piercy C: Risks of contraception and pregnancy in heart disease. *Heart* 2006;92:1520–1525.

Figure 60-2 Fetal and neonatal risks as amplified by concomitant obstetric risk factors. Obstetric factors include history of premature delivery or rupture of membranes, incompetent cervix, or cesarean section; or intra-uterine growth retardation, antepartum bleeding after 12 weeks of gestation, febrile illness, or uterine/placental abnormalities during the present pregnancy. CV, cardiovascular; OB, obstetric. (Data from Siu SC, Colman JM, Sorensen S, et al: Adverse neonatal and cardiac outcomes are more common in pregnant women with cardiac disease. *Circulation* 2002;105:2179–2184.)

The risk related to inheritance merits separate discussion. Baseline probability of a congenitally malformed heart in the absence of an affected relative is from 0.4% to 0.6%, but increases about 10-fold when a parent is affected,⁴⁴ with some studies suggesting a higher rate of transmission when the mother is the affected parent.^{44,45} With certain lesions, the likelihood of transmission is higher. In those with atrioventricular septal defects, the maternal transmission is reported to be 11.6%.⁴⁵ In autosomal dominant syndromes such as Noonan's syndrome,⁴⁶ Holt-Oram syndrome,⁴⁷ Williams syndrome,⁴⁸ Marfan syndrome, and the 22q11 deletion syndromes, the risk is 50%, though penetration and phenotypic expression may vary. Because of successful management of patients with congenitally malformed hearts, there is an expanding pool of potential parents who carry higher genetic risk for

transmission to offspring. The impact that this will have on rates of congenital cardiac disease in newborns is offset to an unknown extent by advances in diagnosis during early pregnancy through fetal screening that may lead to termination of some affected pregnancies.⁴⁹ In our experience, the result of fetal echocardiography in a woman with a known increased risk of carrying a fetus with a congenitally malformed heart is infrequently used to support termination, but rather is applied to facilitate peripartum planning and neonatal management.

We have shown that a careful assessment at least 2 weeks after delivery, supplemented by clinically guided use of echocardiography, can identify additional cases of congenital cardiac disease in offspring of women with congenitally malformed hearts that were not identified by fetal echocardiography.⁵⁰

Lesion-specific Risks, Outcomes, and Strategies for Management

Left-to-right Shunts

Simple left-to-right shunts, including those produced by interatrial communications, ventricular septal defect, and patency of the arterial duct, are generally well tolerated during pregnancy. The increase in volume load is counteracted to some extent by the fall in peripheral vascular resistance, and complications are rare.^{51–53} Potential complications include arrhythmias, deterioration in functional class, cardiac failure, and paradoxical embolism. Arrhythmias were reported in only 1 of 123 pregnancies in women with atrial septal defects, and in no pregnancies in women with ventricular septal defects. None of the patients developed cardiac failure during pregnancy.⁵⁴

Atrioventricular septal defects are more complex, and are associated with regurgitation across both the right and left sides of the common atrioventricular junction. Compared to women with simple lesions, those with atrioventricular

septal defect are more likely to experience cardiac complications.^{53,55} When intracardiac shunts are associated with pulmonary hypertension, the risk again is high, and mainly attributable to the pulmonary hypertension, discussed separately below.

Transposition

Atrial redirection procedures such as the Mustard or Senning operations were the original techniques used to repair patients with transposition, albeit now superseded in most instances by the arterial switch operation (see Chapter 38). Women with arterial switch operations have only recently begun to reach childbearing age, and only limited outcome data is available.⁵⁶ Most women with transposition now of childbearing age, therefore, will have had an atrial repair in infancy, and as a consequence will have the morphologically right ventricle and tricuspid valve supporting the systemic circulation. This is associated with variable degrees of systemic ventricular dysfunction and systemic atrioventricular valvar regurgitation. Additional sequels that may impact on pregnancy include atrial arrhythmias, sinus nodal dysfunction, and obstruction or leak across the atrial baffle. Cardiac failure, functional deterioration, and arrhythmias are the main complications reported during pregnancy.^{57–64} In addition, obstetric complications, such as premature rupture of membranes, premature labour, premature delivery, and thromboembolic complications, were frequent.⁶¹ Those studying the late effects of pregnancy on the systemic right ventricle found late echocardiographic evidence of systemic ventricular dilation in almost one-third of the women, and deterioration in the function of the systemic ventricle in one-quarter.⁶³ Premature delivery is reported in one-third of pregnancies, with one-fifth of babies born small for gestational age.⁵⁴

Congenitally Corrected Transposition

Congenitally corrected transposition is also associated with a morphologically right ventricle supporting the systemic circulation. It is also frequent to find regurgitation of the abnormal systemic atrioventricular valve, ventricular septal defect and pulmonary stenosis, and disturbances of atrioventricular conduction (see Chapter 39). Although maternal deaths have not been reported, cardiac failure, arrhythmias, endocarditis, myocardial infarction, and stroke have been described as complications of pregnancy.^{65,66}

Those with Functionally Univentricular Hearts and the Fontan Circulation

The Fontan procedure, initially developed as a palliation to improve haemodynamics in patients with tricuspid atresia, has been extended to provide palliation for those with other complex congenital cardiac lesions not amenable to biventricular repair. Despite overall benefit, patients remain with functionally univentricular physiology, and have limited ability to increase cardiac output. Late complications in patients with the Fontan circulation include elevated right atrial and systemic venous pressures, arrhythmias, ventricular dysfunction, protein-losing enteropathy, and thromboembolic events (see Chapter 31). All these problems can be provoked or aggravated by the additional haemodynamic load of pregnancy. Therefore, women with the Fontan circulation need to be educated about the potential maternal risks of pregnancy. If they choose to become pregnant, they must be monitored closely. In one retrospective report on 33 pregnancies including 15 live births, supra-ventricular tachycardia occurred in one woman.⁶⁷ In the

same series, two-fifths of women had spontaneous abortions. Others have suggested that maternal cardiac and non-cardiac complications are common,^{68,69} with one study reporting miscarriage in half of those becoming pregnant, with amenorrhoea in two-fifths.⁶⁹

Obstruction of the Left Ventricular Outflow Tract

A bifoliate aortic valve (see Chapter 44) is the most common cause of an obstructed left ventricular outflow tract in women of childbearing age. A smaller number of cases are due to subvalvar or supra-ventricular stenosis, or other abnormalities at the valvar level. Severe obstruction may not be well tolerated during pregnancy because the increased blood volume and stroke volume may provoke left ventricular failure. Furthermore, abrupt changes in preload may be poorly tolerated by the hypertrophied ventricle, so haemorrhage, or the effects of general or regional anaesthetic agents, can lead to profound haemodynamic embarrassment. During pregnancy, women with severe obstruction are at risk for the development of angina, functional deterioration, cardiac failure and arrhythmias, as well as sudden death, though adverse maternal cardiac events are not as common as described in early reports.⁷⁰ Our group found adverse maternal cardiac events in around one-twentieth of women during or immediately after pregnancy,^{70,71} with similar observations reported by others.^{72,73} Our patients frequently required intervention within a few years after pregnancy, up to two-fifths of those with severe stenosis, so this possibility should be addressed during pre-pregnancy counseling.⁷¹ Balloon aortic valvoplasty and aortic valvar surgery have been performed successfully during pregnancy.⁷⁴ Because of the risk to the fetus, such interventions should only be performed if there are no other alternatives. Despite relatively reassuring maternal outcomes, fetal, neonatal, and obstetric complications are common in women with aortic stenosis.⁷¹ Aortic insufficiency, on the other hand, is generally well tolerated unless severe and associated with depressed left ventricular function.

Aortic Coarctation

Most women with coarctation of the aorta have had some type of repair (see Chapter 46). Repair may be associated with sequels, in particular development of aneurysms when Dacron has been used for a patch, or pseudoaneurysms.⁷⁵ Thus, imaging of the site of repair, optimally by magnetic resonance imaging, is optimal prior to conception.⁷⁶ Patients with unrepaired coarctation, or those with repaired coarctation and residual or recurrent obstruction, are subject to upper body hypertension. Antihypertensive treatment directed at the upper body may exacerbate hypotension distal to the coarctation, and thus compromise placental perfusion. This may explain the increased incidence of intra-uterine restriction of growth and prematurity seen in the offspring of such patients.⁷⁷ In contemporary studies, maternal mortality in women with repaired coarctation is rare, but women are at increased risk for pregnancy-induced hypertension, pre-eclampsia, and complications related to the associated bifoliate aortic valve.^{32,76–78} Dissection of the aorta has been reported.

Marfan Syndrome and Other Aortopathies

Pregnancy-related haemodynamic and hormonal changes impact the structure of the aortic wall, and increase the risk of dilation and dissection. This phenomenon manifests as an increased risk of spontaneous dissection, even in

women with no known or diagnosable aortopathy.⁷⁹ This is very low in otherwise normal women. Dissection has best been described in those with Marfan syndrome, but women with other aortopathies that have genetic and/or pathologic similarities, such as familial thoracic aortic aneurysm and dissection syndrome, Loeys-Dietz syndrome, the aortopathy associated with the bicuspid aortic valve, Turner's syndrome, and vascular Ehlers-Danlos syndrome, are also at increased risk of aortic complications.^{80,81}

In a seminal prospective study of women with Marfan syndrome followed through 45 pregnancies, no significant change was found in the size of the aortic root in those initially having roots of normal size, but one-third of women with dilated roots or those having prior surgery suffered either aortic dissection or progressive aortic dilation.⁸² In a recent prospective study, favourable outcomes were reported with no significant changes in aortic root diameter during or following pregnancy when compared to a matched group of childless women. Those with diameters of the root between 40 and 45 mm, however, had a mildly increased rate of growth compared to women with aortic root diameters less than 40 mm.⁸³ Although there are no trials demonstrating benefit of β -blockade during pregnancy in women with aortopathy, we do recommend such treatment during and after pregnancy in women with Marfan syndrome, coarctation of the aorta, and other aortopathies, in the hope that this may attenuate the risk of aortic dilation or dissection.

Pulmonary Valvar Stenosis

Women with pulmonary valvar stenosis have been reported to tolerate pregnancy well, in spite of the pregnancy-associated increase in preload,^{32,72,84} albeit that the risk of hypertensive and neonatal complications may be underappreciated.⁸⁵

Tetralogy of Fallot

Most patients with tetralogy of Fallot will have undergone an intracardiac repair, and many repaired patients will have pulmonary regurgitation and/or right heart dilation and dysfunction in late follow-up. Other potential late complications include surgical scars and patches that can act as a substrate for arrhythmia, residual shunts, and left ventricular dysfunction. One recent study reported adverse cardiac events, including cardiac failure and arrhythmias, in one-eighth of patients.⁸⁶ Another study, including 20 pregnancies in women with unrepaired tetralogy of Fallot, reported adverse events such as arrhythmias, cardiac failure, and progressive right ventricular dilation in one-sixth.⁸⁷ The presence of severe pulmonic regurgitation and/or a dysfunctional subpulmonary right ventricle is known to be associated with worse maternal outcome during pregnancy.³³ The late effects of pregnancy on the dilated, dysfunctional right ventricle, however, are unknown.

Ebstein's Malformation

Ebstein's malformation can manifest a broad spectrum of severity. Those with severe forms of the disease may present early in life with cyanosis or right-sided cardiac failure, whereas those with mild forms may first be detected incidentally in adulthood (see Chapter 34). The ability of the heart to tolerate the increased demands of pregnancy is dependent on the size and function of the functional right ventricle, the degree of tricuspid regurgitation, and the propensity to arrhythmias. Women with interatrial shunts are at risk for reversal of the flow if they are unable to adapt to the increased preload, and women who enter pregnancy with

any degree of right-to-left shunting at the atrial level are likely to demonstrate worsening hypoxaemia and cyanosis as pregnancy proceeds. Despite these potential problems, reported pregnancy outcomes have been favourable.^{88,89}

Cyanotic Cardiac Disease

Cyanosis is the visible manifestation of maternal hypoxaemia. In a woman with manifest or potential hypoxemia due to right-to-left shunting, it should be established whether the shunt is due to pulmonary hypertension, in other words, Eisenmenger's syndrome, or another cause, since pulmonary hypertension itself imparts an extremely high risk to pregnancy, as discussed below.

In the absence of pulmonary hypertension, women with cyanotic disease are at risk for adverse maternal cardiac events during pregnancy, in particular cardiac failure, arrhythmias, thrombosis, embolism, and endocarditis, though death is rare.⁹⁰⁻⁹² The pregnancy-induced fall in systemic vascular resistance will facilitate right-to-left shunting, especially when the shunt is at the level of the ventricles or great arteries. Fetal outcomes are poor. Infants are born small for gestational age.⁹¹ Live births are compromised, and prematurity is common.⁹⁰ If maternal saturation of oxygen is less than 0.85, only one-eighth of fetuses progress to be born alive.^{90,93}

Pulmonary Hypertension

In spite of advances in treatment, pulmonary hypertension continues to provide a very high risk for pregnancy. When associated with a right-to-left shunt, in other words, Eisenmenger's syndrome, the effects of maternal hypoxaemia and cyanosis play a major additional role.⁹⁴ The increased volume load directed through the high-resistance pulmonary circuit will provoke elevations in subpulmonary ventricular pressure, potentially causing subpulmonary ventricular failure, and will augment the right-to-left shunt if present, thereby worsening hypoxaemia. Hypoxaemia acts as a pulmonary vasoconstrictor, thus constituting a vicious cycle. As well, pulmonary thrombosis and pulmonary emboluses are more likely during pregnancy, and may further increase pulmonary vascular resistance. Challenges at delivery, including loss of blood, epidural anesthesia, and vagal responses associated with expulsive efforts of the mother in the second stage of labour, may further facilitate right-to-left shunting, leading to a potential spiral of hypoxaemic pulmonary vasoconstriction, hypotension, and death.

The high mortality of pregnancy in Eisenmenger's syndrome⁹⁵ has remained in the range of 30%, even in more recent reports.⁹⁶ Outcomes may be better with early diagnosis and comprehensive management.^{96,97} In addition, targeted advanced pulmonary vascular therapies applied in specialised centres are likely to provide better outcomes,⁹⁴ though reports of such improved outcomes are sparse at the time of writing, and the risk remains high. As a consequence, the widely held consensus is to advise against pregnancy in women with significant pulmonary hypertension of any cause and, in the event of unexpected pregnancy, to offer termination as the safest option.^{94,97,98}

Prosthetic Heart Valves

Women with any type of artificial heart valve are at increased risk for complications during pregnancy. Bioprosthetic and mechanical valves each have advantages and disadvantages. Careful consideration of the risks and benefits of each is required prior to selection of the type of prosthetic valve in a woman of childbearing age. During pregnancy,

normally functioning bioprosthetic valves are safer than mechanical valves because they are less thrombogenic and do not require ongoing anti-coagulation. Bioprosthetic valves, nonetheless, have limited durability, and women with these valves will generally require repeated surgery in the future.^{99,100} Although some studies have suggested that pregnancy accelerates the degeneration of bioprosthetic valves, other studies have not demonstrated this finding.^{99,101,102} Less information is available on the safety of homografts during pregnancy, albeit that one study found no valve-related complications occurring during pregnancy.¹⁰³

Mechanical valves have better durability than bioprosthetic ones, but are associated with significantly greater maternal and fetal risks during pregnancy. Because pregnancy is a hypercoagulable state, and because anti-coagulation can be difficult to manage with changing body weight during pregnancy, there is an increased risk of maternal thromboembolic events, occurring on average in one-sixth of pregnancies, of which approximately half is valvar thrombosis.^{104–108} Valves in the mitral position give higher thrombotic risks than those in the aortic position, as do early models of mechanical valves, such as those with balls in cages, or the first generation of those with tilting discs. Anti-coagulant therapy is complicated by a risk of bleeding.¹⁰⁹ Specific thrombotic risks are dependent on the type of anti-coagulation used.

Options for anti-coagulants include unfractionated heparin, low-molecular-weight heparin, and oral anti-coagulants such as warfarin and adjunctive aspirin. Heparin does not cross the placenta and therefore is a safer alternative for the fetus. Heparin given subcutaneously, nonetheless, is difficult to manage, and is a less effective anti-coagulant, with higher maternal thrombosis rates than warfarin. Valvar thrombosis, which can be fatal, is less common in pregnancy when oral anti-coagulants are used throughout, when compared to oral anti-coagulants with unfractionated heparin substituted between 6 to 12 weeks of gestation, or heparin is given throughout pregnancy.¹⁰⁹ Heparin may also cause maternal thrombocytopenia and osteoporosis. Warfarin crosses the placenta and is associated with warfarin embryopathy in first trimester use and fetal intracranial bleeding, which is a risk throughout pregnancy.¹⁰⁹ The risk of warfarin embryopathy has been shown to be less if heparin is substituted from 6 until 12 weeks of gestation and also in women whose therapeutic dose of warfarin is less than 5 mg per day.^{110,111} Because intracranial bleeding can occur during vaginal delivery in a fetus exposed to maternal warfarin, heparin should be substituted at least 2 weeks prior to delivery, or the fetus must be delivered by caesarean section. Low-molecular-weight heparin is easier to use than unfractionated heparin, and has better bioavailability. It also does not cross the placenta and therefore is safe for the fetus. Initial reports of valvar thrombosis and maternal deaths could have been due to bias in reporting, and to inadequate dosing and monitoring. Recent guidelines suggest that, if low-molecular-weight heparin is used during pregnancy, dosing by weight is not adequate, and careful monitoring of anti-Xa levels is required.¹¹² Low-dose aspirin is safe and may enhance the effectiveness of heparin in pregnant women with mechanical valves.¹¹² Both heparin and warfarin are safe in the breastfeeding mother.¹¹²

There is no consensus on optimal regimes for anti-coagulation in pregnant women with mechanical valves,

so the choice should be tailored to the individual after risk and benefits are discussed in detail. No randomised trials are available. Guidelines, predominantly based on expert opinion, have been published by the American Heart Association/American College of Cardiology¹¹² (Table 60-4), the American College of Chest Physicians¹¹³ (Table 60-5), and the European Society of Cardiology.³⁴ An alternative approach that incorporates additional risk factors, including the types of valve and their thrombotic potential, was recently recommended.¹⁰⁸

Arrhythmias

Pregnancy is arrhythmogenic in at least three fundamental ways. As a result of the haemodynamic changes, there is chamber enlargement and stretch. Hormonal changes, in particular increased levels of oestrogen, are proarrhythmic.¹¹⁴ There are changes in the autonomic milieu in relation to pregnancy.¹¹⁵ As a consequence, supraventricular and ventricular arrhythmias are more likely to occur during pregnancy in women with preexisting arrhythmias or to appear as new events, and to occur in women with or without structural cardiac disease. If an arrhythmia presents for the first time during pregnancy, the woman should be assessed for structural abnormalities as well, since arrhythmias during pregnancy may be the presenting complaint in a woman with structural cardiac disease, and the impact of a given arrhythmia is more likely to be significant in this setting. It is important to make an accurate diagnosis of the precise mechanism of an arrhythmia, as this is often reassuring, allowing therapy to be withheld, and in any case will guide therapy and avoid application of ineffective and possibly harmful strategies.

Arrhythmias are common in adult patients with congenital cardiac disease, but only a few studies have examined this subject during pregnancy. Studies from our centre have shown that women with a history of arrhythmias, most of whom had structural cardiac disease, were at increased risk for adverse maternal cardiac outcomes during pregnancy.^{32,84} In addition, women who had recurrences of arrhythmias during pregnancy were at increased risk for adverse fetal and neonatal events.¹¹⁶ Nonetheless, because of the potential harmful effects of medications on the fetus, pharmacological therapies should be reserved for patients with significant symptoms, or when sustained episodes result in hypotension. In the case of haemodynamically significant arrhythmias, treatment should not be delayed.

In women of childbearing age, most arrhythmias are supraventricular, and are not life threatening. Recurrence rates of supraventricular tachycardia of up to one-third have been reported during pregnancy.^{117,118} In our experience, supraventricular tachycardia recurred in half of women during pregnancy, predominantly those with structural cardiac disease, with half also suffering atrial fibrillation or flutter, this time almost exclusively in those with structural disease.¹¹⁶ A full discussion of the types of supraventricular tachyarrhythmias and their pharmacological therapies is beyond the scope of this section. Guidelines exist for the treatment of acute exacerbation of atrial arrhythmias in pregnancy.^{119,120} Intravenous adenosine, β -blockers, or cardioversion can be used safely, and other therapies considered depending on risk-benefit assessment.

Ventricular arrhythmias during pregnancy in women without heart disease are rare. In those with congenital cardiac disease, in contrast, ventricular arrhythmias may

TABLE 60-4

AMERICAN HEART ASSOCIATION/AMERICAN COLLEGE OF CARDIOLOGY GUIDELINES FOR SELECTION OF ANTI-COAGULANT REGIMES IN PREGNANT PATIENTS WITH MECHANICAL PROSTHETIC VALVES

Class	Recommendations
Class I	1. All pregnant patients with mechanical prosthetic valves must receive continuous therapeutic anti-coagulation with frequent monitoring. 2. For women requiring long-term warfarin therapy who are attempting pregnancy, pregnancy test should be monitored with discussions about subsequent anti-coagulation therapy, so that anti-coagulation can be continued uninterrupted when pregnancy is achieved. 3. Pregnant patients with mechanical prosthetic valves who elect to stop warfarin between 6 and 12 weeks of gestation should receive continuous intravenous UFH, dose-adjusted UFH, or dose-adjusted LMWH. 4. For pregnant patients with mechanical valves, up to 36 weeks of gestation, the therapeutic choice of continuous intravenous or dose-adjusted UFH, dose-adjusted LMWH, or warfarin should be discussed fully. If continuous intravenous UFH is used, the fetal risk is lower, but the maternal risks of prosthetic valve thrombosis, systemic embolization, infection, osteoporosis, and heparin-induced thrombocytopenia are higher. 5. In pregnant patients with mechanical prosthetic valves who receive dose-adjusted LMWH, the LMWH should be administered twice daily subcutaneously to maintain the anti-Xa level between 0.7 and 1.2 U per ml 4 hours after administration. 6. In pregnant patients with mechanical prosthetic valves who receive dose-adjusted UFH, the aPTT should be at least twice control. 7. In pregnant patients with mechanical prosthetic valves who receive warfarin, the INR goal should be 3.0 IU (range, 2.5–3.5) 8. In pregnant patients with mechanical prosthetic valves, warfarin should be discontinued and continuous intravenous UFH given starting 2–3 weeks before planned delivery.
Class IIa	1. In patients with mechanical prosthetic valves, it is reasonable to avoid warfarin between 6 and 12 weeks of gestation owing to the high risk of fetal defects. 2. In patients with mechanical prosthetic valves, it is reasonable to resume UFH 4–6 hours after delivery and begin oral warfarin in the absence of bleeding. 3. In patients with mechanical prosthetic valves, it is reasonable to give low-dose aspirin (75–100 mg per day) in the second and third trimester of pregnancy in addition to anti-coagulation with warfarin or heparin.
Class III	1. LMWH should not be administered to pregnant patients with mechanical prosthetic valves unless anti-Xa levels are monitored 4–6 hours after administration. 2. Dipyridamole should not be used as an alternative antiplatelet agent in pregnant patients with mechanical prosthetic valves because of its harmful effect on the fetus.

aPTT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

From Bonow RO, Carabello BA, Kanu C, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 Guidelines for the Management of Patients With Valvular Heart Disease): Developed in collaboration with the Society of Cardiovascular Anesthesiologists: Endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. *Circulation* 2006;114:e84–231.

TABLE 60-5

AMERICAN COLLEGE OF CHEST PHYSICIANS GUIDELINES FOR ANTI-COAGULATION REGIMES IN PREGNANT PATIENTS WITH MECHANICAL PROSTHETIC VALVES

1. Aggressive adjusted-dose UFH, given every 12 hours subcutaneously throughout pregnancy; mid-interval aPTT maintained at ≥ 2 times control levels, or anti-Xa heparin level maintained at 0.35–0.70 IU/mL
or
2. LMWH throughout pregnancy, in doses adjusted according to weight or as necessary to maintain a 4-hour post-injection anti-Xa heparin level of about 1.0 IU/mL
or
3. UFH or LMWH, as above, until the 13th week; change to warfarin until the middle of the third trimester; then restart UFH or LMWH therapy until delivery

aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

From Bates SM, Greer IA, Hirsh J, Ginsberg JS: Use of antithrombotic agents during pregnancy: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest* 2004;126:627S–644S.

develop or recur during pregnancy. We found ventricular tachycardia to recur in one-quarter of women during pregnancy.¹¹⁶ Medication for preventing such recurrences should be tailored to the type of tachycardia. For instance, women with catecholamine-sensitive ventricular tachycardia, or long QT syndrome, may best be treated with β -blockers. In the case of long QT syndrome, therapy should be continued for several months after delivery, as this is when most of the reported adverse events have occurred, especially in those with the long QT-2 genotype.¹²¹ For acute management, intravenous procainamide, amiodarone, sotalol, or β -blockers can be used.¹²² When necessary, cardioversion is considered safe during pregnancy, and cardioverter-defibrillators can also safely be implanted.¹²³

PERIPARTAL MANAGEMENT

Detailed discussions about management during and after delivery can be found in other sources.^{34–40} For any woman with a congenitally malformed heart at increased risk of adverse maternal cardiac or neonatal complications

during pregnancy, there should be timely multi-disciplinary assessment, and a plan should be developed for management which provides recommendations for various contingencies. This plan must be available to the medical team who may be tasked with the care of labour and delivery at unpredictable times, and even in unpredictable places. The plan should therefore be written, widely distributed, with a copy given to the patient to ensure timely access.³¹

General principles of management of labour and delivery for women with congenitally malformed hearts of moderate or great complexity include early effective analgesia by regional techniques, and vaginal delivery in almost every case unless obstetric considerations require caesarean delivery. Induction is considered safe in women with cardiac disease.¹²⁴ Assisted vaginal delivery is often indicated in order to limit or avoid maternal expulsive efforts. Caesarean section is rarely indicated for cardiac reasons.

CARDIAC MEDICATIONS AND PROCEDURES DURING PREGNANCY

Drug Use

The use of any drug during pregnancy requires consideration of many factors, including potential fetal toxicity as well as possible pregnancy-related changes in effectiveness of the medication.¹²⁵

Fetal toxicity depends on timing of administration. Prior to implantation, the effect is all-or-none. Teratogenic effects are seen with exposure between 3 and 10 to 12 weeks. Later in pregnancy, effects are mixed and depend on the drug and the magnitude of exposure. General principles with respect to avoiding fetal toxicity include choosing drugs known to be safe when possible, using the least number of drugs for the shortest possible time in the lowest effective dose, and avoiding medications during the first trimester when possible, since the teratogenic effects of most drugs are not well known. The balance of risk to benefit with respect to maternal and fetal health must be calculated. Evaluation subsequent to exposure must consider magnitude of risk. Even if a potentially toxic drug has been used inadvertently, the risk to the fetus may not be high enough to warrant more aggressive steps than earliest possible discontinuation or substitution. Most drugs, except high-molecular-weight molecules such as heparin, are not held back in an important way by the placental barrier, and equilibrate in the fetal circulation over time.

Pregnancy impacts maternal response to a drug through changes in drug absorption, transport, binding, metabolism, and excretion. The impact of these pregnancy-related changes on a specific drug needs independent consideration. For example, drugs predominantly excreted through the kidney will need an increased frequency of administration because of the pregnancy-associated increase in glomerular filtration rate.¹³

Certain common cardiac drugs have known fetal toxicity and should be avoided. Blockers of angiotensin receptors and inhibitors of angiotensin-converting enzyme cause second-trimester fetal nephrotoxicity,¹²⁶ and in addition, inhibitors of angiotensin-converting enzyme have been shown to be teratogenic.¹²⁷ Warfarin fetal toxicities are to

some extent dose related¹¹⁰ and must be balanced against the maternal need for the drug.

Prophylaxis against Endocarditis

There is a long history of use of prophylactic antibiotics prior to various procedures to prevent endocarditis. The evidence base for such practices has never been robust, and recommendations of guideline committees have changed over time. In consensus documents published between 2004 and 2007, recommendations have become more restrictive. The European Society of Cardiology guidelines from 2004¹²⁸ do not recommend prophylaxis for vaginal delivery or hysterectomy, and are silent on the subject of caesarean section. Guidelines from the British Society for Antimicrobial Chemotherapy from 2006¹²⁹ propose that prophylactic antibiotics be given for caesarean section or vaginal hysterectomy, but not for vaginal delivery. The guidelines from the American Heart Association/American College of Cardiology appearing in 2007¹³⁰ state that prophylaxis solely to prevent endocarditis is not recommended for any type of obstetric delivery.

Diagnostic and Therapeutic Interventions

Diagnostic testing for a woman contemplating pregnancy should optimally be completed before conception. This allows comprehensive assessment without concern about the impact of the testing procedure on the pregnancy, and also allows the application of surgical or therapeutic interventions prior to pregnancy when indicated.³¹ This is not always possible. If adequate current information about the cardiac status is not available for a woman who is already pregnant, the investigations should be completed expeditiously. Echocardiography is safe. Exercise stress testing is probably safe,¹³¹ though guidelines on how to interpret and apply results of stress testing done during pregnancy do not exist. Cardiac resonance imaging avoids ionizing radiation, and often produces information of high diagnostic quality, so should be considered, even though fetal risks have not been well characterised. The latter include the effects of heat and noise, and the theoretical effects on fetal development of the fixed and dynamic magnetic fields. Risk may be lessened by avoiding first-trimester studies if possible, by avoiding use of gadolinium contrast, by minimizing time in the coil, and by using lower magnetic energy.¹³²

Ionizing radiation, as produced in X-ray and nuclear studies, exposes the fetus to the risk of teratogenesis, and to an increased risk of cancer. The majority of tests that might be contemplated, nonetheless, expose the fetus to radiation doses well below 50 mGy, and no congenital abnormalities have been reported with exposure below this threshold. Shielding should be used, though most fetal irradiation is received through scatter, and thus not prevented by shielding. The incremental lifetime risk for cancer can be calculated, but is exceedingly small. For these reasons, necessary X-ray and nuclear procedures should not be withheld solely because of pregnancy if effective alternative techniques are unavailable.^{133,134}

Cardiopulmonary bypass during pregnancy is contemplated only in urgent situations, and the maternal mortality is no higher than for similar emergency procedures

in the non-pregnant patient. Fetal mortality is high, in the range of one-third. There is a general belief, although weakly documented, that there has been a trend to reduced fetal mortality in recent years in centres with experience. Outcomes may be improved by applying normothermic techniques involving pulsatile bypass at high rates of flow, and by administering tocolytics preemptively. Interventional or off-pump procedures should be considered instead if feasible. Delivery of the fetus 24 or more hours prior to cardiopulmonary bypass may be preferable in late pregnancy, but prior to 32 weeks of gestation the risk of prematurity may be unacceptable to some patients in spite of the acknowledged risk of cardiopulmonary bypass while the fetus remains in the womb.¹³⁴

Preparing the Young Adult with Complex Congenital Cardiac Disease to Transfer from Paediatric to Adult Care

GARY D. WEBB and JOHN E. DEANFIELD

Most children born with congenitally malformed hearts now survive to adult life, as a result of the spectacular achievements of paediatric cardiology and surgery over the past half-century. This has created a new and growing population of adults who often have complex congenital cardiac malformations which are unfamiliar to conventionally trained adult cardiologists. The need for an integrated strategy of care for such patients with congenitally malformed hearts, who usually require life-long medical care, has been recognised. Several panels of international experts have provided frameworks for provision of services.¹⁻⁹ These share a number of common recommendations. First, all recognise the need for management in an adult environment, as the average age of the population of adults with congenital cardiac disease increases. Second, all recommend a hierarchical structure for care, with specialist centres providing a full range of diagnostic facilities and treatments interacting, and often sharing care, with other adult cardiac units. Third, all accept the need for training of a new subspecialty of medical and allied health practitioners with expertise in the management of congenital cardiac disease and the care of adults. Despite the numerous statements expressing consensus, many adolescent patients with congenital cardiac disease still do not have the opportunity to participate in a defined process of transition that aims to optimise clinical education and social outcomes. As a result, few of these patients or their families have learnt what they need to know about their conditions and their responsibilities, and many have been lost to appropriate follow-up.¹⁰ In this chapter, we focus on the steps required for the processes of transition, and then transfer of care, for young adults who have chronic childhood illnesses in general, and complex congenital cardiac diseases (Table 61-1) specifically. We will review important general aspects of transition, as well as the key elements for an orderly programme of transition, which include timing of transfer, location, and staffing. Attention to the provision of care at this important stage of the journey of the patient is essential to maintain the excellent standards of care that are usually provided in the paediatric age group, and to insure that patients become empowered to take over their

own issues with health, becoming autonomous and competent young adults.

THE PROCESS OF TRANSITION

Transition is the generic process that applies to all children and adolescents with chronic disease.¹¹⁻¹³ It can be defined as an educational and experiential process that prepares patients to take responsibility for their own health care. The process takes time, and is not necessarily completed on entry to adult care. Its duration varies considerably from patient to patient, and is influenced by a number of factors, including the background, development, and intellect of the patient and the level of support provided by the family. The whole process may take several years, and is only successfully achieved when the patient is fully able to take responsibility for their own health and issues of lifestyle. It is important, therefore, that during the process, young adults with complex congenital cardiac malformations appreciate that, although they have the potential to live healthy and productive lives, most will require life-long cardiac surveillance. They also need to understand the requirement to obtain appropriately skilled care. This remains a challenge in many medical systems. During the

process, issues both generic and disease-based need to be addressed. This has an important impact for provision of services, both in terms of location and staffing of the clinic responsible for the transition. Frequently, the coordinated transfer of care from the paediatric to the adult health care environment is the final step in a successful process of transition. This depends importantly on the relationship between the staff of the clinic responsible for transition and the patient, which should have been built up over the years. During and after this time, the nature of the relationship between doctor and patient will change.

Paediatricians tend to consult predominantly with the parents, whereas adult practitioners seek to develop a partnership with the patient. This involves directing information and education towards the patient and, at the same time, encouraging responsibility and self-reliance. It is critical that, during adolescence, in the transition clinic, this connection with the young patient is successfully achieved, so that the patients begin to understand the need for an active role in their own health and cardiac management. If this fails, adolescents and young adults may disappear from medical follow-up and return only when potentially avoidable problems have developed. In a recent review, lapse of medical care, for a median duration of 10 years, occurred during the process of transition in two-thirds of grown-up patients with congenitally malformed hearts. Those who lapsed in this way were three times more likely to require urgent cardiac intervention when next seen. It is the lack of understanding by physicians of the need for continued care into adulthood that may underlie failure of effective communication.¹⁰

Key Issues for the Process of Transition

When Should Patients Begin the Process of Transition and Transfer?

The timing of entry from a paediatric clinic into a service responsible for transition, and the subsequent transfer to adult clinics, will vary according to the provision of local services and the individual needs of the patient. It is important, however, that transition and transfer occur in a predictable and planned manner.¹⁴ Referral to the clinics responsible for transition should ideally begin by 12 years of age. Attendance at such clinics involves a change in approach from the typical paediatric cardiac clinic. Parents should continue to attend, but there should be greater emphasis on communication with the adolescent, including opportunities for confidential one-on-one discussion with doctors, nurses, and other relevant counsellors. The approach to communication needs to evolve as the teenager grows older, with provision for discussion appropriate to age and maturity. Transfer from the transition clinic to the adult clinic most commonly occurs at the age of 18 years, on completion of schooling. The timing, however, should be flexible so as to meet the needs of the patient. For example, if a patient has developmental delay, or multiple medical problems under active follow-up in the paediatric hospital, transfer may need to occur at an older age.

Patients should understand that transfer to adult care is a natural process and part of growing up. Early discussion, and agreement on an age of transfer, removes the frequent anxiety of families that expert care is being lost, and makes transfer to adult care a development to be viewed optimistically. In

some medical systems, provision of adult services for grown-up patients with congenitally malformed hearts is not yet available at a level comparable to that provided during childhood. In these cases, delay of transfer is clearly advisable.

Where Should Care Be Undertaken?

Availability of clinical resources will determine the location of the transition clinic. Ideally, this should be within the paediatric hospital, as this makes the first move from the paediatric clinic less traumatic to the patients and their families. Those staffing the clinic have the opportunity, during several visits over years, to organise the subsequent transfer to adult care, which may need to be to a different hospital.

Facilities for in-patient care should be designed around the needs of young people, and ideally should be separate from paediatric and adult wards, with a different atmosphere and focus. A dedicated adolescent environment for patients with a range of medical conditions can work well for the needs of cardiac patients. This permits provision of facilities, including Internet access, a study area, television, a social area, and kitchen facilities. The adolescent ward should be organised by staff with special awareness and training in the issues of this age group.

Who Should Be Involved in Transitional Care?

The balance of staffing for the transition clinic depends on local resources. It is, however, essential that members of the team providing paediatric care and of the team looking after their future needs as adults with cardiac problems are both involved. This provides an opportunity for discussion between teams of the specific medical needs of the patient, as well as creating a visible connection for the patient and their families. This, in our experience, is a key step to avoiding lapse of care and loss to follow-up when the patient is eventually transferred.

Specialist nurses play a crucial role in successful transition. They should have experience in the needs of adolescents and young adults with congenitally malformed hearts, and should have received training in counselling.¹⁵ There should be facilities for the specialist nurses to consult with the patient separately from the doctor, as this encourages early discussion of sensitive problems and anxieties. The specialist nurses frequently are the main contact with the patient and his or her family, developing a unique relationship with them.

What Is Involved in an Ideal Transitional Programme?

The programme involves both continuation of high-level care for cardiac and non-cardiac problems as well as a specific transitional curriculum designed to prepare the adolescent and young adult for successful transfer. In many centres, a comprehensive transitional curriculum has been developed, which covers education about the cardiac condition, its impact on future life, and strategies to smooth transfer into adulthood.¹⁶

All children with congenitally malformed hearts should have a plan of care established prior to transfer. Ideally, this is initiated in childhood, and developed during transition. It should be based on a multi-disciplinary process of consultation, and communicated effectively to the adolescent and his or her family. A clear route of transfer to an appropriate level of adult cardiac services is an essential part of this plan. A major potential barrier to successful transition is the belief of patients and families that cardiac surgery or catheter intervention has cured their condition. Patients and families need to have explained to them, in a sensitive

manner, that although in many cases life expectancy can be normal or near-normal, the patient's heart is not normal and the patient requires life-long follow-up. It is important that patients understand that, despite treatment, their cardiac condition remains fundamentally different from that of most adult patients, and that relatively few providers have been trained to monitor their care. This should be accompanied by reassurance that their care plan will involve attendance, at least once, at a specialist unit dealing with adults with congenitally malformed hearts. It is equally important at the end of transition to decide which patients do not require long-term cardiac follow-up. Our current policy is to keep patients with conditions deemed to carry low risk on the database, with very infrequent visits. The premised value of this approach is to allow support for issues of life such as employment. Regular cardiac checks of patients with a very low risk of further complications, however, may have adverse consequences. For example, repeated visits may lead to an unnecessarily high level of anxiety about future health. Indeed, there is evidence for this in other medical conditions.

The complexities of the process of transition can seem so daunting that, as a result, little or nothing is done to prepare the young patient. It is clearly important that some steps be taken and that the transition become an integral part of the journey through life of the patient with a congenitally malformed heart, rather than simply being ignored because a comprehensive process seems unachievable. One approach is to adopt a strategy of starting small and aiming to improve. For a disease-based model, some basic information should be put together about the patient and transmitted to him or her clearly and repeatedly. Such a minimalist message might resemble the following:

You have had surgical repair of tetralogy of Fallot. As a result, you have a leaky pulmonary valve. You will need to be followed annually by a cardiologist who knows about congenital cardiac defects. In order to stay healthy, you should see such a person once a year for the rest of your life. If you have any cardiac problems, you should contact this person. You should become knowledgeable about your health history. You should have a copy of your own health information. You should make sure you always have good quality health insurance, and know how to get it. You are at risk for infective endocarditis, and should be sure that your teeth and gums are always healthy to reduce this risk.

The agenda can then be broadened beyond this brief approach by regular consultations with the patient. A more complete curriculum for the transition can be communicated using different strategies, involving the cardiologist and specialist nurses. These strategies can include seminars for patients and families and information provided on paper or online. These methods are invaluable, in particular, when providing access to new information. In many ways, the educational aspects of the transition should continue indefinitely, as patients often feel a greater sense of control over their medical health and management if they are able to seek new knowledge. Close collaboration with support groups for children and adults with congenitally malformed hearts, which have been established in many countries, is invaluable for promoting education.

While the needs of some patients during adolescence are straightforward, others may require cardiac or non-cardiac

medical or surgical care. Access to services, including obstetrics and gynaecology, psychiatry, nephrology, respiratory, neurology, and orthopaedics, is important, and this should be provided either within the specialist institution or within a network of linked local centres. A recent model of care developed by the Department of Health in the United Kingdom illustrates a model for primary, secondary, and tertiary provision of care for adults with congenitally malformed hearts (Fig. 61-1).¹⁷

The clinic providing services during transition should have access to the full range of cardiac diagnostic and treatment modalities, including echocardiography, magnetic resonance imaging, computerised tomography, specialist electrophysiology, interventional catheterisation, and surgery. Easy access to specialists in anticoagulation and, increasingly, provision of anticoagulant management in the home, are also important. As during childhood, optimal management of those with congenitally malformed hearts requires a multi-disciplinary planned approach, involving nurses, technicians, anaesthetists, intensivists, cardiologists, and surgeons. During the years of transition, pathways can be established to ensure standardisation of care and communication. The specialist nurse plays a key role in coordinating this process, including the individual medical and non-medical needs of the patient.

A co-ordinated process of transfer is often the final step in the successful transition to the adult cardiac environment. A carefully prepared summary, or passport, outlining the state of health, is a key element. It should be given to the patient, and should include information on the diagnosis, details of previous treatment, including catheter interventions and surgery, diagnostic tests, as well as current and previous follow-up and medical treatment. It should also include details of contacts for those staffing both the transition clinic and the future clinic for care as an adult with congenital cardiac disease, including a telephone number for the specialist nurse. This is important, as problems often arise between leaving the transition clinic and making the first visit to the adult clinic. The contents of the passport should be discussed with the patient, as it is essential that he or she understand the information and the value of the document. Currently, archiving of and access to important long-term medical records are less than optimal in many health care systems, and similarly communication between centres which may be involved in the care of the adolescent and young adult with congenital heart disease can be poor should the patient move around the country. These situations emphasise the need to empower the patient with understanding of his or her own health care needs as a key part of the process of transition, and to provide effective support when required.

The first visit to the adult cardiac clinic is often very stressful to the patient and his or her family. Patients should know to expect a different experience in the adult cardiac setting, with the focus shifting from the parent to the patient. The style is often perceived as more business-like and less relaxed. Transfer provides an opportunity for the patients to see themselves as young adults. The providers of paediatric services should reassure the patients that the new providers in the adult setting are capable and can be trusted. Support groups can play an important role in alleviating anxiety around this time, as well as providing additional social interaction and help with a range of issues relating to everyday life (see below).

Figure 61-1 A model for transition for adults with congenitally malformed hearts. (Adapted from Hudsmith LE, Thorne SA: Transition of care from paediatric to adult services in cardiology. *Arch Dis Child* 2007;92:927-930.)

Specific Issues during Transition

Adolescence is often the first time that the patient takes responsibility for a wide range of issues relating to medical needs and the continuation of life, and the transition should provide opportunity and sufficient time to address them with nurse specialists, physicians, and other relevant counsellors. Some of the key topics that need to be addressed on a regular basis are listed in Table 61-2.

Cardiac Issues

It is crucial for the patient to understand his or her cardiac defect and its consequences. This is rarely the case when the patient enters the transition clinic. Effective communication requires repetition, especially when patients have learning disabilities, complex cardiac conditions, or low levels of education. Protocols for cardiac care for specific conditions are invaluable to ensure consistency of management, and to explain the reasons for any proposed testing, treatment, and follow-up to the patient. Understanding by the patient of the proposed plan for health care greatly reduces anxieties about unexpected deterioration in his or her condition. Patients should be taught about potential symptoms, and the various options for management which might be required in the future. In addition to the plan for cardiac care, patients need to understand the potential risks involved in non-cardiac medical or surgical treatment. This is particularly important in those with pulmonary hypertension and cyanosis, in whom even innocuous procedures can be life-threatening. Proper planning of procedures, such as anaesthesia for dental care, should involve consultation with the cardiac team responsible for the transition, as the risks are often not appreciated by non-cardiac practitioners.¹⁸

Contraception

One of the most important issues that is frequently neglected by paediatric cardiologists is contraception and pregnancy. There are now more than 1 million adults living in the United States with malformed hearts, and half are women. Studies show that the cardiologist needs to take the lead in providing information relating to contraception, and the process should begin before the patient reaches adolescence or becomes sexually active. A teenager has a 90% chance of becoming pregnant within a year if sexually active and not using appropriate contraception. The range of options for contraception, with their advantages and disadvantages, should be discussed.¹⁹ This must be conducted in a manner appropriate for the age and maturity of the patient, and needs to take place throughout the transition. It is imperative that there be private opportunities to talk with the doctor or specialist nurse in the absence of parents, and the patient should be reassured that the contents of these discussions will remain confidential.

Pregnancy

Pregnancy is increasingly feasible for many adults with congenitally malformed hearts, and the potential risks to the mother and the unborn child should ideally be discussed before conception. An unwanted pregnancy can be a major medical and psychosocial problem. It should not be the stimulus, as is sometimes the case, for precipitous transfer to adult care. Understanding the impact of pregnancy on the maternal cardiac disease, as well as the risk from her cardiac condition to the fetus, enables the adolescent or young adult to make informed decisions and plan for the future. This will involve consideration of both the

number and timing of pregnancies in the context of the likely future cardiac course. Links between the transition clinic and a clinic specialising in obstetrics should be established. Recent reports have shown not only the potential risks of poorly managed pregnancies but the outstanding results that can be achieved through a multi-disciplinary approach with a team that includes practitioners in congenital cardiac disease, anaesthesia, obstetrics, and fetal medicine.^{19,20}

Risk of Recurrence

The risk of recurrence in the offspring of parents with congenitally malformed hearts is one of the most frequently asked questions. Understanding of the genetic basis of complex cardiac malformations is increasing exponentially, and should lead in the near future to a more refined model for prediction of risk. Average values for recurrence in the region of 2% to 4% are often quoted, but the known range is between 2% and 50%.²¹ Genetic counselling should be offered to selected patients, particularly when there is a syndrome or a family history. Fetal echocardiography before 18 weeks of gestation plays an important role, often providing reassurance of normal cardiovascular structure and function throughout the remainder of the pregnancy.

Infective Endocarditis

Patients must be educated regarding the importance of dental health, good oral hygiene, and the need for regular dental check-ups. The potential risk of body piercing, acne, tattoos and insertion of intra-uterine contraceptive devices should be explained. Patients should be taught to recognise the symptoms of endocarditis, and how to access care promptly. The recent change in recommendations regarding antibiotic prophylaxis has confused and upset some patients and their families, so clear explanation is important.²²

Issues Relating to Lifestyle

Adolescence is a time when patients are confronted with many lifestyle issues. For example, they wonder how their cardiac disease will affect their ability to obtain a job, health or life insurance, or a mortgage. Provision of support and counselling on such issues during the transition to adulthood is essential. Many children and young people with congenitally malformed hearts will be able to have any career they may choose. The future of some patients, however, will include physical or other limitations. They may need to be advised to pursue appropriate education and career pathways. For example, a patient with the Fontan circulation should know not to become a bricklayer or a commercial trucker. These patients, and their parents, should have a chance to discuss such issues before the patient reaches high-school age, and before important decisions are made, or actions taken, such as choosing a curriculum or dropping out of school. As the long-term outcome of many complex cardiac conditions becomes clearer, evidence-based recommendations can be made in regard to future careers. These will carry weight with future employers, and represent an opportunity for the clinic staff to act as advocates for their patients, who are often otherwise disadvantaged by the stigma attached to chronic cardiac disease.

Many patients will have difficulty in obtaining both health and life insurance. They may be denied coverage, or offered a heavily loaded premium based on out-of-date information relating to the risk of death. Studies have shown highly variable attitudes to coverage, and patients should be helped to obtain the best deal.²³ Support groups, such as the Grown Up Congenital Heart Disease Association in the United Kingdom (available at: <http://www.guch.org.uk>), have excellent links with insurance companies. In the United States, the difficulties encountered by young patients with chronic conditions in obtaining health insurance are now recognized. Opportunities vary between states, and it is hoped that legislation to provide a more uniform level of support will be enacted in the next few years.

The importance of a healthy lifestyle, including avoidance of smoking and obesity, should be emphasized. Counseling regarding the use of alcohol or recreational drugs and, in particular, the potential interaction with prescribed drugs such as anticoagulants, requires sensitive private discussion. Maintenance of a healthy lifestyle requires regular physical exercise. During childhood, inappropriate limitations are often imposed. These can have important implications for the confidence of patients, their sense of well-being, and their social interactions.²⁴ Objective exercise testing should be part of assessment during the process of

transition. This should be used to provide recommendations based on the potential beneficial and deleterious effects of exercise on the haemodynamics of the individual patient, as well as on the risk of serious arrhythmia. Standard protocols in adult clinics, often devised for the detection of myocardial ischaemia, are usually inappropriate for adolescents and young adults with congenitally malformed hearts. Advice on travel and driving should also be provided, based on the regularly updated national guidelines.

TRAINING OF PRACTITIONERS TO PROVIDE SERVICES FOR TRANSITION

There is a clear need to develop a new group of specialists to deal with the long-term needs of patients with congenitally malformed hearts. This should include medical practitioners, specialist nurses, and allied health professionals. Recent recommendations emphasise the need for training in adult and paediatric cardiology, as well as familiarity with general medical issues. The provision of services with appropriately trained staff is developing rapidly in some countries but lagging behind in others. Such resources will affect the design and composition of the services. Any necessary compromises, however, should not distract from the need to develop programmes of high quality, which cover seamlessly the entire life course of the patient with a congenitally malformed heart.

SUMMARY

Transition of care from paediatric to adult services is a crucial period for patients with congenital cardiac disease. If managed badly, patients fail to understand their disease, its impact on their life, and the need for long-term follow-up. As a result, they frequently default from care,

and their outcome is adversely affected. If managed well, patients can be empowered to graduate from the paediatric environment to take control of their own health. This ensures not only continuity of high-level cardiac treatment, but successful integration into normal adult life. All systems for health care that embark on the treatment of children with congenital cardiac disease must, therefore, undertake to provide an effective service for transition to appropriate adult care.

Psychological and Social Aspects of Paediatric Cardiac Disease

KATHLEEN MUSSATTO

What are the outcomes that really matter to patients, families, and societies living with the implications of congenital and acquired paediatric cardiac disease?

Survival and physiological function are certainly paramount. Dramatically improved survival, and reduced morbidity for virtually all lesions, nonetheless, has now shifted focus to the question of quality versus quantity of life. The patients that we follow are not hearts, they are children, incredibly complex and multi-dimensional, and they belong to families of equal complexity. Chronic illness in a child results in psychological stress, not only for the affected child but also for the parents, siblings, caregivers, and social contacts with whom that child interacts. The cumulative effects of the stress of paediatric cardiac disease may impact psychosocial function and quality of life for the child, parents, siblings, and the family as a whole. The process of adjustment to this stress is a complicated, multi-factorial, process that involves an interaction of both risk and resistance factors and, above all, a highly subjective, personal interpretation of the impact of disease on one's life.

In general, children and families are incredibly resilient. They respond to the challenges of chronic disease with a process of adjustment and adaptation that most commonly results in successful normalisation and integration into society. When this process does not occur successfully, a host of problems can result, including psychopathology, reduced quality of life, family disruption, and social discrimination.¹⁻⁵ Providers of healthcare to children with paediatric cardiac disease, as well as other social contacts such as teachers, social workers, and play therapists, are in a unique position to assess and intervene with the intention of optimising the adaptation of the child and the family.

Today, the vast majority of congenital cardiac conditions are diagnosed in infancy, and the majority of surgical reconstructive procedures are conducted during the first year of life.⁶⁻⁹ It is well recognised that only a small minority of congenital cardiac conditions are completely cured despite anatomical repair. In the majority of patients, particularly those with complex lesions, the cardiac malformation results in a chronic condition that requires ongoing medical observation and care. In contrast, acquired paediatric cardiac disease in a previously healthy child can be diagnosed at any age. Although treatment in some situations may afford a complete recovery without cardiac sequels, some conditions, for example cardiomyopathy requiring cardiac transplantation, result in a chronic condition necessitating life-long

care. Some postulate that a congenital condition may result in more effective adaptation because the child knows no other existence.^{10,11} Other research has not supported this. For example, Varni and Setoguchi¹² found no difference in adjustment for children with congenital versus acquired deficiencies of the limbs. Congenital cardiac disease commonly includes long periods of time during which the child may be relatively asymptomatic. Hence, the child may not be afforded the benefit of adjustment that may occur with a more visible or persistent disorder. The nature of the heart as an organ vital to survival may result in perceptions of stress related to cardiac disease that are out of proportion to the severity of the diagnosis.^{13,14} Psychosocial outcomes are inherently subjective in nature. The perspective of the child, the family, and the implications for society must all be considered individually, whilst recognising that significant interactions likely influence the interpretation of the psychosocial impact of cardiac disease in a child.

THE PATIENT

A Developmental Approach to the Psychological Stress of Paediatric Cardiac Disease and Its Treatment

The stress associated with the diagnosis and treatment of congenital or acquired paediatric cardiac disease will vary both with the trajectory of the illness and the natural developmental progression of the child. Chronic illnesses are characterised by relatively stable periods that may be interrupted by acute episodes requiring medical attention or intervention. Thus, there is a risk for both chronic psychological stress and acute crises. The particular stressors and responses of a child receiving care for cardiac disease must be interpreted within the context of the developmental stage. It is well known that children with cardiac disease are at risk for a wide range of cognitive and neurodevelopmental impairments (see Chapter 64). Thus, they may not exhibit age-appropriate responses. Interventions to reduce stress must be targeted to the level of the specific developmental maturity of the child.

It is difficult to assess the psychological stress experienced by sick neonates and young infants. The setting of intensive care required for treatment of these babies is clearly an environment that is alien to the experience of a healthy infant. Hospitalisation and surgery rob an infant of many of the normal stimuli known to foster optimal growth and development, including the physiological protection offered by parents, normal touch and

neurological stimulation, and basic satisfaction of needs, for instance feeding and nurturance.¹⁵ In addition, intensive care imposes several noxious stimuli not typically experienced so early in development, including painful interventions, excessive noise and light, sedation, and presence of multiple caregivers. Miranda and colleagues^{16–18} have demonstrated that infant rats exposed to repeated painful stimuli demonstrated altered behaviour and visceral hyperalgesia when becoming adults. Of equal concern, however, is evidence that anaesthetic agents commonly used to protect infants from pain during surgery, such as ketamine, isoflurane, and nitrous oxide, may also have a negative impact on neonatal cerebral development.^{19–22} It can be concluded that hospitalisation early in life results in an environment that makes the infant vulnerable to disruptions in normal neurobehavioural development, and disturbances of physiological stability. A model for developmental care has been advocated in most neonatal and infant intensive care settings to reduce the inherent risks of hospitalisation. This model promotes minimal handling, reduction of noise and light, support of natural positioning, and individualised care planning with a family centred approach. These interventions have been shown to improve short-term physiological stability. Research on the impact on long-term outcomes, nonetheless, remains inconclusive, and interpretation is problematic due to the presence of multiple confounding variables.^{15,23}

In later infancy, babies become increasingly aware of their environment. Hospitalisation at this stage may impart stress due to the anxiety of separation, and the interruption of normal comforting behaviours, such as feeding, cuddling, and non-nutritive sucking. Sedation and physical restraints are often used to prevent an infant from causing harm to themselves during recovery. As the infant is allowed to become fully conscious, immobility and separation from the comforting behaviours of parents may be particularly distressing. An infant may progress through stages in response to separation from their normal environment. Initially there is protest, manifested by excessive irritability and crying. Then there is despair. The crying may stop, but the infant appears despondent and withdrawn, and there may be loss of previously acquired developmental skills. Ultimately, there is detachment. Parental return may be met with apathy, the infant appearing more absorbed with objects and the immediate environment.²⁴ A shift toward allowing unlimited parental presence in most settings providing healthcare for children has helped to diminish, but cannot eliminate, this stress. Children experiencing prolonged hospitalisations are at increased risk for negative responses. Promoting a home-like environment with family photos and familiar objects may reduce the disruptive effects of hospitalisation.

The toddler and preschool-aged child continue to be extremely sensitive to separation from parents and intrusions by strangers. Painful procedures are met with vehement protests, and the child may be confused by the inability of the parents to rescue them from what seems a treacherous environment.²⁴ Memories are beginning to be formed, and the young child may associate certain people or places with distress, causing reactions even before anything bad has happened. Refusal to eat or take medications, or excessive combativeness, may

reflect the attempt of the young child to regain control of his or her environment. Fear of bodily injury is common in those who have yet to commence schooling. It may be impossible for them to conceptualise that something can allegedly be cured by cutting it open. Illness or hospitalisation may be perceived as punishment for something they have done wrong. At this age, play and exploration are used to help children master their environment and gain autonomy. Opportunities for medical play and socialisation while hospitalised may help to decrease fear and anxiety. Safe places, such as play rooms, must be established in the hospital where the child does not have to fear procedures. Young children often understand far more than they are able to express. The need to prepare them for procedures or experiences should not be underestimated.²⁴ Specialists in the life of the child, and play therapists, can provide guidance for strategies of preparation that are developmentally appropriate.

The young child beginning school, aged from 6 to 12 years, possesses an immature but developing understanding of his or her body and how it works. The function of the heart as a vital organ is understood by most young children, and the concept of a disease of the heart requiring intervention may be particularly upsetting. Hospitalisation and surgery at this time may invoke fears of bodily injury and death. Children perceive their parents to be their ultimate protectors, and may be frustrated by the inability of their parents to shield them from what they interpret as dangerous invasions of their body. Activities that promote healthy skills for coping, and expression of feelings, will benefit these children. In addition, whenever possible, children at these ages should be allowed to participate in some aspect of decision-making regarding their care, for instance to have a chest tube removed in a procedure room or at their bedside. This may help to provide them with a sense of mastery and control. Many hospitals for children offer classroom experiences, or tutoring at the bedside, to help those hospitalised maintain their academic progress, and to promote normalcy.

In a sample of 182 subjects that had undergone surgery for congenital cardiac disease early in life, and ranging in age from 2 to 18 years at time of survey, parents of children aged 8 to 12 years reported the lowest quality of life on overall, physical, emotional, social, and educational domains.²⁵ Children aged 8 to 11 with congenital cardiac disease were also found to report lower quality of life and emotional functioning than their counterparts aged 12 to 16.²⁶ It may not be until the children reach the age of 8 to 10 years that they can conceptualise their own mortality and risk of vulnerability in relation to issues devolving on health.²⁴ For patients with several forms of congenital cardiac disease, particularly those that require valvar replacement, this age range can be a common time for reintervention. The child may perceive procedures considered to be relatively minor and requiring a short hospital stay as a crisis.²⁷ Children of these ages are also more sensitive to the levels of anxiety in their parents. The level of distress manifested by their parents, therefore, may influence their own responses.²⁴

Adolescents are striving to establish their identity and independence. Restrictions of activity, distorted body image or self-concept, altered peer relationships, the

unpredictability of care and treatment for their condition, and uncertainty about prognosis may all serve as threats to these developmental achievements.²⁸ Denial of the underlying condition and its implications may be a common method of coping, and may manifest itself in poor adherence to recommendations for treatment, or a general lack of knowledge regarding risks and factors promoting health. The natural history of congenital cardiac disease typically consists of periods when the individual is clinically stable, and times that require significant intervention, such as cardiac surgery, to preserve or improve health. The adolescent with stable cardiac disease may view him or herself as well, and may experience the need for treatment as an unwelcome threat to their ability to control their lives and a bitter reminder that their condition is indeed chronic. Dilemmas of normality, social integration, independence, and the development of effective strategies for coping have all been identified as challenges facing adolescents with congenital cardiac disease.²⁹ Adolescents with a more positive attitude toward their illness have been found to demonstrate lower levels of anxiety and depression.³⁰ Support from their peers is vital to adolescents. Visitation by friends, and appropriate activities such as access to computers and video games, may lessen the strain of hospitalisation. The Starlight Starbright Children's Foundation is an Internet-based network designed to provide children with chronic illnesses a method to connect with peers facing similar challenges.³¹ Issues of privacy and confidentiality are also of great importance. The healthcare team needs to work creatively with parents and children to promote autonomy and participation in planning of treatment through effective programming of adolescent care.

Be they infants, children, or adolescents being treated for paediatric cardiac disease, therefore, all experience stressors related to treatment and hospitalisation. There is great potential to ameliorate this stress with sensitivity to the developmentally appropriate challenges and responses. Developmental aspects of chronic illness and possible supportive interventions are listed in Table 62-1.³² Explanations of the illness, and necessary care, must be made in a way that the child can easily comprehend. These explanations must be revisited frequently as the child matures.¹⁴ Creation of a nurturing environment specifically designed for children and families, and promoting practices of care centred on the family, should be a goal for all providers of healthcare for children.

Psychological and Behavioural Outcomes for Children with Cardiac Disease

Patterson and Geber³³ stated that 'Children with chronic illnesses or disabilities are normal children in abnormal situations. They have the same developmental needs as all children. But in many different ways, the accomplishment of their developmental tasks is made more difficult by an extra set of demands and hardships associated with the chronic condition'.

The potential for chronic illness in a child to result in abnormal psychological and behavioural outcomes has long been recognised. Emotional disturbances are estimated to be 2 to 2.5 times more common in children with chronic illness than in healthy children.³⁴

Psychological adjustment of a child to a chronic illness such as cardiac disease is a complex process that is quite difficult to measure and interpret. Multiple factors will influence adjustment, including aspects of the illness and its treatment, characteristics of the child, and factors relating to the parents and family.^{3,35,36} A large body of research in children with chronic illnesses in general, and paediatric cardiac disease specifically, has been conducted in an attempt to characterise the long-term psychological and behavioural implications of this experience.^{3,35-39}

Coincident with the improved survival of children with congenital cardiac disease in the 1960s and 1970s, it was quickly recognised that these children were at risk for a negative psychological impact.⁴⁰⁻⁴³ Although extensive research has been conducted in this area, findings have been disconcertingly inconsistent, making interpretation quite challenging. The strategy used for sampling, the criteria for inclusion and exclusion, the informant utilised, and the outcomes measured, all bear influence on the generalisability of the findings. A universally agreed upon definition of psychological and behavioural outcomes does not exist. Hence, several different criteria have been used to characterise children with cardiac disease and other chronic illnesses as having normal or abnormal outcomes.^{35,36,39} Very few studies have systematically assessed all of these components simultaneously. Assessment of long-term outcomes is needed. There is little agreement in the paediatric literature, however, as to when long-term starts or finishes. Outcomes have been measured in children as young as toddlers to those of adults living with congenital cardiac conditions. The impact of confounding variables on psychological and behavioural outcomes is likely to increase with age. Continual shifts in care-giving practices, and changes in biomedical technology, also impact the interpretability of the findings. The children of today benefit from an armamentarium of strategies designed to impart neuropsychological protection during care for cardiac disease. Findings based on investigation of older survivors may not be representative of outcomes for a newborn today. There is also a much broader awareness and attention to these issues in children with chronic illness in general. This will hopefully result in early recognition and intervention for problems whose course can potentially be reversed.

The most widely used measure of psychological and behavioural outcomes has been the Child Behaviour Checklist.⁴⁴ An estimate of overall emotional and behavioural problems is calculated from a report on items relating to both competence and problems. The score can be further categorised to reflect the degree of internalising problems, for example, anxiety, depression, and social withdrawal, as opposed to externalising problems such as hyperactivity, inattention, and aggression. There are four versions of the instrument available to allow for responses from the parent, via the Child Behaviour Checklist, from the patient, using the Youth or Young-Adult Self-Report, or from the teacher, using the Teacher's Report Form. The measure has been widely used in samples of both healthy and chronically ill children, and has excellent psychometric properties. Caution has been advised, however, in using the Checklist in children with a chronic illness.⁴⁵ Skills for social function may be underestimated because of the reliance on social activities as a measure of competence. Symptoms of a somatic nature may be overly emphasised

TABLE 62-1

DEVELOPMENTAL ASPECTS OF CHRONIC ILLNESS OR DISABILITY IN CHILDREN

Developmental Tasks	Potential Effects of Chronic Illness or Disability	Supportive Interventions
<i>Infancy</i>		
Develop a sense of trust	Multiple caregivers and frequent separations, especially if hospitalised	Encourage consistent caregivers in hospital or other care settings
Attach to parent	Deprived of consistent nurturing	Encourage parents to visit frequently or room-in during hospitalisation, and to participate in care
Learn through sensorimotor experiences	Delayed because of separation, parental grief for loss of dream child, parental inability to accept the condition, especially a visible defect	Emphasise healthy, perfect qualities of infant
Begin to develop a sense of separateness from parent	Increased exposure to more painful experiences than pleasurable ones	Help parents learn special care needs of infant to enable them to feel competent
	Limited contact with environment from restricted movement or confinement	Expose infant to pleasurable experiences through all senses (touch, hearing, sight, taste, movement)
	Increased dependency on parent for care	Encourage age-appropriate developmental skills (e.g. holding bottle, finger feeding, crawling)
	Over-involvement of parent in care	Encourage all family members to participate in care to prevent over-involvement of one member
<i>Toddlerhood</i>		
Develop autonomy	Increased dependency on parent	Encourage independence in as many areas as possible (e.g. toileting, dressing, feeding)
Master locomotor and language skills	Limited opportunity to test own abilities and limits	Provide gross motor skill activity and modification of toys or equipment, such as modified swing or rocking horse
Learn through sensorimotor experience, beginning preoperational thought	Increased exposure to painful experiences	Give choices to allow simple feeling of control (e.g. choice of what book to look at or what kind of sandwich to eat)
<i>Preschool</i>		
Develop initiative and purpose	Limited opportunities for success in accomplishing simple tasks or mastering self-care skills	Institute age-appropriate discipline and limit-setting
Master self-care skills	Limited opportunities for socialisation with peers; may appear like a baby to age-mates	Recognise that negative and ritualistic behaviors are normal
Begin to develop peer relationships	Protection within tolerant and secure family may cause child to fear criticism and withdraw	Provide pleasurable sensory experiences (e.g. water play, sandbox, finger paint)
Develop sense of body image and sexual identification	Awareness of body may center on pain, anxiety, and failure	Encourage mastery of self-help skills
Learn through pre-operational thought (magical thinking)	Sex role identification focused primarily on mothering skills	Provide devices that make tasks easier (e.g., self-dressing)
	Guilt (thinking he or she caused the illness or disability, or is being punished for wrong-doing)	Encourage socialisation, such as inviting friends to play, day care experiences, trips to park
		Provide age-appropriate play, especially associative play opportunities
		Emphasise child's abilities; dress appropriately to enhance desirable appearance
		Encourage relationships with same-sex and opposite-sex peers and adults
		Help child deal with criticisms; realise that too much protection prevents child from learning realities of world
		Clarify that cause of child's illness or disability is not his or her fault or a punishment

School Age

Develop a sense of accomplishment
Form peer relationships
Learn through concrete operations

Limited opportunities to achieve and compete (e.g., many school absences or inability to join regular athletic activities)
Limited opportunities for socialisation
Incomplete comprehension of the imposed physical limitations or treatment of the disorder

Encourage school attendance; schedule medical visits at times other than school; encourage child to make up missed work
Educate teachers and classmates about child's condition, abilities and special needs
Encourage sports activities (e.g., Special Olympics)
Encourage socialisation (e.g., Girl Scouts, Campfire, Boy Scouts, 4-H Clubs, having a best friend or a club)
Provide child with knowledge about his or her condition
Encourage creative activities (e.g., VSA arts)

Adolescence

Develop personal and sexual identity
Achieve independence from family
Form heterosexual relationships
Learn through abstract thinking

Increased sense of feeling different from peers and less able to compete with peers in appearance, abilities, special skills
Increased dependency on family; limited job or career opportunities
Limited opportunities for heterosexual friendships; fewer opportunities to discuss sexual concerns with peers
Increased concern with issues such as why he or she got the disorder; whether he or she can marry and have a family
Decreased opportunity for earlier stages of cognition may impede achieving level of abstract thinking

Realise that many of the difficulties the teenager is experiencing are part of the normal adolescence (rebelliousness, risk taking, lack of cooperation, hostility toward authority)
Provide instruction on interpersonal and coping skills
Encourage socialisation with peers, including peers with special needs and those without special needs
Provide instruction on decision-making, assertiveness, and other skills necessary to manage personal plans
Encourage increased responsibility for care and management of the disease or condition, such as assuming responsibility for making and keeping appointments (ideally alone), sharing assessment and planning stages of healthcare delivery, and contacting resources
Encourage activities appropriate for age, such as attending mixed-gender parties, sports activities, driving a car
Be alert to cues that signal readiness for information regarding implications of condition on sexuality and reproduction
Emphasise good appearance and wearing stylish clothes, use of makeup
Understand that adolescent has same sexual needs and concerns as any other teenager
Discuss planning for the future and how condition can affect choices

From Whaley and Wong's *Nursing Care of Infants and Children*, Sixth Edition (pp. 1006–1007), by D. Wong, M. Hockenberry-Eaton, D. Wilson, M. Winkelstein, and E. Ahmann, 1999, St. Louis, MO: Mosby. Reprinted with permission.

in children that have symptoms related to their condition. The instrument may lack the sensitivity to detect mild problems with adjustment.⁴⁵ Methodological issues, therefore, must be considered when interpreting findings using these instruments. Other indicators of psychopathology used in research in paediatric cardiac disease have included diagnostic criteria for psychiatric disorders, and measures of anxiety, depression, self-concept, and general psychosocial functioning.

Sample characteristics, variables assessed, and measures utilised have varied widely in studies of children with cardiac disease. Consequently, findings have been highly variable. Despite this, several important themes have emerged that warrant attention. Some well-designed studies with fairly large samples have revealed virtually no or very small differences in psychosocial function in subjects treated for paediatric cardiac disease compared to normative values or healthy controls.^{46–48} Multiple studies, in contrast, have identified a higher than expected incidence of behavioural problems in children with cardiac disease.^{49–59} Internalising problems, in particular, social withdrawal, anxiety, and somatic complaints, and externalising problems, most commonly, attention deficits and hyperactivity, have both been reported. The impact of severity has been inconsistent, with some studies reporting more problems in children with more severe cardiac disease,^{47,52,55,58–61} and others demonstrating little to no effect of severity.^{39,46,48–50,62} In general, it has been found that factors relating to the specific disease have lower correlations with adjustment than do the characteristics of the child or the parent and family themselves.³⁵ Some authors have speculated that factors related to the underlying diagnosis contribute to a cumulative risk that moderates the relationship between the stress experienced by a child and their ultimate level of adjustment.^{35,36,47,63}

General deficits in psychosocial functioning in children with cardiac disease have been identified. Psychiatric disorders such as anxiety and depression were present in just over one-quarter of a sample awaiting transplantation or cardiac surgery. The prevalence of disorders decreased in those undergoing conventional cardiac surgery post-operatively, but persisted in those undergoing transplantation.^{64,65} A higher rate of psychiatric problems was found in children with severe cardiac disease compared to those with repaired atrial septal defects, the effects on psychological functioning considered moderated by both physical capacity and family difficulties.⁶⁰ Similarly, children at approximately 6 years of age were found to have more problems than healthy controls, albeit that the differences disappeared when taking account of the effects of intelligence and neurological impairment.⁶⁶ Concomitant conditions, including behaviour, learning, anxiety, attention problems, and depression were also shown to contribute to a score for psychosocial function that was significantly lower than population norms, with lower familial socioeconomic state also having a negative impact on psychosocial outcomes.⁶⁷

Temperament or general life view may impact on psychosocial adjustment. Anxiety, and medical fears, in the child have been found to be closely related to maternal anxiety and behavioural problems.^{61,68} High trait anxiety has been shown to contribute to biases in the perception of stress-induced cardiac symptoms in those treated for

congenital cardiac conditions.⁶⁹ Altered self-concept has also been reported in children with cardiac disease.^{70–73} Children with congenital cardiac disease rated themselves as weaker, more frightened, and more ill than a comparison of healthy controls. These differences disappeared, however, when assessed 1 year after surgery.⁷³ Physical self-concept was lower in children with cardiac disease than healthy controls, albeit that family, school, appearance, emotional and general self-concept did not differ from controls.⁷² A lower self-concept was found in male adolescents with cardiac disease that was speculated to be directly related to diminished physical capacity. On a more positive note, adolescents with cardiac disease were found to have less anxiety, and a higher sense of self-control, than healthy controls, reflecting the development of positive skills for coping with the challenges of their condition.⁷⁰

Meta-analytic techniques³⁹ have revealed that only older patients, with a mean age of greater than 10 years, demonstrate more total, internalising, and to a lesser extent, externalising behavioural problems, with severity of the disease not related to the behavioural problems. The problems demonstrated are more likely related to a cumulative experience of life, with both risk and protective factors related only in part to the cardiac disease. Longitudinal studies in children with cardiac disease are needed to illuminate further the contributions of important variables, such as self-perception, social experiences, parenting style, and collective life stress on psychological and behavioural outcomes.

Quality of Life

Quality of life has been frequently cited as an important measure of outcome for children living with paediatric cardiac disease.^{74–77} Despite this, it remains poorly conceptualised in the literature. Lack of a uniform definition for quality of life, and inconsistent strategies of measurement, have resulted in problematic methodological issues for many studies purporting to address this concept. Moons and colleagues⁷⁸ reviewed 70 studies relating to paediatric cardiac disease published between January 1980 and October 2003 which discussed quality of life as an outcome. They evaluated the studies using 10 previously published criteria to evaluate validity and methodological rigour in the assessment of quality of life.⁷⁹ Overall, the findings revealed a collection of work that was inconclusive, difficult to interpret, and not generalisable to the population of patients with paediatric cardiac disease. Of the articles, one-quarter presented conclusions about quality of life, but did not explicitly measure it. More than two-fifths discussed quality of life in their abstract or discussion sections, but did not account for its measurement in the methods or results sections. Only one study provided a conceptual definition of quality of life that served as a basis for the investigation. On the whole, just over half of the manuscripts reviewed did not meet any of the 10 criteria evaluated, and only 2 had a summary score of 50 or higher out of a possible 100.

An evaluation of the variables or measurements used to assess quality of life for a patient with paediatric cardiac disease is a critical starting point when attempting to interpret the extant literature. Traditionally, researchers have focused on objective measures as indicators of quality of life. These

have included functional state, general health, severity of disease, exercise tolerance, categorisation with the system devised by the New York Heart Association,⁸⁰ socioeconomic level, state of employment, educational level, size of support network, marital state, and number of offspring, among others. Clinical variables, such as the need for reoperation, number of hospitalisations, life expectancy, and need for chronic medication, have also been used as proxy indicators of quality of life.^{81–88} Although each of these variables may have an influence on quality of life, alone they are not an adequate substitution for a more comprehensive measurement. None of the variables used as proxies for quality of life has been shown to have a reproducible predictive relationship. Physical functional state has been the most significant predictor of quality of life, whereas severity of illness has been repeatedly shown to have only a minor association with self or parent-reported outcomes.^{25,89,90}

It is currently thought that quality of life is primarily determined by subjective mechanisms and interpretations, such as attitudes, perceptions, aspirations, and the personal degree of importance assigned to various domains of life.^{91,92} In general, it is agreed that quality of life is multidimensional in nature and represents a global assessment of several core domains including physical, emotional, social, spiritual, and achievement, the latter measured both educationally or occupationally.^{92–95} Using these criteria, quality of life has been defined as ‘the subjective and personally derived assessment of overall well-being that results from evaluation of satisfaction across an aggregate of personally or clinically important domains’.⁹² Hence, the personal and subjective analysis of the individual regarding his or her situation is the primary force guiding the perception of quality of life, not the objectively measured criterion. For this reason, some have argued that quality of life cannot be quantitatively measured and that assessment must also capture a qualitative evaluation of the importance of functional outcomes to the individual.^{67,87,96} In children, however, it is difficult to obtain a subjective assessment of the importance of various domains from the children themselves. They may be too young or too ill to respond directly. They may lack the conceptual maturity to comprehend the value of varying levels of function. Their present-focused attention may limit their ability to conceive of the long-term implications of different functional states.⁹⁵ For this reason, parents are the most commonly employed proxy reporters for the quality of life of their children. Teachers and other providers of healthcare have also been used. Use of alternative respondents, although necessary at times, has significant drawbacks. Objective observers such as parents tend to report more visible aspects of behaviour and functioning. Child self-reports may identify more internal experiences and symptoms. In addition, self-assessment of functioning may be different from that perceived by the parent or other observer.⁹⁵ Despite these limitations, several well-validated instruments exist to measure functional state in the various domains known to be directly related to quality of life. Both generic and disease-specific measures exist that allow conclusions to be drawn regarding quality of life in physical and psychosocial realms.^{97,98}

Since the call of Moons and colleagues⁷⁸ for increased methodological rigour in the assessment of quality of life in subjects with paediatric cardiac disease, several studies have emerged that have systematically pursued a greater

understanding of this important outcome. In a sample of 321 attendees of a paediatric cardiac clinic representing a mix of diagnostic backgrounds, parents completed the Child Health Questionnaire⁹⁹ and reported overall physical and psychosocial quality of life to be similar to a normative sample. Better outcomes for the children with cardiac disease were reported for the subscales self-esteem, family cohesion, and bodily pain/discomfort, but worse outcomes were demonstrated with respect to physical functioning, general health perceptions, family activities, and parental impact—emotional. The greatest impact on physical quality of life was noted in those with the greatest functional limitations, namely children with cardiomyopathy and those requiring major interventions.¹⁰⁰ Parent-report of quality of life for children with paediatric cardiac disease was found to be significantly lower than a healthy normative sample for overall, physical, emotional, social, and school function in two studies with large samples using the generic module of Pediatric Quality of Life Inventory.^{25,94} Child self-reports were similar to those of parents. Children, nonetheless, rated their physical function better than did their parents.⁹⁴ The instrument was able to distinguish between levels of severity in those subjects who had undergone multiple cardiac operations, with those having functionally univentricular or complex biventricular anatomy reporting lower quality of life than those who had undergone a single reparative surgery, namely the arterial switch procedure.²⁵ Parents identified anxiety relative to treatment and cognitive problems as the most concerning disease-specific areas of function.⁹⁴ In children with functionally univentricular anatomy, quality of life has been reported to be lower than healthy controls, particularly in the areas of social and emotional function, behaviour, and cognition.^{67,101,102} In contrast, assessments of patients after repair of transposed arterial trunks have demonstrated quality of life to be essentially equivalent to the general population.^{81,103}

Quality of life, therefore, is an important assessment of outcome for children with paediatric cardiac disease, but it presents many challenges for measurement. If perceptions of quality of life are to be used to guide counselling for families, it is crucial for research to utilise sound methods to assess this outcome. Strategies to incorporate the level of importance assigned by the child and family to various areas of function must continue to be developed. Providers of healthcare must suspend their assumptions regarding the impact of state of health on overall quality of life, and seek the subjective interpretation of the individual. It must be recognised that overall adjustment and well-being are determined by complex relationships between multiple factors relating to the child, the family, and the illness that may impart either risk or resistance.^{1,35,36,104} Ideally, assessment of quality of life in children with paediatric cardiac disease will become a routine part of clinical follow-up, and ultimately will serve as a guide for clinical decision-making.

THE FAMILY

Adjustment and Adaptation

Paediatric cardiac disease results in distress not only for the affected child, but also for the entire family network of which that child is a part. Individual family members,

including mothers, fathers, and siblings, as well as the family unit as a whole, are required to adapt to the complex challenges of chronic illness, and each will likely follow their own trajectory of adjustment.¹⁰⁵ Similar to the responses of individual children, the response of the family to the diagnosis and management of chronic illness in a child is a complex and multi-faceted process.^{1,2,5,104,106,107} Overwhelmingly, families demonstrate incredible resilience, and ultimately most will successfully adapt to the challenges of the condition.^{5,107} When this does not occur, poor adaptation may be manifested by excessive stress, psychological illness, negative impact on quality of life for the child or family members, and negative impact on the overall adjustment of the affected child.^{1,3,35,36,108,109}

Specific phases of a chronic condition such as paediatric cardiac disease will present unique challenges to families. The time of diagnosis, exacerbation of symptoms, need for intervention, or even routine clinical follow-up may each present as critical times requiring response from the family.^{107,110} Additionally, the routine progression through normal developmental stages for the affected child may cause the family to view the illness within a new context. Specifically, entering school, adolescence, and successful transition to adulthood may be times when the family must reassess their appraisal of the impact of the cardiac disease on the ability of the child to function.^{111,112} Family units and individual members typically move in and out of stages of adjustment that range from helpless floundering to developing expertise, and ultimately to successful normalisation and incorporation of illness-management strategies into their everyday lives.¹⁰⁶ Several child, family, and illness-related characteristics will influence the perception by the family of stress, abilities to cope, and their eventual adaptation. A model proposed to account for these factors is presented in Figure 62-1.^{5,113-115}

The appraisal of the stress of chronic illness in a child, or its perceived threat to integrity and ability to function, is a significant factor in determining response.^{2,5,106-108,116} Illness-related variables to consider include age of onset, severity and prognosis of the disease, predictability of symptoms, the type and degree of limitations, and the effectiveness

and consequences of treatment.^{2,5,106,107} The uncertainty regarding long-term outcomes for several forms of paediatric cardiac disease may pose additional stress for families.^{74,117} Age, gender, developmental stage, and ability of the child to comprehend the condition and treatment will also influence the interpretation of these illness-related factors.^{1,2,35} Prior experience with stress may have a positive or negative influence on adaptation. Previous success with managing stress in particular, previous health-related challenges, may provide a family with a sense of mastery and practiced skills for coping with new situations. It is recognised that families typically experience a pile-up of various types of stress related to both normal and unexpected transitions. For the family dealing with an excessive burden of stress, the addition of a child with a complex cardiac disease could overwhelm their resources to cope.^{2,107} Individual levels of anxiety at baseline, and in response to stressful situations, are likely to influence how the impact of cardiac disease is perceived.¹¹⁸ The developmental stage of the family accounts for the evolution of families over time as they are exposed to a variety of life events. Child-rearing families are challenged with developing a family identity that is both flexible and stable.^{119,120} Flexibility is needed to incorporate changes and face stress, allowing the family to evolve to a new level of functioning. Stability defines the ability of the family to maintain its identity, and re-establish equilibrium, despite the need for ongoing adaptation. Maturity in families promotes higher levels of organisation, and thereby improves flexibility and stability.¹¹⁹ First-time parents facing the diagnosis of paediatric cardiac disease may lack the skills necessary to differentiate between normal behaviour or symptoms of their infant and those that are a result of the underlying condition.¹²¹⁻¹²³ They may also lack an established style of parenting that promotes optimal development of the child.⁵⁸

The ability to cope with the stress perceived to be associated with the diagnosis of cardiac disease in a child will be influenced by characteristics inherent to the family, and aspects of the socio-cultural network in which that family exists. Demographic variables, such as socioeconomic state, structure and size of the family, and culture will exert an

Figure 62-1 Adaptation by the family to cardiac disease in a child. (Adapted from McCubbin, Thompson, and McCubbin, 1996; Leske, 2000; Leske, 2003 {1335 McCubbin, Hamilton I. 1996; 701 Leske, J.S. 2000; 700 Leske, J.S. 2003; } } Cardiol Young 2006;16(suppl 3):110-116, with permission.)

influence on adaptation in addition to social and community support networks on which the family can rely. Characteristics unique to the individual family, such as their established patterns of functioning, their skills for solving problems and communication, and their innate degree of hardiness or resiliency, will also guide their process of adaptation.^{1,2,5,35,107} Both what the family has, their strengths and resources, and what the family does, their behaviours for coping, will influence their potential for successful adaptation. The degree of social support perceived by the family is an important illustration. It is not merely the presence of a strong social network that is beneficial, but the perception that this network effectively meets specific needs, which may be for emotional, self-esteem, or practical family support.^{4,5} Maternal perceptions of the implications of cardiac disease in a child, whether warranted or not, have proven to be more significant predictors of child and family adjustment than the medical severity of the condition.^{108,116,124,125} Helping families to achieve realistic perspectives through education and guidance regarding expectations for their children with cardiac disease may have important implications for improving adjustment in children and families.

Effects on Parenting

From the moment of diagnosis, parents of children with cardiac disease are thrust into a world that requires them to adjust expectations dramatically, gather information, and make decisions in an area in which the great majority of them are exceedingly unfamiliar. Parents experience a vast array of emotions during their early adjustment to the diagnosis of cardiac disease in a child. These may include denial or disbelief, intense helplessness over their inability to prevent the condition and protect the child from harm, guilt over their role in causing or failing to recognise the disease, dismay and dread at witnessing pain and suffering, fear that the child will die, and anxiety about the uncertainty of what the child and family will endure in the future.^{126,127} Persistent symptoms of post-traumatic stress disorder have been identified in parents of children diagnosed with life-threatening conditions.^{128–130} Higher trait anxiety, smaller social networks, and greater perceived intensity of treatment and threat to the life of the child were identified as risk factors for post-traumatic stress disorder in parents of children with childhood cancer.¹³⁰ While this phenomenon has not been extensively explored in parents of children with cardiac disease, it is clear that their experiences would put them at risk for extreme distress. Recently, moderate to severe symptoms of post-traumatic stress disorder were found in nearly two-fifths of parents sampled at a median time of 2½ years after cardiac transplantation.¹³¹

Providers of healthcare must be extremely sensitive to the needs of parents during this critical time. The antenatal diagnosis of cardiac disease results in a uniquely sensitive and challenging situation. Individual parents will have different approaches to decision-making that are influenced by their prior experiences, internal characteristics, and general beliefs about parenting.^{132,133} When forced to make decisions, even for an unborn child, parents are assuming a parenting role, and desire to make the best decision for their baby and family.¹¹⁰ Some families may prefer a more paternalistic approach from those providing healthcare, with clear guidance toward the best option. Other

parents may have predetermined opinions about what would or would not be acceptable to them, and may be offended by options that do not fit with their lifestyle, or those perceived to be presented in a biased fashion. Rempel and colleagues¹¹⁰ provided eloquent insight into the process of decision-making for parents receiving an antenatal diagnosis of cardiac disease. They cautioned that providers of information 'must gain an understanding of each family's beliefs and values and provide information and counselling that is responsive to parents' different decision-making approaches'. This advice also applies to families facing a postnatal diagnosis. Of note, both parents receiving an antenatal diagnosis of congenital cardiac disease, and those receiving a postnatal diagnosis, were shown to demonstrate similar elevated psychological distress at the time of diagnosis.¹³⁴ At 6 months after birth, the levels of distress in those receiving postnatal diagnosis had returned to normative values, while those receiving the news prior to birth continued to demonstrate elevated distress.

In an effort to cope with the diagnosis of cardiac disease in a newborn, parents may respond by distancing themselves from the infant, or demonstrating altered attachment to the baby as a way of protecting themselves from the pain and loss that they fear.¹³² This has important implications for bonding and later parent-infant interactions. Infants with congenital cardiac disease and their mothers were shown to demonstrate less positive affect and engagement during interaction than a non-cardiac group when assessed both prior to and 6 months after corrective surgery.¹²² The temperament of infants with cardiac disease has been described by mothers as more withdrawn, more intense, and as having lower thresholds to stimulation than healthy infants.¹²³ These characteristics may impact parental involvement with the child, and could have a negative influence on development.

Exploration of styles of parenting for parents of children with moderate-to-severe cardiac disease has identified lower expectations^{58,112} and lower levels of discipline⁵⁸ than in parents of healthy children. Mothers reported high levels of vigilance with their children and a desire to normalise the child and their family life as much as possible. Interestingly, aside from these acknowledgements of the impact of the cardiac disease, in this study, mothers of children with cardiac disease and mothers of healthy children were otherwise notably similar on both self-reported measures of parenting and child behaviour and videotaped interactions.¹¹²

The vulnerable child syndrome originally described by Green and Solnit¹³⁵ is defined as a reaction characterised by disturbance in psychosocial development often occurring in children whose parents expect them to die prematurely. It has been described in several populations of children with chronic illnesses, and may contribute to long-term behavioural and social problems.¹¹³ Over-protection and reduced expectations of a child with a complex condition may be a very normal response. When overdone, this could have a negative influence on physical, emotional, and social development, and eventually the quality of life. Counselling and reinforcement for parents to treat their child with cardiac disease as a normal child may help to reduce this impact. Although most parents adjust effectively to the challenges of having a child with a complex condition such as cardiac disease, the adjustment may come at a significant emotional and psychological cost that may manifest itself in other

aspects such as marital satisfaction, depression, or personal fulfillment. Opportunities to provide support, anticipatory guidance, and ongoing education, regarding both the cardiac condition and strategies for parenting, should be incorporated into the routine follow-up of children with cardiac disease.

Psychological Responses of Parents and Families of Children with Cardiac Disease

The responses of parents and families to the challenges imposed by cardiac disease in a child are influenced by multiple variables, as previously described, and are inherently difficult to predict or generalise. The last decade has witnessed a flourish of research designed to shed light on these responses. Lawoko and Soares^{136–138} studied reports from a large sample of Swedish parents of children with congenital cardiac disease, parents of children with other diseases, and parents of healthy children. Higher levels of distress, hopelessness, and reduced quality of life were identified in the parents of the children with cardiac disease, being more prevalent in mothers than fathers. Socio-economic factors, such as the financial burden imposed by the disease and changes in career trajectories due to the illness, have demonstrated an influence on perceptions of quality of life by both the child and the parents.^{137,139,140} Parental perceptions of their individual quality of life may have an effect on how they perceive quality of life for their child.¹⁴¹ In one-fifth of families surveyed, Wray and Maynard¹³ identified significant negative influences related to the presence of paediatric cardiac disease on several aspects of family functioning, particularly recreational and social activities, and negative effects on siblings of the affected child. Of note, however, over two-fifths of the sample reported that their family had been drawn closer together by their experience. The presence of additional health problems, not uncommon in children with cardiac disease, added a significant negative contribution to overall family morbidity. Little information is available on marital satisfaction and stability in families living with paediatric cardiac disease. The presence of chronic illness in a child has been related to greater marital role strain, but does not necessarily result in marital dissatisfaction or depression.^{142,143}

As one might expect, several groups have documented higher than expected levels of stress for parents of children with cardiac disease. Goldberg and colleagues¹⁴⁴ found that parents of young infants with cardiac disease reported the highest scores for stress on the child domain of the Parenting Stress Index¹⁴⁵ in the areas of child acceptance, mood, distractibility/hyperactivity, and reinforcement of parent compared to parents of healthy children or children with cystic fibrosis. Similarly, parents of older children with cardiac disease demonstrated higher than expected levels of stress in the child domain.¹⁴⁶ This domain assesses qualities of the child that may make them difficult to parent such as extreme temperament¹²³ and may impact parent-infant interactions and attachment.¹²² Level of stress in the child domain has been found to be correlated significantly with the presence of child behavioural problems in school-aged children with surgically treated complex congenital cardiac disease.^{109,113,147} Excessive stress in a parent may influence the development of such problems. Strategies to alleviate stress, or to help parents develop skills for management of

stress, may benefit the individual parent, the affected child, and the family as a whole.

The severity of the underlying cardiac disease has not been found to be a reliable predictor of parenting stress,^{146,148,149} with daily stress and more emotional methods of coping being significantly predictive of maternal adjustment to children with cardiac disease.¹⁴⁸ Differences in reports of mothers versus fathers regarding demands of care-giving for infants with cardiac disease have also been studied.¹²² Although similar levels of demands were reported by both parents, mothers and fathers identified different aspects of care as the most time-consuming or stressful. Mothers spent the majority of their time addressing the physical needs of their infants, especially feeding. Fathers reported the most time spent attending to the infants' emotional and developmental needs. Interestingly, families with other children experienced higher levels of stress and transitions than did first-time parents. Fathers have been traditionally under-represented in family outcomes research. In two qualitative studies exploring the experience of fathers of children with cardiac disease, several conflicting themes were identified including joy versus sadness, feeling powerful versus helpless, and maintaining versus losing control.^{150,151} Interventions to provide psychological support for the unique needs of fathers are ripe for further investigation.

Effects on Siblings

Brothers and sisters of a child with paediatric cardiac disease experience a wide range of emotions in response to the illness. How they interpret the impact of cardiac disease will be influenced by a number of variables, including their age and level of development, the nature of the illness, the degree of change in routines and interactions with the parents that the illness imposes, the relationship with their ill sibling, and the resources available to the family both in terms of socioeconomic state and social support.²⁴ Unrecognised stress in siblings may manifest itself as behavioural problems, changes in school performance, alterations in eating or sleeping habits, or heightened anxiety at separation.¹⁵²

Young children may be most vulnerable to stress due to their inability to conceptualise causation. They may fear that they will also become ill, or worry that through some action or thought they have caused the illness in their sibling. Younger children are also more distressed by separation from parents and alterations in routines. Older children may experience greater anxiety over the health and prognosis of their ill sibling. Anger and resentment over attention paid to the ill child, and the change in responsibilities for the older child, might also occur.¹⁵² Typically, paediatric cardiac disease is not highly visible. Healthy siblings, therefore, may have difficulty understanding how the ill child is different, or why they require special care or attention. As an example, the family of a young boy that had undergone cardiac transplantation as an infant had always explained his condition by saying that he had received 'the heart of an angel'. His mother reported that his younger sibling protested loudly in anger one day, 'I want an angel heart too!' Healthy siblings of children with cardiac disease are more likely to exhibit behavioural problems when the illness has a high impact on family life, and the intensity of treatment or visibility of the condition is low.⁵² Behavioural problems have been identified more

frequently in siblings of transplanted patients than in those of children with congenital conditions.¹³ Greater visibility of a chronic condition and regular treatment routines may facilitate better sibling acceptance and adaptation.

Hospitalisation and need for surgery result in physical separation from both the ill sibling and the parents. The well children left behind may feel abandoned and helpless. Structuring responsibilities so that there is minimal disruption to the routine of the healthy child is beneficial. The level of maternal education has been demonstrated to lessen anxiety amongst siblings, likely due to a greater sense of responsibility to provide support and information, as well as access to more resources.¹⁵² To facilitate positive adjustment, it is important for parents to provide siblings with accurate and developmentally appropriate explanations of the cardiac condition and its treatment.⁵² When a newborn requires immediate hospitalisation, the siblings at home may have difficulty believing the baby is real. The healthy children should be provided with opportunities to visit, see pictures of the baby, and to send them special things such as drawings or toys, in order to build a sense of connection to the new family member. The healthcare team, in particular child life specialists, should provide guidance to the family to facilitate visits by the siblings, age-appropriate preparation, and to provide siblings an opportunity to express their feelings and concerns.²⁴

Meeting the Needs of Families

Awareness of the potential psychological and social burdens for families living with the diagnosis of cardiac disease in a child is critical for the entire team of those providing healthcare. We will fall far short of our potential to support our patients and their families if we focus only on the physical needs of the affected child. Parents and other family members should be made to feel welcome to express their greatest fears, concerns, and questions.^{14,153} Frequent communication from consistent caregivers is needed to allow families to gain a detailed understanding of the condition of their child and its implications.^{14,154–156} Information delivered at times of high stress is not fully absorbed or retained, yet parents may be unwilling to volunteer that they do not understand aspects of the condition. Asking parents to describe what they know or believe about the condition may provide insight into areas where they need further education or clarification. This education needs to be revisited frequently as the child progresses through normal developmental stages, and when the cardiac condition or plan for management acutely changes.

When a child has an uncertain prognosis, or remains critically ill for an extended period of time, parents look to providers of healthcare for accurate information and reason to maintain hope.¹⁴ At these times, professionals must cope with their own frustrations at their inability to predict every outcome, and attempt to provide families with the most realistic information possible. Frequently, a plethora of caregivers becomes involved in the care of children with complex malformations. Parents may ask the same questions of multiple providers, and begin to compare and contrast answers. Inconsistencies in information will decrease trust and increase anxiety. Remember that parents are also at risk for stress related to events they witness in the critical care environment, and sharing of experiences with

acquaintances made in the waiting room. Conferences for interdisciplinary care that include parents are needed to facilitate planning that accounts for the information needed by the family.

Psychosocial support for families may come from many sources. Support groups coordinated by the hospital or other families may provide valuable opportunities to share experiences and feelings. Today it is common for people to seek information on-line from formal support networks, and from individuals that share information regarding their personal experiences. Parents should be cautioned to evaluate critically the quality of information received from non-medical sources, and reminded that no two children undergo the exact same experience. Parents should be provided with directions to reliable sources of electronic information, such as hospital websites, the American Heart Association,¹⁵⁷ the Congenital Heart Information Network,¹⁵⁸ the European Congenital Heart Disease Organisation,¹⁵⁹ or the Children's Heart Federation,¹⁶⁰ among others. Often the experience of meeting another parent and child that have been through a similar course of events can be incredibly helpful. A cohort of parents and children that are willing to speak with newly diagnosed families can be coordinated by liaison nurses, social workers, psychologists, or child life specialists. DeMaso and colleagues¹⁵³ used an electronic journal to link families and children to personal narratives that were similar to their own experience. Results included decreased social isolation, increased understanding of feelings related to the illness, and more positive reactions in mothers.

Efforts should be made to support the confidence of the parents in their ability to master the needs for care of their child, and to recognise signs and symptoms that may require attention. Systematic discharge planning that includes living in hospital, and caring for the child while he or she is still hospitalised, provides an opportunity for parents to practice their skills and receive important feedback.¹⁵⁵ Home visits by trained nurses and follow-up phone calls can also provide valuable reassurance. Ideally, parents should be provided with clearly defined parameters that should prompt contact with the system providing healthcare, and a reliable method to reach someone who will understand the cardiac condition, for instance a cardiac nurse hot-line.¹⁶¹ Ongoing information was the most common area of need identified by families.¹⁵⁴ Parents desired written information and diagrams about diagnosis and previous operations, information for both themselves and their child on the practical implications of the diagnosis such as activity restrictions, side-effects of medications, details to share with schools, and updated information on prognosis and the development of new approaches to treatment.

When a Child Is Dying

Despite our best efforts, there are times in the management of paediatric cardiac disease when no cure or palliation is possible, and it becomes inevitable that the child will die. These situations pose a profound challenge for health professionals. Communication with children and their families at these times is critical yet delicate. Many health professionals may not be well trained in how to approach these situations.^{133,162} Consultation with experts

in mental health, palliative care, and bereavement to support the child, parents, and siblings can provide invaluable assistance. If the affected child is at an age where they are aware of their condition, they should be provided with opportunities to express concerns about their future without fear that they will upset their family members or members of the team providing care. Children may have fear of impending pain or abandonment that can be alleviated with assurances from trusted adults.^{14,163} Parents, although inherently hopeful, may find some comfort in hearing that death may be unavoidable. This acknowledgement may help them to address their fears and begin the process of grieving. Total denial of impending death will only make its acceptance more difficult, and may leave parents with feelings of guilt or blame.¹⁴ Because parents are the ultimate makers of decisions regarding the care of their child, they may experience regret over a choice to pursue surgery or a specific treatment. An opportunity to review with staff the situation and care after a child has died may help parents gain comfort in knowing that they made the best decisions possible, and that their child has not been forgotten by those who provided care.

Attention must also be directed to the emotional needs of siblings at this difficult time. Opportunities for siblings to express their feelings by asking questions, drawing pictures, telling stories, and spending time with the ill child should be provided. Parents should be given information on the typical responses of children to the loss of a sibling which commonly include attention-seeking behaviour, irritability, sleeping difficulties, guilt at surviving, health complaints, and confusion over their new role in the changed family.¹⁶³ Whenever possible, families should be supported in their desire to fulfil culturally or spiritually important traditions when a child is dying. Choices of how the family wants to say goodbye, and support for the departure of the family from the hospital, should be provided. Leaving their child in the arms of a favourite or trusted staff member may help a family conclude this final visit.¹⁶³ Provision of bereavement support should be made available by those providing care for as long as the family finds it beneficial.

SOCIAL ISSUES

Every child and family affected by paediatric cardiac disease exists within a network of social structures that include financial, legal, political, educational, cultural, religious, and healthcare systems. The impact of chronic illness in a child must be considered within the context of each of these systems.

The financial implications of paediatric cardiac disease are associated with the expense of delivering care, the impact of lost wages and contribution to society from a parent that leaves the work force to care for an ill child, and the long-term abilities of the affected children to gain employment and support themselves. Although children with special needs comprise less than one-fifth of the overall population of children in the United States of America, they account for more than four-fifths of the costs of providing healthcare.¹⁶⁴ Whether this burden is absorbed by private health insurance, national health plans, or individual families, it is a formidable expense that, in some form or another, is transferred to society. Many private insurance plans have a cap of \$1 million or less for lifetime coverage

of an individual. Although this may sound generous to most parents, it is not uncommon for children that require multiple hospitalisations and surgeries to reach this limit before they reach school age. This may result in a job-lock phenomenon, where parents are unable to leave their current job for fear of losing insurance coverage.¹⁶⁵ Social work services should be made available to parents of children with complex cardiac disease to ensure that they are aware of the support programmes available to them. Adolescents with cardiac disease require career counselling regarding appropriate educational and vocational goals, and adults should be informed of the legal protections in place to reduce discrimination based on disability.^{166–168} They may also need guidance regarding their needs and eligibility for insurance once they are no longer covered by the policies of their parents. Further legal protections, such as the Americans with Disabilities Act,¹⁶⁹ are in place to ensure civil rights for persons with disabilities regarding their access to education, employment, and other public benefits.

Systems providing public education are mandated to provide full access to all educational opportunities for children with special needs, albeit that these services are often limited by the economical constraints of the system. Whilst the majority of children with cardiac disease will achieve educational accomplishments similar to their peers of the same age, it is clear that some will demonstrate learning challenges that may require special education services (see Chapter 64). Individual tutoring, and strategies for specialised teaching, may be cost-prohibitive in some school systems. Children with relatively minor learning problems may be grouped with more severely retarded children in order to conserve scant resources. School teachers may also lack the training necessary to deal with issues associated with chronically ill children in the school system.¹⁷⁰ It is important that parents are equipped with the information necessary to communicate with educators of their child to assure that children with cardiac disease are encouraged to reach their full potential.

Providers of care to children and families living with cardiac disease must be sensitive to diversity in several aspects of family life, including differences in ethnicity, race, cultural beliefs and mores, socioeconomic state, spirituality, and religious affiliations and traditions. Sensitivity requires more than just the recognition of individual differences, and must also include an attempt to understand the implications of these differences for the care of the child. Certain treatments, such as blood transfusion for a Jehovah's witness, may put the individual at risk of being ostracised from his or her community. Other recommendations including dietary changes, or accepting support from non-family members, may be so incongruent with the culture that they become nearly impossible to implement. Health beliefs, behaviours, and expectations or acceptance of various outcomes will also vary by cultural background. Improved relationships will result from recognition of culturally driven assumptions, and sensitive consideration to appropriate strategies for treatment.^{171–173}

Providers of healthcare for children face personal and ethical challenges associated with the care of patients with paediatric cardiac disease. The ethical principals of justice and beneficence relate to equitable treatment and allocation of resources for individuals, as well as the mandate for providers of healthcare to promote good at both

the individual and societal level.¹⁶⁷ Whilst infants are rarely restricted from needed care, access to resources may diminish as children mature.¹⁶⁷ Disparities in access to paediatric specialists have been associated with both economic state and race.^{174–176} Balancing the greatest good for society with that of the individual is a delicate task. Preserving the life of a child with a complex condition will undoubtedly impart future costs in terms of morbidity, and the potential for transmission of the condition to future generations. It is not possible, however, to value the benefits of the contribution of any individual to society.

The burden to staff looking after children in terms of emotional stress may be exceptional. Paediatric nurses and physicians are at risk for compassion fatigue and burn-out due to their repeated exposure to difficult procedures and treatments performed on children, and the emotional burden of caring for families.¹⁷⁷ More than half of surveyed paediatric critical care physicians reported to be at risk or burned out with perceptions about the value of their work, and feelings of success and satisfaction, being highly associated with those considering themselves burned out.¹⁷⁸

Suffering by, or demise of, a child can be one of the most emotionally devastating events of which anyone can be a part. Staff form attachments to both patients and families, and need to recognise their own feelings and grief when they are unable to save the child. Given the medical technology available to sustain life today, many deaths in the paediatric intensive care unit will be related to decisions to limit or withdraw life-sustaining treatment. These decisions typically follow a prolonged course in the intensive care environment, and the relationships developed between patients, family members, and staff must be acknowledged. Nurses are commonly at the bedside of critically ill children on a continual basis. Family members often share concerns or fears with nurses that they are not able or willing to express to physicians. Disagreement and poor communication among staff may occur when there is conflicting information about what families have been told or their understanding of treatment decisions.^{14,179} It is helpful to encourage discussion of psychosocial and ethical issues when planning daily care in those with complex malformations among the entire medical and non-medical team. Documentation about what families have been told, and the concerns they have expressed, can help to reduce missteps in communication. Formal meetings with the family must be conducted to achieve a consensus on the plan of care when benefit from further therapy appears futile.¹⁷⁹ The goal of a humane and dignified death that corresponds as much as possible to the wishes and beliefs of the family should be paramount for all caregivers that face this regrettable situation.

SUMMARY

The outcomes that really matter to patients, families, and societies living with the implications of congenital and acquired paediatric cardiac disease extend far beyond mere survival. Psychosocial outcomes for patients include the perception of stress related to treatment, psychological and behavioural development, quality of life, and the societal consequences of life with a chronic illness. Families face unique challenges as they are called upon to adapt to life

with a child with paediatric cardiac disease. There may be effects on parenting and psychological well-being, as well as important implications for siblings and other family members. Social systems also need to adapt to and accommodate the needs of children with special needs and the growing population of adults that survive paediatric cardiac disease.

Psychosocial outcomes are highly subjective in nature and are determined by complex interactions between factors concerning risk and resistance inherent to the child, the family, the illness, and the social systems in which they exist. Individual perceptions and values must be recognised as an important determinant of successful adaptation. Professionals caring for these patients and families must support communication, and explore the psychosocial needs and concerns. The entire team providing care must also acknowledge its own feelings in order to meet the needs of the patients and families served. Building on the strengths of an individual child and family, and supporting efforts in coping, will enhance adaptation and well-being. The human spirit is incredibly resilient, even in times of great adversity. May the strength of the children and families we care for be an inspiration to all of us.

"Our greatest glory is not in never falling, but in rising every time we fall."

—Confucius

ANNOTATED REFERENCES

- Spijkerboer AW, Utens EM, De Koning WB, et al: Health-related quality of life in children and adolescents after invasive treatment for congenital heart disease. *Qual Life Res* 2006;15:663–673.
The authors have extensive history in the evaluation of psychological and social outcomes for children with cardiac disease. In this manuscript, the health-related quality of life was examined for 113 children aged 8 to 15 years that had undergone surgical intervention for repair of a congenital cardiac defect. Quality of life was reported as worse than a healthy reference group. Children aged 8 to 11 years scored lower than adolescents aged 12 to 15 years. There were no differences based on gender or diagnostic group.
- Karsdorp PA, Everaerd W, Kindt M, Mulder BJ: Psychological and cognitive functioning in children and adolescents with congenital heart disease: A meta-analysis. *J Pediatr Psychol* 2007;32:527–541.
In a meta-analytic review of the literature from 1980 to May, 2005, addressing psychological and cognitive functioning of children and adolescents with cardiac disease, the authors found that only older children demonstrated an increased risk for behavioural problems. They concluded that the presence of cardiac disease alone does not necessarily impart problems with psychological function. They recommend longitudinal study of children with cardiac disease to improve understanding of the complex factors that influence long-term adjustment of children.
- McCrindle BW, Williams RV, Mitchell PD, et al: Relationship of patient and medical characteristics to health status in children and adolescents after the Fontan procedure. *Circulation* 2006;113:1123–1129.
The investigators of the Pediatric Heart Network conducted a cross sectional study of 537 patients that had undergone Fontan palliation for complex paediatric cardiac disease to examine the relationships of patient and medical characteristics to perceived state of health. Problems with attention, learning, development, behaviour, anxiety and depression were identified. Both physical and psychosocial function scores were lower than the instrument norms. Lower socioeconomic state added an independent negative impact on outcome.
- Moons P, VanDeyk K, Budts W, DeGeest S: Caliber of quality-of-life assessments in congenital heart disease: A plea for more conceptual and methodological rigor. *Arch Pediatr Adolesc Med* 2004;158:1062–1069.
Moons and colleagues reviewed 70 studies relating to paediatric cardiac disease published between January, 1980, and October, 2003, which discussed quality of life as an outcome. They evaluated the studies using 10 previously published criteria to evaluate validity and methodological rigour in the assessment of quality of life. Few studies met the specified criteria, resulting in a collection of work that was inconclusive, difficult to interpret, and not generalisable to the population of patients with paediatric cardiac disease. A call for greater methodological rigour in the assessment of this important outcome was issued.

- DeMaso DR, Campis LK, Wypij D, et al: The impact of maternal perceptions and medical severity on the adjustment of children with congenital heart disease. *J Pediatr Psychol* 1991;16:137–149.
The authors, psychologists, and paediatric cardiologists at Children's Hospital, Boston, examined the hypothesis that maternal perceptions would be more significant predictors of emotional adjustment for children with cardiac disease than the clinical severity of their illness. In the 99 mothers sampled, maternal perceptions were the most potent predictor of emotional adjustment in the children accounting for 33 percent of the variability in adjustment whereas severity of illness accounted for only 3 percent. The mother-child relationship and accurate perceptions of the impact of the condition appear to be critical factors in adjustment.
- Visconti KJ, Saudino KJ, Rappaport LA, et al: Influence of parental stress and social support on the behavioral adjustment of children with transposition of the great arteries. *J Dev Behav Pediatr* 2002;23:314–321.
The authors, part of the Boston Circulatory Arrest Study group, examined the relationships between parental stress, social support, and behaviour problems at 4 years of age in children that had undergone surgical repair of transposed arterial trunks. Outcomes were favourable with parents reporting less stress, more social support, and fewer behaviour problems than normative samples. Families with less social support reported higher levels of stress related to parenting. Higher levels of stress reported by parents correlated with a greater number of behaviour problems in the children. This manuscript illustrates the multiple factors that contribute to adjustment of children and families.
- Lawoko S, Soares JJ: Quality of life among parents of children with congenital heart disease, parents of children with other diseases and parents of healthy children. *Qual Life Res* 2003;12:655–666.
In a large sample of parents in Sweden, the authors compared quality of life for parents of children with cardiac disease, parents of children with other diseases, and parents of healthy children. Parents of children with cardiac disease reported significantly lower quality of life than parents of healthy children. Mothers reported worse outcomes than fathers. Distress, hopelessness, and financial stress were more important than the presence or severity of the condition of the child in predicting outcomes.
- Goldbeck L, Melches J: The impact of the severity of disease and social disadvantage on quality of life in families with congenital cardiac disease. *Cardiol Young* 2006;16:67–75.
Psychologists in Ulm, Germany, investigated the combined impact of social disadvantage and severity of the cardiac condition of the child on quality of life for 132 children and their caregivers. A significant interaction effect between the two predictors was identified, such that mild disease with social risk had virtually the same impact as severe disease with no social risk. Both medical and social risks for a poor response to the stress of cardiac disease in a child must be considered.
- Wray J, Maynard L: The needs of families of children with heart disease. *J Dev Behav Pediatr* 2006;27:11–17.
Psychologists from the United Kingdom conducted a mailed survey to examine the perceived needs of children with cardiac disease and their families. The greatest need identified by two-fifths of the sample was for information about the child's condition. Nearly three-fifths of the sample had one or more unmet need and this increased with the age of the child. Provision of ongoing support and education for children with cardiac disease and their families is emphasised.
- Kamphuis M, Vogels T, Ottenkamp J, et al: Employment in adults with congenital heart disease. *Arch Pediatr Adolesc Med* 2002;156:1143–1148.
This group providing paediatric cardiac care in the Netherlands examined job participation and career-related problems in adults with complex and mild congenital cardiac disease. They found a higher rate of unemployment, and problems with career, due to health in those with complex malformations. This highlights just one aspect of the social consequences of congenital cardiac disease. The need for counselling related to education and career planning is emphasised.

Ethics and Consent

MARTIN J. ELLIOTT and TONI ELLIS

In his introduction to the equivalent of this chapter in the second edition of this book, G. R. Dunstan¹ pointed out the increasing role and understanding of ethical principles in paediatric cardiology. At that time, it might have been tempting to think that the specialty had encountered all the ethical issues it could reasonably expect to face. Not so. The last few years have seen new ethical issues emerge, and new thinking is needed. These issues include improved prenatal diagnosis, more genetic and epidemiological information, the increased use of mechanical circulatory support and a reduction of available organs for transplantation, and, with the evolution of the Internet, the rise of the expert patient or family. Interactions between physician, parents and child are complex and challenging. They have been described poetically² as 'a dance with three partners', in which the physician must learn both to lead and to follow. Ethical treatment in the context of a child within a family must take into account all relevant aspects. The physician must be aware not only of the consequences of the diagnosis but also of the quality of life after treatment, as well as its quantity. The physician must help the family understand the consequences of decisions both to treat and not to treat. As the Royal College of Paediatricians and Child Health pointed out in 1997,³ generally the physician will ask, 'How shall we help this baby to live?' Sometimes he or she must ask, 'Ought we to help this baby to live, given the means we have and the predictable outcome?'

In many countries and cultures, legal frameworks have evolved to attempt to deal with these developments and changing relationships, and these are usually expressed as changes to the rules for obtaining consent. Yet there is variation in practice, and as ethical behaviour remains, at least in part, culture-dependent, the reader is reminded that the general points made in this chapter are delivered from the perspective of United Kingdom residents with a largely European bias. We have attempted to highlight different practice where possible.

International and intercultural differences in economic and political factors also influence clinical practice, and these may have significant ethical implications over which the physician may have little control. For example, if a country has major problems with water supply, or an excessive incidence of malaria or acquired immunodeficiency syndrome, it may be considered unethical to offer treatment to children with hypoplastic left heart syndrome. Not to do so in, for example, the United States might induce the opposite interpretation. This ethical relativity must always be understood and allowed for.

Despite the evolving success of our relatively young specialty, one of the most distressing aspects of our work is the

persistent uncertainty of long-term outcome. Uncertainty is very difficult to cope with, and if combined, as it often is, with a series of interventions involving considerable risk, it is not surprising that families find uncertainty stressful. The physician has to exercise informed judgement in the face of this uncertainty, in partnership with the family.⁴ In every aspect of the above discussion, a key element is the relationship developed between physician and family, a relationship which must be built on trust. It is all about communication.

COMMUNICATION WITH PATIENTS AND FAMILIES

Paediatric cardiology presents specific difficulties in communication with families. Not only are congenital heart disease and its treatment difficult to understand, but the language we professionals use is beset by shorthand and abbreviations, for example, hypoplast, VSD, DORV, SVR, and so on. Even if we use these only between ourselves at the bedside, they can have the apparent effect of excluding the family, and thus lay us open to accusations of elitism or paternalism. Those of us dealing with children need to understand these problems, but as has been pointed out in an excellent recent review,⁵ few of us have had any explicit training in such three-way communications. This chapter is not the place to teach the basics, and we recommend this piece of work⁵ as a good foundation. Much of it is common sense. For example, making sure the environment is child- and family-friendly, peaceful and calm. Always make a point of introducing yourself. Always be well prepared, making sure you have read the notes. Ask questions, listen, share information, explain carefully with visual aids or models as needed, and always ensure that the family understands by asking them to report back to you what you have said. Good understanding is expressed by maintaining eye contact, the asking of questions, and a positive body language, such as is achieved by leaning forward. Poor understanding can be inferred from opposite behaviours. Our own anecdotal observations demonstrate the fact that even these basic techniques are patchily applied. In our own unit, we have found role-play and video analysis helpful in reversing the practice of bad communication. A key question you might ask yourself is, 'Would this standard of care, or communication, be acceptable to me or my family?' If the answer is 'no', then you should take responsibility and change your behaviour. Other good summaries of these basic aspects of effective communication are presented elsewhere,^{6,7} and in the Framework of Competencies for Basic Specialist Training in Paediatrics,

published in October 2004 (Available at: http://www.rcpch.ac.uk/doc.aspx?id_Resource=2429).

CONSENT

The principle of informed consent, aimed at the lawfulness of health assistance, reflects the concept of autonomy and decisional auto-determination of the person requiring and requesting medical or surgical interventions.⁸ Evidence exists that forms of consent probably existed in classical cultures, and are certainly implied in that fundamental element of the Hippocratic oath: 'First, do no harm'. Informed consent requires the giving of information, the certainty of the understanding of that information, time for reflection, and the actual giving of consent for the therapeutic intervention. Whilst there is variation in the mode of application of these components in different countries, particularly in the need for the signing of consent forms, which are compulsory in the United Kingdom and the United States, but not currently needed in Sweden or Belgium, the basic principles are consistent.

The concept of consent has changed over time.⁹ Until the 1970s, consent was a rather paternalistic process. The doctor knew best, and was not afraid to say so, and society accepted this role. Society trusted doctors, who were perceived as figures of professional authority to whom respect was owed for their knowledge and wisdom. As decisions became more complex, and doctors less well trusted, this paternalistic model began to fade, and was replaced by one reflecting the autonomy of the patient in decision-making. This model presumes that the physician can translate his or her knowledge and experience in a manner that allows patients and families to grasp the implications and nuances of a particular decision. Sadly, this presumption has proved impossible to achieve, since as has been pointed out,⁹ you would need to be able 'to infuse the patient with the contents of a textbook and the accumulated experience of the physician' for this really to be possible. Thus, a new model has emerged, that of shared decision-making. This model assumes that the physician and family will, and can, evaluate the available options in a systematic way, arriving at a clear and logical decision aware of the burdens as well as the benefits of treatment. The model still assumes a high degree of information availability, but more accurately reflects the realities of current practice.

There are three situations in paediatric cardiology that need to be considered in understanding the potential of the last model in our practice. These are prenatal counselling, a previously undiagnosed postnatal surgical or medical emergency, and an elective procedure to someone after regular clinical review.

Prenatal Counselling

In this situation, the family, previously happily looking forward to a new child, are suddenly thrust into a situation in which anxiety, sadness, guilt, and numbness dominate their emotions. In the midst of this psychological turmoil, they are expected to grasp the complexities of the congenitally malformed heart, acquire some understanding of the treatments and their consequences, and begin to understand concepts of risk and uncertainty, which are difficult enough under the happiest of circumstances. It is not surprising

that families are vulnerable to the imposition of the preferences of the medical team involved. The impact of cultural influences on the given advice, or the response to it, has been described in the context of hypoplastic left heart, comparing religious and pro-life America with more secular and pro-choice Europe.¹⁰ Such a societal bias to a pro-life stance means that abortion or termination of pregnancy is likely to be chosen much less frequently. This is just an example of the need to provide information in as many ways as possible to aid understanding. In fetal practice, nurse specialists, professional counsellors, and specific physicians combine to aid the family in making their decision. Most families will also search the Internet, consult friends or other family members, and require time to decide with regard to termination or continuance of pregnancy. The mother, particularly, will experience all sorts of emotions at this time. Because she lacks the medical knowledge of the physician, her assessment of risk must be even less certain than the professional view.

The duty of the doctor is not done when a factual explanation has been provided, and a request made for the mother's consent or decision. Should things not turn out well, her burden of regret or loss will be heavier than that of the professional. It is not to her good if she adds to it a burden of guilt. Guilt may be lessened or avoided if she can feel that her decision had the warrant of the approval or support of her doctor. Certainty cannot be required. Indeed, it is unattainable. But if a doctor feels sufficiently encouraged by the data to suggest the procedure in the first place, there seems to be no reason why, without over-reaching, that encouragement cannot be shared with a responsible parent. The same consideration is apt, although it is not the only one, in discussing the option of terminating a pregnancy after the detection of grave fetal abnormality. It has even stronger force when a medical decision is taken, as licitly it may be in ethics and in law, to desist from further efforts to keep alive a severely ill baby. Doctors have to learn to live with such decisions. Parents should not be obliged to. Most teams have no problems understanding parents who opt for termination if they so wish, but in societies which have adopted a primarily pro-life stance, this may become a significant source of tension. Such tension is more evident in the postnatal emergency example.

Postnatal Medical or Surgical Emergency

In this setting, and in the absence of prenatal diagnosis, the parents are confronted with new and shocking information, and little time to decide. The cardiologist or surgeon is aware that a procedure can be performed, palliative or otherwise, which will undoubtedly permit life, but which may often form just one step in a longer-term strategy of uncertain outcome but with certain shortening of life. The doctors will know little of the family circumstances, and less of their personalities and beliefs. Information may be given, but may well be less understood than when more time is available. The family will have little time to consult elsewhere, or to conduct their own Internet research. This is a situation closer to the old paternalistic model, and places specific demands upon those obtaining consent. Attempts to transfer an understanding of risk, uncertainty, and predicted outcomes should be made, and great care must be exercised in trying not to impose treatment for which

there may be little or guarded enthusiasm. Unit policy may be invoked as a rationale for treatment, but in the absence of family context, this could be interpreted as persuasion rather than consent. Again, the quality of the consent process is dependent upon a team of people, usually doctors and nurses, being willing and able to take the time to help the parents understand the problem, along with the consequences of any decision. Sympathy, care, and understanding are key elements in the process. We find it wise to think of creating a relationship which allows for questioning and mutual respect.

There is no substitute for the truth, and certainly no place for lies, yet we know that huge bias exists in the information provided to parents by physicians.¹¹ Physicians promote treatments that they believe work, that are done well in their own institution, and yet whose results may bear little relationship to their estimates of outcomes. Thus, both doctors and patients may base decisions on estimates of outcome and risk that may have little accurate foundation in fact. We could argue that it is like the partially sighted leading the blind. Over the coming years, we need to place the outcomes of our work into the public arena in much more interpretable and accessible forms to improve the quality of this process of consent.

Elective Treatment after Regular Review

In this situation, consent is more clearly and appropriately a chronic process, in which the family and child are gradually educated over time by their cardiologist and his or her team in the vagaries of the condition and its treatment. Such understanding evolves with exposure to echocardiography, sharing images and explanations, review of pre-prepared patient information, and, in the current era, parent- or child-driven Internet research. As an example, in our clinic only recently, a child was busy searching the Internet on his iPhone as the interview with his parents proceeded. The subsequent questions from the child were profound, searching, and relevant.

After such longer-term, chronic evolution of understanding of what is going to happen, and with the resultant greater opportunity to build a relationship, the subsequent consent to a procedure might be considered to be a formality. Sadly, this has not been our experience. Often, cardiologists have indeed taught the family the general issues associated with treatment, and the benefits and significant risks of the procedure to come may well have been covered. But the surgeon obtaining consent at a pre-admission clinic, or the day before surgery, may well be faced with a situation in which, for the first time, the family is asked to confront such specific risks as cerebral damage associated with open-heart surgery, the risk of delayed closure of the chest, mediastinitis, long stay in the intensive care unit, and so on. The obtaining of consent turns into a litany of risk, rather than a confirmation of an understood balance of risk and benefit. This becomes even more of an issue if consent is also being sought for any or several research projects, since research governance mandates specific and detailed consent for all studies. At this time, it can be very difficult for a family to see the wood from the trees. They are anxious, having thought that the procedure had been decided, and have come to terms with it. Then, suddenly, the benefits of the

procedure may be lost in the welter of risk which they are forced, by the legislation of consent, to hear. It seems that the process of consent may sometimes become a burden all of its own, and great care should be exercised to avoid that. Whenever possible, time should be allowed between the consent and the procedure, allowing a period for reflection, further questioning, and confirmation of understanding. Once again, the pressures on hospitals to be efficient may make such demands difficult to meet, but in our view such difficulties should be overcome by the process of change, rather than by bad practice in obtaining consent.

EXPLAINING AND UNDERSTANDING RISK

Understanding risk is one of the most difficult things to do. This is reflected by the recent decision of the University of Cambridge to establish a Professorial Chair in The Human Understanding of Risk. Predicting risk is notoriously difficult. Thus, if poor prediction is combined with poor understanding, it is not surprising that there can be important misunderstandings in communication. In obtaining consent, or in defining the optimal treatment, it is also important to rank risk and to balance it against benefit. This tends to be done intuitively by physicians, but for the frightened family, these issues of balance need to be laid out with care and patience, using as many techniques as necessary to ensure understanding.

Who Should Get Consent and How?

In the United Kingdom, the General Medical Council has issued an outstanding document entitled 'Consent; patients and doctors making decisions together', which provides guidance to cover these issues. Its title reflects that change towards consensus, rather than patronage or autonomy. The following list, paraphrased from that document, describes what the General Medical Council concluded the doctor must explain to the patient and family:

You, the doctor, must give patients the information they want or need about:

- The diagnosis and prognosis
- Any uncertainties about the diagnosis or prognosis, including options for further investigations
- Options for treating or managing the condition, including the option not to treat
- The purpose of any proposed investigation or treatment and what it will involve
- The potential benefits, risks, and burdens, and the likelihood of success, for each option; this should include information, if available, about
 - Whether the benefits or risks are affected by which organisation or doctor is chosen to provide care
 - Whether a proposed investigation or treatment is part of a research programme or is an innovative treatment designed specifically for their benefit
 - The people who will be mainly responsible for and involved in their care, what their roles are, and to what extent students may be involved
 - Their right to refuse to take part in teaching or research
 - Their right to seek a second opinion

- Any bills they will have to pay
- Any conflicts of interest that you, or your organisation, may have
- Any treatments that you believe have greater potential benefit for the patient than those you or your organisation can offer

Clearly this is an extensive list. It takes time and commitment to take consent on these terms, and the consenters must clearly be well informed, able to explain but also to listen. It is impossible to obtain informed consent if one is oneself uninformed! The General Medical Council also provides important guidance on the issue of delegation of the responsibility for consenting. The General Medical Council states:

If you are the doctor undertaking an investigation or providing treatment, it is your responsibility to discuss it with the patient. If this is not practical, you can delegate the responsibility to someone else, provided you make sure that the person you delegate to is suitably trained and qualified

has sufficient knowledge of the proposed investigation or treatment, and understands the risks involved

understands, and agrees to act in accordance with, the guidance [in this booklet]

If you delegate, you are still responsible for making sure that the patient has been given enough time and information to make an informed decision, and has given their consent, before you start any investigation or treatment.

The doctor has to explain all this information in a way that is understandable, and allow the family and the patient to question, and develop understanding of, the issues. These rules apply equally to children and adults who may well be able to grasp the issues, and who should be involved in any decision-making. Specific allowance must be made to help them understand, either by additional teaching materials, or with the help of colleagues, such as nurses or play specialists, even if the ultimate legal responsibility rests with the parent or guardian.

Knowing whether a child is able to give consent on his or her own behalf is a skill and also depends on the legal rulings in the country concerned. In the United Kingdom, a child may be judged able to give consent if he or she is so-called Gillick competent. This follows from a case in the 1980s, in which Mrs Gillick challenged the lawfulness of guidance provided by the Department of Health that doctors could provide contraceptive advice and treatment to girls under the age of 16 without parental consent or knowledge in some circumstances, after her daughter had been given contraceptives by the family doctor without her knowledge. The House of Lords decided against the mother, on the grounds that it was lawful if, amongst other issues, 'the child had sufficient maturity and intelligence to understand the nature and implications of the proposed treatment'. This advice was initially limited to the issue of contraception, but a later judgement widened it to include other aspects of sexual health, and the term Gillick competent was born. It has provided a good rule of thumb in clinical practice for many of us to help ensure true partnership in decision-making with children of any age, clearly able to understand the issues. The message is simple. Respect the

child and family, and treat them as you would wish to be treated, namely with respect and care.

Current Ethical Dilemmas

The management of patients with congenitally malformed hearts has produced some important ethical issues over the years. In finishing, we discuss a representative selection of some of the current problems.

Hypoplastic Left Heart Syndrome

Despite improving results at all stages of the treatment of this condition, there remain sufficient doubts over the long-term results, quality of life, and limited options for end-stage treatment that many doctors feel that the decisions regarding termination of pregnancy after prenatal diagnosis, and the provision of so-called comfort care rather than therapy postnatally, remain extremely difficult. These concerns relate to the perceptions of the quality of life, strains on the family, and beliefs that the non-cardiac associations of the treatment and condition will also make the burden of disease too great. In some countries, notably France, these views are widely held, and contrast strongly with attitudes in the United States.¹⁰ As with many ethical debates, there is no correct answer, and hopefully detailed studies of quality of life and the burden of disease will effectively influence debate in the future. Nonetheless, we have heard arguments forwarded at professional meetings in the United States that the hospital concerned ought to put the child into the care of the courts if the parents refuse treatment, in order that the child can benefit from the Norwood strategy. The ethics of refusing treatment, or forcing it upon an unwilling family in this setting, have not yet been tested. The issue has been reviewed in excellent fashion.¹² Clearly, the decision not to allow the child to undergo surgery, when everything and everyone around seems devoted to providing that care, is difficult, a kind of environmental coercion. These issues have been movingly described by a parent who opted for no treatment for a child with hypoplastic left heart syndrome.¹³ Although times have moved on since then, and attitudes to treatment have altered, the emotions presented in this article make important reading.

Prenatal Diagnosis, and Difficult Decisions in Neonatal and Infant Critical Care

The attitude of doctors towards termination of pregnancy at various fetal ages and for various conditions is, perhaps surprisingly, highly variable and as a result very contentious. What data or values are they using to support their advice? This issue has recently been debated, with the conclusion reached that this area needs greater research both legally and medically.¹⁴ Importantly, it was also stated that doctors must guard against forcing their own values onto the wider society. Most Western societies abort more normal fetuses than they do abnormal ones, and yet prenatal diagnosis can provide considerable reassurance for those seeking to have a normal baby. Excellent prenatal scans can raise difficult dilemmas for the parents, particularly as they may have to choose from options including initial treatments which carry high risks, or significant uncertainty over the long term. The ethics around this have been widely reviewed, recently by the Nuffield Council on Bioethics,¹⁵ which concluded, 'We consider that a pregnant woman who has chosen to continue her pregnancy has strong ethical

obligations to protect the health of the future child. We are not persuaded, however, that the law should require pregnant women to submit to medical or surgical interventions to benefit a fetus against their will'. It seems to us that this statement represents an accurate summary of ethical attitudes in most of the world.

BRIDGING TO TRANSPLANTATION

Ethical issues sometimes emerge so quickly, as a result of rapid medical progress, that we are unprepared to deal with them, and discover too late that we should have undertaken ethical review in parallel with the medical development. Such a situation is emerging with the use of ventricular assist devices as a bridge to transplantation in children. The mismatch between supply of, and demand for, donor hearts to manage end-stage cardiac failure from whatever cause in children prompted the development of devices to support the circulation until an organ became available, or recovery occurred.

The success of the Berlin Heart Device throughout the world has surprised us all, and now it has become the support of choice in many centres. Yet, simultaneously, the number of donors has fallen, and thus an increasing number of children exists, waiting on such support and hoping for the appearance of a heart. All the patients in whom a Berlin Heart has been inserted in the United Kingdom are on an urgent list. Cynics may say that the only way to obtain a transplant is to be supported on a Berlin Heart. Where does this lead? What should we tell families? Who should be given a Berlin Heart—all or few? Are all those on such support equal, or should scoring be introduced to rank urgency, such as on the basis of the duration of support? How do we deal with the massive costs, and thus the opportunity cost to other groups of patients? Who should decide about rationing? There are of course no simple answers, but we do have a responsibility to address the issue, and to find frameworks for dealing with it which are rational and fair. So far we have failed, driven perhaps by the need to make progress, or to do better than our peers. The balance between progress, resources, ambition and expectations, real or unreal, is hard to find, but is a responsibility of medicine. This dilemma is often characterised by the question 'Just because we can, should we?'

There will, of course, be many other examples which any reader might wish to propose. It is not the purpose of this chapter to provide guidance for all situations. Rather, we wanted to emphasise the need for ethical review and self-criticism. We should make ourselves open to comment and criticism, and learn to use the expertise and advice of those in society who are trained to consider without bias the wider issues. We wish again to emphasise the importance of putting the patient and family at the centre of thinking, sublimating personal ambition or greed to that greater good.

Intuition: Personal and Corporate

Decision is a day-to-day, hour-to-hour reality in practice. Decisions are taken at every step throughout the course of treatment, to the time of discharge or allocation to long-term or short-term nursing care. These decisions are often taken rapidly, and in the heat of battle. The doctor is

trained to gather relevant information, to interpret it, and to frame his or her duty accordingly. As time has passed, we have become able to access ever more information, and outcomes are much better understood. We have a responsibility to be aware of these results, and to make them available to whomsoever needs them, including families. The Internet has greatly contributed to this freedom.

Reflection, and an elementary self-awareness, teach that the strictly scientific element in reaching decisions is sometimes limited. Such scientific data, such as readings from scans, dials, graphs, biochemical values and the like, rarely dictate decision. Indeed, they may paralyse decision, for they may pull in different directions. Only a personal decision can resolve the conflict. Scientific logic might argue that, given one gap in a particular pattern of knowledge, experiment or research in one direction might fill it. If the research would require the violation of some vulnerable interest, however, it cannot be undertaken. And, of course, in an individual patient, there would not be time. Scientific logic cannot have the last word.

Decisions, therefore, though grounded as they are in medical science, contain an important intuitive element. The acquisition and sharpening of a disciplined intuition are part of a thorough medical and social training. Medical intuition is essential to the humane practice of medicine. When autonomous, however, it can be a menace.

There is, therefore, another ethical demand. It is for what might be called a corporate intuition, a community of minds working together by which personal intuitions and subjective judgements may be checked, validated, or countermanded. Paediatric cardiology requires work in a multi-disciplinary team, within which consultation and discussion precede decision-making. The development of a corporate conscience, a facility in moral reasoning together, is a necessary condition if decisions are to be made that, on the one hand, take the empirical data into account, and, on the other, amount to the best apparent choice possible from the available options, none of which may be ideal. Such common possession of wisdom is not acquired without discipline. The present organization of specialist hospital medicine should, in theory, favour it. The balance between experienced, senior team members, and new, often transient, staff provides a good basis for new ideas to be tested against experience and policy. Between them there is an interchange not only in terms of science and technical education, but also in values, generating the necessary tensions that constrain and encourage the transmission of ethics from generation to generation.

Medical ethics is first a corporate possession, that of a profession. It is embodied personally as each member makes it his or her own. Codes like the Helsinki Declaration governing medical research are markers of minimum demand and social expectation. The living practice of the ethics, and its necessary development, is ideally an activity of the functional team. The individual works best as a moral agent in small, tangible societies. The Latin root of that word is *societas*, for which the old English translation is fellowship, as old, incidentally, as the translation of mores, or morals, as manners. Models of collegiate fellowship exist within the common experience, in which knowledge is valued, pursued, ordered, and transmitted. Standards, intellectual and professional, are set, acquired and maintained. Members are disciplined. Persons are fulfilled. Ethics is an

activity proper to humans as rational and social beings. It is vital for staff involved in the care of patients with congenitally malformed hearts.

ANNOTATED REFERENCES

- Pantell CL, Lewis CC: Talking with children: How to improve the process and outcome of medical care. *Medical Encounter* 1993;10: 3–7.

This paper outlines with great clarity the issues which one needs to take into account when talking to children and their families. Like many good reviews on this subject, it emphasises the need to listen and to respect.

- Royal College of Paediatricians and Child Health: Withholding or Withdrawing Life Saving Treatment in Children: A Framework for Practice. London, 1997.

Reports from working parties can be dry and of little help. This one is different. The group has addressed many of the practical and ethical problems we face as front-line cardiologists and surgeons, and their advice is of great importance. As presented, they reflect the law of the United Kingdom, and provide indications of what must be considered when terminal care is required.

- Maguire P, Pitceathly C: Key communication skills and how to acquire them. *BMJ* 2002;325:697–700.

This paper presents an excellent summary and checklist for all of us needing to communicate with patients and relatives. It is straightforward and well written.

- Mallardi V: The origin of informed consent. *Acta Otorhinolaryngol Ital* 2005;25:312–327.

An interesting diversion into the history of consent, providing a context for current ethical thinking. There is little new in history, but plenty of advice!

- Mercurio MR, Peterec SM, Weeks B: Hypoplastic left heart syndrome, extreme prematurity, comfort care only, and the principle of justice. *Pediatrics* 2008;122:186–189.

This important paper covers all aspects of decision-making when comfort care is being considered. The principles of justice, applied to all participants, are clearly explained, and the subsequent balance which emerges is of great common sense.

- Vuilleumot L: The fate of baby Amy. *New York Times* 1988; 25 Sept.

Although rather dated in context, this article by a parent encompasses pretty well all that a parent might feel, and leaves the reader with a profound sense of respect, which can be carried into daily interactions with families.

The Central Nervous System in Children and Young Adults with Congenital Cardiac Disease

AMANDA J. SHILLINGFORD and GIL WERNOVSKY

Prior to the early 1980s, it was uncommon for children with complex congenitally malformed hearts to survive into later childhood. The nearly simultaneous advances in congenital cardiac surgery, echocardiography, and intensive care were coupled with the availability of prostaglandins and the developing discipline of interventional cardiology. Together, these factors resulted in a dramatic fall in surgical mortality, with complex repairs taking place at increasingly younger ages. At many large centers, palliative surgery followed by later repair was replaced by primary repair in infancy, while staged reconstructive surgery for various forms of functionally univentricular heart, including those with hypoplastic left heart syndrome, was improving with steadily falling rates of surgical mortality.¹⁻⁴ As a result, the early part of the 21st century has seen an increasing number of children entering primary and secondary schooling. Research into their academic and behavioural outcomes has revealed some sobering realisations about the outcomes in these survivors of paediatric cardiac surgery.

For the purposes of this chapter, complex congenital cardiac disease will refer to morphological abnormalities significant enough to require surgical or catheter intervention as neonates or young infants. As a group, patients with such malformations have a significantly higher incidence of academic difficulties, behavioural abnormalities, fine and gross motor delays, problems with visual motor integration and executive planning, speech delays, inattention, and hyperactivity.⁵⁻¹⁷ Abnormalities of the central nervous system in infants with congenital cardiac disease is characterised by abnormalities of tone, difficulties with feeding, delays in major motor milestones, and speech deficits.^{5,8,18,19} In children with congenital cardiac disease, the need for special services in school is significantly increased compared to the general population.^{6,11,13,20} As children progress through school, low scores in terms of academic achievement, learning disabilities, behavioural problems, difficulties with social cognition and attention deficit/hyperactivity disorder may result in academic failure, development of poor skills in both the classroom and socially, low self-esteem, behavioural disinhibition, and ultimate delinquency.²¹⁻²³ Recent reports have also shown that quality of life is affected in children with complex malformations.²⁴

Dependent upon a number of factors, including the underlying congenital lesion and the associated surgical management, genetic contributions, additional perinatal events such as profound hypoxia-ischaemia from a delayed diagnosis,²⁵ or post-operative events such as low cardiac output syndrome,²⁶ the incidence of abnormalities may range

from infrequent to ubiquitous. For example, in studies of children with transposition, a small fraction may have severe developmental impairment, perhaps one-half are normal in all respects, and nearly one-half will have a combination of speech, motor, behaviour or learning issues.^{6,27} Compared to children with transposition, the proportion of children with other forms of complex disease, such as obstructed totally anomalous pulmonary venous connection, hypoplastic left heart syndrome, or interruption of the aortic arch who are developmentally normal is significantly decreased, with perhaps only one-third of those tested having no dysfunction in any domain.^{11,12} While most of these abnormalities are relatively mild, and may only be determined by formal testing, they result in a so-called high-prevalence, low-severity developmental signature. A schematic representation is shown in [Figure 64-1](#).

Importantly, the combined outcomes of developmental delay, academic difficulties, and behavioural abnormalities represent the single most common morbidity affecting the quality of life in surviving patients with congenital cardiac disease when they reach school age. This complication is more common than late mortality, severe exercise impairment, unplanned reoperations, bacterial endocarditis, or significant arrhythmias. The later implications of these findings through adulthood are uncertain, and must continue to be a robust area of research. Our current understanding of the aetiology of these findings is discussed below.

SCOPE OF THE PROBLEM IN ADULTS WITH CONGENITAL CARDIAC DISEASE

Surprisingly, although the current number of adults with congenital cardiac disease is at least as many as the number of children with congenital cardiac disease, there is a paucity of studies investigating outcomes relating to the central nervous system, particularly with regard to behaviour and cognition. In contrast, there is an increasing number of investigations evaluating employment, physical activity, insurability, and quality of life in these adults, which complement nicely the recent data on younger children. The results of these studies in adults are mixed. Some suggest over-achievement in life-related activities, employment, and quality of life, while others describe deficits in social functioning, lifetime earnings, and health-related quality of life.²⁸⁻³² These mixed results are most likely due to the heterogeneous nature of congenital cardiac malformations, as well as the multiple non-cardiac reasons for suboptimal outcomes. As patients are further removed from surgery, it

Figure 64-1 Schematic representation of developmental abnormalities in children with congenital cardiac disease. Children with milder forms of congenital cardiac disease, for example, ventricular septal defect without an associated genetic syndrome, as a group, have a low incidence of developmental abnormalities, and more than mild abnormalities are rare. Increasingly complex forms of congenital cardiac disease, for example transposition or totally anomalous pulmonary venous return, are associated with increasing numbers of children with developmental deficits, and only the minority of children with extremely complex heart disease, for example, functionally univentricular heart, are completely normal in all respects. Those having congenital cardiac disease associated with chromosomal abnormalities, for example Down and Di-George syndromes, or multiple congenital anomalies, are nearly always associated with developmental abnormalities, in many cases, severe. (From Wernovsky G: Current insights regarding neurological and developmental abnormalities in children and young adults with complex congenital cardiac disease. *Cardiol Young* 2006;16[Suppl 1]:92–104.)

is likely that the social and environmental milieu are more responsible for shaping long-term outcomes, compared to the underlying structure of the brain, or the effects of hypoxaemia, low cardiac output, and cardiac surgery.

At this point, it must be emphasised that it is ill-advised to suggest that the current findings in adults are applicable to current children, or will be predictive of later dysfunction in the next generation of patients with congenital cardiac disease. The diagnostic capabilities, surgical techniques, and importantly, interventional philosophy were quite different when current adults with congenital cardiac disease were children. For example, a child born in the 1960s or 1970s with tetralogy of Fallot would most likely have been managed with one or more systemic-to-pulmonary arterial shunts prior to a complete repair in later childhood. The outcomes 30 years on in these patients are likely to be different than those for a child born in the current era who undergoes a single-stage correction in early infancy.

We believe, nonetheless, that the recent reports of adverse outcomes in children currently of school age, such as behavioural and academic difficulties, deficits in motor function, social cognition and social interactions, set the stage for functional difficulties seen later in adult life. One model that has been proposed for analysis of outcomes in patients with cancer is that the ultimate outcome of interest results from a combination of environmental influences in the susceptible host. In patients with congenital cardiac disease, environmental influences include, but are not limited to, the effects of cardiac surgery in general and cardiopulmonary bypass in particular, hypoxaemia, low cardiac output, hospital complications, social class, psychosocial interactions, and the implications of chronic disease on the family unit. Host, or patient-related, factors similarly include, but are not limited to, birth weight, the physiology caused by the underlying cardiac malformation, genetic abnormalities including recognised syndromes and allele

polymorphisms, and additional congenital anomalies, especially in the brain, which affect long-term outcomes.

CONGENITAL CEREBRAL DISEASE

Given that the central nervous and cardiovascular systems form nearly simultaneously in early gestation, it is not surprising that there is an increased incidence of structural abnormalities of the brain in children with co-existing structural abnormalities of the heart. Many children with multiple congenital anomalies or chromosomal abnormalities, many of whom have co-existing congenital cardiac disease, will have developmental delay and behavioural issues as a significant component of late morbidity. In addition to genetic factors which may affect both systems from a macroscopic perspective, congenital cardiac disease may alter cerebral blood flow, delivery of oxygen, or both, and result in secondary effects of the vulnerable fetal central nervous system.

The brain of the full-term neonate with congenital cardiac disease structurally resembles that of a preterm neonate,³² and interestingly, survivors of complex cardiac surgery, when they reach school age, have developmental findings which are very similar to survivors of premature birth, suggesting a similar pathological response to injury. Serial studies of the fetal brain, using ultrasound and magnetic resonance imaging, are currently underway, and are increasing our understanding of the interactions between the abnormal fetal cardiovascular system and cerebral development.

Microcephaly

The circumference of the head at birth is a surrogate for growth of the brain, and in neonates without congenital cardiac disease, microcephaly is independently associated with later developmental delays and academic difficulties.

Multiple studies have shown the incidence of microcephaly at birth is increased in children with congenital cardiac disease, approaching one-fourth of children in some reports,^{33–36} and persists into later infancy.^{37,38} In a group of 318 neonates with various forms of congenital cardiac disease evaluated at our institution between 1992 and 1997, the incidence of congenital microcephaly, defined as a circumference of the head at or below the second percentile, was nearly 1 in 10.³⁴ More complex lesions have a higher incidence. In a series of consecutive neonatal autopsies at The Children's Hospital of Philadelphia, approximately one-third of infants with hypoplastic left heart syndrome were noted to have congenital anomalies of the central nervous system and/or were microcephalic.³⁹ While the causes are speculative, and most certainly multifactorial, a recent report in children with hypoplastic left heart syndrome, where the median circumference of the head at birth is only at the 18th percentile of that reported for normal neonates, revealed that patients with microcephaly had significantly smaller ascending aortas than those without, suggesting that reduced flow to the brain from the left ventricle secondary to anatomical hypoplasia of the ascending aorta may result in diminished brain growth.³³

The Open Operculum

The opercular region is that covering the so-called insulae Relie, and is made up of frontal, temporal, and parietal cortical convolutions. In magnetic resonance and computed tomographic imaging studies of neonates with complex congenital cardiac disease, underdevelopment of the operculum may be seen in nearly one-quarter of the patients, and is a marker for functional immaturity of the brain.^{35,40} This may be a unilateral or bilateral finding, and has been termed underoperculinisation, or an open operculum (Fig. 64-2). The operculum is thought to be related to oral motor coordination, taste, and speech, particularly to expressive language. In adults who develop a stroke in this area of the brain, the so-called Foix-Chavany-Marie syndrome, deficits include impairment of voluntary movements such as chewing and deglutition, dysarthria, and problems with taste.⁴¹ In macaque monkeys, receptive fields on the tongue, lips

and palate have been mapped to the operculum.⁴² Given the high prevalence of problems with feeding,³⁶ delay with expressive language, and oral-motor apraxia in children with complex cardiac malformations,^{5,12,27} as well as the increasing recognition of a high prevalence of an open operculum, we speculate that some patients with these developmental disabilities may have a structural underdevelopment of the operculum. We are currently pursuing this hypothesis.

Periventricular Leucomalacia

Injury to the white matter, a common finding in premature infants, has been increasingly recognised in full-term neonates with congenitally malformed hearts.⁴⁰ It has also been suggested that decreased flow to the brain pre-operatively was significantly associated with lesions in the white matter, affecting slightly over one-quarter of neonates before surgery.³⁵ Periventricular leukomalacia was also found in slightly over half of a cohort of patients who underwent surgery for congenital cardiac disease as neonates, but was rarely detected in those who underwent surgery between 1 and 6 months of age.⁴³

All of these studies were carried out using populations of children who underwent cardiac surgery with deep hypothermic circulatory arrest. Because of concerns that the use of this technique during cardiac surgery is directly related to cerebral injury, many centres have adopted regional perfusion of the brain using low flow as an alternate strategy which decreases the period of cerebral ischaemia during cardiac surgery. Studies using magnetic resonance imaging of patients corrected with this technique⁴⁴ showed evidence of ischaemic lesions in one-quarter of the cohort prior to cardiac surgery, and in almost three-quarters after surgery. The majority of the ischaemic injury seen after surgery was in the form of periventricular leucomalacia, a proportion that is similar to those patients undergoing deep hypothermic circulatory arrest.⁴⁵ In another study,⁴⁶ injury to the white matter and/or stroke were identified in 22 infants pre-operatively, while another one-third of the survivors developed new evidence of brain injury on post-operative imaging. More sophisticated magnetic resonance imaging³² has shown not only a high incidence of injury to the white

Figure 64-2 The normal external appearance of the brain (A) is compared with underdevelopment of the operculum (B). (From Wernovsky G: Current insights regarding neurological and developmental abnormalities in children and young adults with complex congenital cardiac disease. *Cardiol Young* 2006;16[Suppl 1]:92–104.)

matter, but also evidence of immature brain metabolism and microstructure, which are strikingly similar to findings seen in the premature population.

Periventricular leucomalacia is believed to arise from several factors, including the high susceptibility of the immature oligodendrocyte to hypoxic ischaemic injury, as well as the watershed distribution of flow of blood to this area between the small arteries that penetrate from the cortex and those that arise centrally and run radially outward. This watershed area is particularly prone to ischaemia during decreases in cerebral perfusion pressure. In premature infants, severe degrees of periventricular leucomalacia have been associated with cerebral palsy, while mild degrees of injury have been associated with developmental delay,⁴⁷ motor difficulties, and behavioural disorders,⁴⁸ a developmental signature remarkably similar to school-age children with congenital cardiac disease.

Additional Anatomical Findings at Birth

Congenital anatomical anomalies of the central nervous system are known to be coincident with malformations of the heart.^{39,49–51} Cerebral abnormalities have been noted in one-quarter of a cohort of infants, with nearly half, such as holoprosencephaly and agenesis of the corpus callosum, present prior to any surgery.⁵²

Fetal Cerebrovascular Physiology and Delivery of Oxygen

Ultrasound studies in the fetus have revealed that cerebral vascular resistance is altered in the presence of congenital cardiac disease. Fetuses with left-sided disease, for example, hypoplastic left heart syndrome, were shown to have decreased cerebral vascular resistance compared to normal.^{53,54} In patients with aortic atresia, the fetal cardiac output from the arterial duct must deliver flow cephalad to the brain as well as caudad to the low resistance placenta. It is speculated that cerebral vascular resistance must therefore be lower than normal to allow adequate blood flow to the developing brain. Fetuses with right-sided obstructive lesions, for example, tetralogy of Fallot, were also shown to have increased fetal cerebral vascular resistance.⁵³ In these children, it is speculated that the obstruction to flow into the pulmonary arteries changes the usual delivery from the patent arterial duct caudad to the placenta. In these cases, the left ventricle must contribute to placental blood flow antegrade from the ascending aorta, with a resultant increase in cerebral vascular resistance. The impact of these alterations in fetal cerebral vascular resistance is unclear, but almost certainly plays a role in subsequent neurological development.

In the normal fetus, the intracirculatory patterns created by the normal fetal connections result in preferential streaming of the most highly oxygenated fetal blood to the developing brain, and most desaturated blood to the placenta. When significant structural disease exists within the heart, these beneficial patterns are likely to be altered. Although not yet confirmed by fetal magnetic resonance spectroscopy, fetuses with transposition are likely to have the blood with the lowest saturation of oxygen returning to the ascending aorta and brain, while blood with the highest saturation will return to the abdominal organs and

placenta. Speculation on the consequences of the transposed fetal circulation as an explanation for the high incidence of macrosomia in these infants dates back 40 years,⁵⁵ and has also been offered as an explanation for the increased incidence of relative microcephaly seen in transposition.⁵⁶ Complete mixing, as seen in those with functionally univentricular hearts, will produce intermediate values of fetal cerebral saturations of oxygen, but lower than those seen in the normal fetus (Fig. 64-3).

PERI-OPERATIVE CONTRIBUTORS

Pre-operative Factors

Neonates with complex congenital cardiac disease frequently require hospitalisation immediately after birth, many to receive intravenous infusions of prostaglandin, some requiring intubation, mechanical ventilation, or invasive interventions such as balloon atrial septostomy. All of these interventions carry risks to the central nervous system, especially the potential for paradoxical embolus to the brain of air or particulate matter in children with intracardiac right-to-left shunts. These patients also have saturations of oxygen that are below normal, potentially compromising cerebral delivery of oxygen. In addition to diminished content of oxygen, neonates with critical congenital cardiac disease also have diminished flow of blood to the brain.³⁵ Such a finding of reduced flow to the brain, and abnormal vascular reactivity, has recently been confirmed in a neonatal piglet model of functionally univentricular physiology.⁵⁷

Intra-operative Factors

The conduct of cardiopulmonary bypass, and other support techniques used during open heart surgery, has received considerable attention, and has been the subject of active research. As opposed to all of the risk factors for abnormal neurological development discussed thus far, variation in intra-operative support, such as the conduct of cardiopulmonary bypass, is one of the few modifiable risk factors which may be altered to improve long-term neurological outcomes. Potential modifiable technical features of cardiopulmonary bypass are shown in Table 64-1, and we pay particular attention to three of these.

pH Management

In one very important trial at Children's Hospital, Boston, developmental and neurological outcomes were evaluated in infants undergoing repair of a variety of cardiac defects at less than nine months of age who were randomised to either alpha-stat or pH-stat management during deep hypothermic cardiopulmonary bypass. Eligibility was limited to children undergoing various forms of biventricular repair in the first 9 months of life. Although there were some benefits reported with the use of pH-stat management for outcomes in the immediate peri-operative period,⁵⁸ the use of either strategy was not consistently related to either improved or impaired neurodevelopmental outcomes at one to four years of age.⁵⁹ On the Bayley Scales of Infant Development, there was no effect of treatment on the Psychomotor Development Index. The Mental Developmental Index, in contrast, varied significantly depending on the underlying anatomical diagnosis. For patients with transposition and tetralogy of Fallot, use of pH-stat resulted in a slightly higher mental developmental index, although the

Figure 64-3 The fetal circulation is compared between the normal heart (A), transposition (B), and hypoplastic left heart (C). Colours represent differing levels of oxygenation, with the highest oxygen content, from the umbilical vein, in red, and the lowest oxygen content, from the superior and inferior caval veins, in blue. In the normal heart, the blood with the highest oxygen content is preferentially directed to the fetal brain, while blood with the lowest oxygen content is directed to the placenta. The benefits of this preferential streaming are altered in the face of many congenital heart lesions. In transposition, blood with the lowest content is redirected back to the fetal brain. In hypoplastic left heart syndrome, complete mixing of oxygenated and deoxygenated blood takes place in the fetal atrium. See text for details. (Courtesy of PA-C Eliot May. Reproduced and modified with permission from Johnson BA, Ades A: Delivery room and early postnatal management of neonates who have prenatally diagnosed congenital heart disease. Clin Perinatol 2005;32:921–946, ix.)

difference was not statistically significant. In patients with a ventricular septal defect, the effect was opposite, with use of alpha-stat management resulting in significantly improved scores. There was a significant effect of cardiac diagnosis on outcomes. Both scores of the Bayley examinations were significantly higher in those with transposition compared to the other cardiac defects. Despite the equivocal data in this early report, with no longer-term follow-up yet available, many centers are currently utilising pH-stat management exclusively in all operations on neonates and infants.^{60–62}

Further research in this area, based upon additional potential modifiers, for example, cardiac diagnosis, age, pre-operative hypoxaemia, or presence of major systemic-to-pulmonary collateral arteries, should continue.

Deep Hypothermic Circulatory Arrest

Much has been written on the potentially deleterious effects of prolonged circulatory arrest with profound hypothermia in cardiac surgery for neonates and infants. It is generally agreed that very prolonged periods of uninterrupted circulatory arrest may have adverse neurological outcomes.

TABLE 64-1

POTENTIALLY MODIFIABLE INTRAOPERATIVE RISK FACTORS OF CEREBRAL INJURY

Air or particulate embolus
Rate and depth of core cooling (if utilized)
Deep hypothermic circulatory arrest (if utilized)
pH management during cardiopulmonary bypass
Hematocrit management during cardiopulmonary bypass
Reperfusion injury and inflammation
Rate of core rewarming/hyperthermia
Postoperative delivery of oxygen
Hypoglycaemia
Hyperoxia/hypoxaemia

Close inspection of the data shows that the effects of short durations of circulatory arrest are inconsistently related to adverse outcomes, and that the effect of circulatory arrest is not a linear phenomenon.^{63,64} The effects are most likely modified by other pre-operative and post-operative factors related to the patient. Some reports, most in an earlier era of cardiac surgery demonstrate a detrimental effect of circulatory arrest on a variety of outcomes relating to the central nervous system,^{7,9,65–68} while some demonstrate either an inconsistent effect or no effect.^{12,37,69,70} Some have taken the stance that, since the majority of studies suggest a negative effect of circulatory arrest, it should be avoided at all costs. Innovative and challenging strategies have been designed to provide continuous cerebral perfusion during reconstruction of the aortic arch or intracardiac repair. The avoidance of circulatory arrest, however, by necessity requires an increased duration of cardiopulmonary bypass.⁷¹ This has consistently been shown to have an adverse effect on outcomes in both the short and longer term.^{72,73} A randomised trial comparing circulatory arrest to continuous cerebral perfusion has recently been completed at the University of Michigan.⁷⁴ This demonstrated no improvement in developmental scores at one year of age. Similar findings were reported in a contemporaneous but non-randomised study at Children's Hospital of Boston.⁷⁵

It seems imprudent to change practice based upon studies with only short-term developmental assessment. Developmental studies in infants have very limited predictive validity for long-term outcomes, either for patients with^{6,76} or without⁷⁷ congenital cardiac disease. Perhaps the best conducted study in this regard, which emphasises this point, is the Boston Circulatory Arrest Study.^{5,6,63,76,78–81} In this study, a cohort of children with transposition undergoing an arterial switch were randomly assigned to intra-operative support predominantly by deep hypothermic circulatory arrest or predominantly by cardiopulmonary bypass at low flow. Earlier reports suggested that the group as a whole was performing below expectations in many aspects of evaluation, with worse outcomes for the those undergoing circulatory arrest in the areas of post-operative seizures,⁸⁰ motor skills at 1 year of age,⁷⁹ as well as behaviour, speech, and language at the age of 4 years.⁵ Mean intelligence quotient at the age of 4 was lower than expected at 93, with no difference according to assignment. Many centers began avoiding even short periods of circulatory arrest based upon these and other reports.

In 2003, assessments of quality of life,⁸² and detailed standardised testing⁶ were reported. Neurodevelopmental analyses when the patients were aged 8 years revealed that the intelligence quotients for the cohort as a whole are now closer to normal, at 98 versus the population mean of 100. The patients did demonstrate significant deficits in visual-spatial and visual-memory skills, as well as in components of executive functioning such as working memory, hypothesis generation, sustained attention, and higher-order language skills. In other words, the children had difficulty coordinating skills in order to perform complex operations. Those repaired using circulatory arrest scored worse on motor and speech functioning, while those undergoing bypass at low flow demonstrated worse scores for impulsivity and behaviour. When compared to a normative sample, parents of the entire cohort reported significantly higher frequencies of attention problems, developmental delay, and problems with learning and speech. More than one-third of the population required remedial services at school, and one in ten had repeated a grade. Thus, in this population of patients who underwent the arterial switch operation between 1988 and 1992, there appears to be a correlation between congenital cardiac disease and its surgical repair, with difficulties occurring later with speech and language, behavioural difficulties, and execution planning in childhood.^{6,16,63,82} Whether current modifications of techniques will improve the outcomes in the long term remains the subject of ongoing study.

This well-designed trial, with superb follow-up, enrolled neonates who were planned to undergo an arterial switch operation between 1988 and 1992. Hence, the results reflect the peri-operative and surgical care delivered in that era, and thus may not be generalisable to the current era, or to other congenital cardiac lesions. For example, some features of routine post-operative care, including extension of the anaesthetic period for at least 48 hours,⁸³ active rewarming in the intensive care unit after surgery, and hyperventilation to reduce the risk of pulmonary hypertension, may each independently and adversely affect neurodevelopmental outcomes. In addition, those patients randomised to predominantly continuous bypass did undergo a brief period of circulatory arrest. Thus, the study does not compare use of circulatory arrest to no circulatory arrest. The results, nonetheless, serve to show the multiple factors which influence developmental outcome at school age, and show that factors related to poorer outcome, such as deep hypothermic circulatory arrest, which seem apparent and significant on early testing, may be attenuated or even abolished during longer-term follow-up, as other factors assume a more important role.

Haematocrit During Bypass

During cardiopulmonary bypass, haemodilution has been widely applied based upon the notion that increased viscosity would be detrimental during periods of profound or even moderate hypothermia. Work in animals suggesting that higher levels for the haematocrit confirmed better cerebral protection⁸⁴ was recently investigated in two randomised clinical trials.⁸⁵ The results of these trials indicated that levels for the haematocrit up to 24% were associated with increasing scores in the psychomotor development index, although the improvement was not linear at levels greater than 24%. In addition, lower levels were associated with higher fluid balance and higher levels of lactate in the serum.^{61,85,86}

Post-operative Factors

It has long been recognised that systemic flow is reduced in the first 24 to 48 hours following cardiac surgery, typically reaching a nadir in the first post-operative night.^{73,87,88} At this time, the central nervous system may be especially vulnerable to secondary insults of decreased delivery of oxygen, particularly after circulatory arrest. To minimise the potential effects of low cardiac output following intra-operative ischaemia and reperfusion, the routine use of extracorporeal membrane oxygenation has been proposed for neonates at particularly high risk, such as those with hypoplastic left heart syndrome.⁸⁹ Post-operative mechanical support, however, has the potential to produce multiple deleterious effects, and the relative risks and benefits of this approach, as well as short- and long-term outcomes, are currently under investigation by those who performed the initial study.⁸⁹ Currently, close attention to cardiac output, and delivery and consumption of oxygen, seems warranted from the stance of the central nervous system, albeit that techniques for quantitative assessment of these parameters at the bedside is limited, particularly if there are residual intracardiac shunts.

Following cardiopulmonary bypass, with or without circulatory arrest, autoregulation of cerebral flow may be impaired, making the neonate and infant particularly vulnerable to periods of low cardiac output and/or hypoxaemia.⁹⁰ Although many studies in laboratory animals demonstrated various factors that adversely affect cerebral flow following cardiopulmonary bypass, it has previously been difficult to reproduce these studies in post-operative neonates and infants. Recently, transcranial Doppler and cerebral near-infrared spectroscopy techniques have been used to study cerebral flow in the cardiac intensive care unit following biventricular repair.⁹¹ Approximately one in six of the patients studied demonstrated abnormalities of cerebrovascular pressure autoregulation, with risk factors including hypercapnia and higher mean arterial pressure during the time of the measurements. To date, the potentially deleterious effects of significant hypocapnia, which decreases total flow to the brain, and hypotension, the latter for ethical reasons, have not been studied in post-operative neonates. Further research is needed to determine the combined effects of cardiac output, mechanical ventilation, and cerebral flow, especially in the immediate post-operative period.

There have been recent reports following cardiac surgery in adults, as well in critically ill children with non-cardiac disease, suggesting that hyperglycemia is associated with adverse outcomes. These reports had stimulated some centers to develop protocols to control glycaemia, including continuous infusions of insulin, following congenital cardiac surgery in neonates and infants. However, recent reports have shown that hyperglycaemia is not a risk factor for adverse neurological or non-neurological outcomes in children after cardiac surgery.^{92,93} In fact, hypoglycaemia may be more detrimental to the neonatal myocardium and brain. Thus, the treatment may be worse than the disease. This emphasises the point that extrapolation of research and management from patients without congenital cardiac disease to the neonatal and infant population following cardiac surgery should be undertaken with great care, skepticism, and after well-designed specific research.

Seizures have been reported to occur in the immediate post-operative period in up to one-fifth of neonates, depending upon the method used for detection. Clinical seizures are significantly less prevalent than those detected on continuous electroencephalographic monitoring.^{78,94} The aetiology is most likely multi-factorial, but likely to be more prevalent in younger patients, those with prolonged periods of circulatory arrest, or those with co-existing abnormalities of the central nervous system. Peri-operative seizures are a marker for early injury, and have previously been reported to be associated with worse scores on developmental testing in children with transposition studied in the Boston Circulatory Arrest Trial,^{5,79} although more recent data may show less of an impact than previously identified.⁹⁵

In addition to the identified factors above, the immediate post-operative period typically requires invasive monitoring, mechanical ventilation and significant medical support, especially in the neonate and young infant.⁴ While these therapies have resulted in significant improvements in mortality,⁹⁶ they increase the risk factors which may adversely affect the central nervous system, including paradoxical embolus of air or particulate matter from peripheral or central intravenous access, fever, hypoglycaemia and swings in cerebral flow brought on by acute changes in mechanical ventilation. As was previously reported in a group of children who underwent the Fontan procedure,⁹ longer stay in hospital and in the intensive care unit in the neonatal period was associated with worse developmental outcomes at the age of 8 years.⁸¹ These effects were significant, even when controlling for other factors known to adversely affect long-term outcome, such as seizures, intra-operative support duration, reoperations and other post-operative events. Children with transposition whose length of stay was in the fourth quartile had mean intelligence quotients 7.6 points lower than those in the first quartile. Further investigation into the multiple potential mechanisms of injury to the central nervous system in the intensive care environment must continue.

There has been increasing interest in monitoring of the central nervous system in the intensive care unit, with interventions aimed at improving short-term cardiac outcomes, as well as longer-term neurodevelopmental outcomes.^{96,97} In particular, the increasing use of cerebral near infrared spectroscopy holds great promise in this regard.^{98,99} The benefits and risks of near-infrared spectroscopy, as well as the longer-term predictive validity of lower scores has not yet been studied in detail. Nonetheless, this technology is currently in use in a large number of centres caring for neonates and infants with critical congenital cardiac disease.¹⁰⁰

Continuous recording of the electroencephalogram, either with multiple channels or in an integrated fashion, also holds promise for peri-operative monitoring of the central nervous system. Abnormalities of the background electroencephalogram have been shown to be significantly related to other morbidities in the cardiac intensive care unit, such as the duration of mechanical ventilation, a longer length of stay in the hospital, and the need for supplemental tube feedings at hospital discharge.¹⁰¹ These surrogate markers of injury are likely to be predictive of later neurological and developmental abnormalities.

Following discharge from hospital, some neonates remain at risk for ongoing injury to the central nervous system. Chronic hypoxaemia, as a result of ongoing palliation

and/or residual intracardiac right-to-left shunting, may result in neurodevelopmental impairment. In children with transposition, older age at repair, as a surrogate for duration of hypoxaemia, has been associated with worse outcomes during follow-up.¹⁰² Studies, many from a much earlier era of cardiac surgery when delayed repair was common, consistently show lower scores in children with cyanotic as opposed to acyanotic lesions.^{103–113} Simple comparisons of defects with and without associated hypoxaemia, however, are confounded by the multiple factors present in children with cyanotic disease, including earlier age at repair and exposure to bypass, more complex surgical procedures, abnormal fetal patterns of flow, and many of the factors mentioned in this review. In children with structurally normal hearts and hypoxaemia from other causes, such as chronic lung disease, sleep disordered breathing, or high altitude, chronic or intermittent hypoxaemia has been associated with adverse effects on development, behaviour, and academic achievement.¹¹⁴ The presence of hypoxaemia undoubtedly plays some role in patients with congenital cardiac disease, but is most likely modified by other factors, as it is difficult to measure the effect of hypoxaemia in isolation. The most recent studies comparing neurodevelopmental outcomes following repair of tetralogy of Fallot with those following isolated ventricular septal defect, support the potential impact of chronic hypoxaemia in these children.^{27,115–117}

GENETIC AND ENVIRONMENTAL FACTORS

Socioeconomic state is perhaps the strongest predictor of eventual neurodevelopmental outcome, and is a reflection of both the environment and the genetic factors for development inherited from the parents. Multiple studies have shown the relationship between socioeconomic state and/or parental intelligence and outcome in children with congenital cardiac disease.^{6,7,9,117,118} In adolescents and young adults who have undergone the Fontan procedure, socioeconomic state accounted for one-sixth of the variability in scores for intelligence quotient, whereas the percent variability explained by circulatory arrest and all other surgical variables accounted for only just over one-twentieth.¹¹⁹ Curiously, this effect was not seen in a small cohort of teenagers with hypoplastic left heart syndrome.⁶⁹

Children with identified genetic syndromes with known chromosomal abnormalities, such as Down, Williams, and DiGeorge syndromes and trisomy 13 and 18, as well as multiple associations of congenital anomalies, such as the CHARGE and VACTERL associations, frequently have co-existing congenital cardiac disease. In total perhaps one-third of all children with complex congenital cardiac disease have additional abnormalities besides their cardiac disease. Subchromosomal genetic abnormalities are being discovered with increasing frequency in this population, and most studies report worse outcome in children with associated congenital anomalies compared to children with the same lesion without additional anomalies.

Trisomy 21 is universally associated with mental retardation and other neurological impairments,^{120,121} and is associated with a variety of cardiac defects, some associated with hypoxaemia, and many which require cardiopulmonary bypass for repair. Microdeletion of the 22nd chromosome has been shown to result in the phenotype of DiGeorge or velo-cardio-facial syndrome, with many of these children

having abnormalities of the ventricular outflow tracts, such as tetralogy of Fallot, interruption of the aortic arch, and common arterial trunk, isolated ventricular septal defects, or abnormalities of branching of the aortic arch.¹²² While some of the developmental delay and behavioural problems seen in these patients may be related to the underlying congenital cardiac disease and/or its treatment, as discussed above, and some of the speech delay may be related to the associated palatal abnormalities, recent reports suggest that there is an increased incidence of abnormalities in the white matter,¹²³ as well as a predisposition to psychiatric abnormalities.^{124,125} Studies are currently underway to determine the relationship of these findings to the haploinsufficiency of genes on chromosome 22q11.¹²⁶

Apolipoprotein E is also known to be important in the regulation of cholesterol metabolism, and is thought to effect neurological recovery following a variety of injuries to the central nervous system. Genetic polymorphisms of apolipoprotein E are related to abnormal neurological development, with a significantly smaller head circumference found in children aged 1 year who underwent open heart surgery as neonates or young infants.¹²⁷ The effect of the genotype was independent of ethnicity, socioeconomic state, cardiac defect, and the use of deep hypothermic circulatory arrest.

CURRENT OUTCOMES IN CHILDREN AND YOUNG ADULTS FOLLOWING REPAIR OF TETRALOGY OF FALLOT

Despite a nearly 60-year history of surgical intervention for tetralogy of Fallot, there are surprisingly few studies documenting neurodevelopmental outcome in this population. In addition, follow-up studies in such patients are confounded by the era in which surgery was conducted. For the contemporary population of adults, surgical management often entailed initial placement of a shunt as a source of supplemental pulmonary flow, followed by a more complete repair in later childhood. These patients, therefore, remained hypoxaemic for a longer duration of time. In the current era, most centers elect to perform a complete repair in infancy.

In spite of these limitations, patterns of deficiencies are emerging. Reports of patients in their third and fourth decades reveal that the mean scores for intelligence quotient are generally in the low normal range. This population, however, is facing challenges with respect to academic achievement and employment.^{128,129} Comprehensive neurodevelopmental testing in such patients revealed significant deficits in executive function, including problem solving and planning strategies. In addition, a relatively small number of subjects pursued higher education and most did not have employment commensurate with the level of education. Interestingly, there was a correlation between the occurrence of pre-operative cyanotic spells and low self esteem and problems with executive functioning in adults.¹²⁸ Follow-up testing of early school age children who underwent surgical repair in the 1990s similarly indicates that while scores for intelligence are lower compared to the general population, the mean for the group is still within the normal range. Problems with executive function, attention, memory, language, visual-spatial skills, and sensory motor skills, nonetheless, are prevalent.^{115,117,130}

Another important consideration when describing the neurodevelopmental and behavioural patterns in patients with tetralogy of Fallot is that approximately one-quarter

have an extracardiac abnormality, including a genetic syndrome or a chromosome abnormality, which is independently associated with neurological impairment.¹³¹ In particular, microdeletion of chromosome 22q11.2 is present in one-eighth of all patients with tetralogy of Fallot, and up to half of those patients who also have a right aortic arch.¹²² Microdeletion of chromosome 22q11, in the absence of congenital cardiac disease, is associated with lower intelligence, learning disabilities, attention deficit hyperactivity disorder, and schizophrenia.¹³² Accordingly, the association of genetic alterations in patients with tetralogy of Fallot adversely affects neurological outcomes.^{70,133}

CURRENT OUTCOMES IN CHILDREN WITH TRANSPOSITION

In addition to the well documented longitudinal findings in the Boston Circulatory Arrest cohort, a number of additional studies have demonstrated similar findings. These include cognitive outcomes in the normal range in the majority of survivors, with a relatively high prevalence of mild learning disabilities, speech and language delays, behavioural problems, and inattention/hyperactivity.^{118,134–138} The majority of a cohort undergoing an arterial switch as neonates between 1986 and 1992 described a good quality of life, and had not required a cardiac re-intervention.^{134,135} Similar to the findings from the Boston Circulatory Arrest Study, patients had normal scores on formal cognitive testing, but had significant deficiencies in the areas of language and speech, gross and fine motor coordination, as well as behavioural problems. A correlation was also found between peri-operative events, such as significant hypoxaemia or acidosis, prolonged cardiopulmonary bypass, or low cardiac output, and adverse neurodevelopmental and behavioural testing.^{118,135}

CURRENT OUTCOMES IN CHILDREN FOLLOWING THE FONTAN PROCEDURE

Children with a functionally univentricular heart manifest many, if not all, of the risk factors for adverse long-term neurological and developmental outcomes. Most have abnormal fetal cerebral physiology, as well as ductal-dependant circulation at birth, require intensive care, early cardiac surgery with cardiopulmonary bypass with or without circulatory arrest, have prolonged and multiple hospitalisations, and a prolonged period of hypoxaemia. Thromboembolic complications and stroke may occur at any stage of surgical reconstruction and during follow-up.^{139,140} Studies investigating the risk factors for adverse long-term outcomes in these patients are hampered by the interrelationship of most of the risk factors, and the frequent changes in surgical management. Studies of teenage children and young adults with the Fontan circulation have shown a higher than expected incidence of neurological problems. It is impossible to know if these outcomes represent sequels of management in the late 1980s and early 1990s, are inherent to the central nervous system of children with a functionally univentricular heart, or are a combination of these features. More recent studies have suggested better results,¹⁴¹ but the predictive validity of pre-school testing for the long-term is limited.⁷⁷

As reported in children with transposition, deficits in visual-motor integration were common in those with the Fontan circuit,⁶⁷ and as a group, patients with the Fontan circulation and hypoplastic left heart syndrome had low-normal intelligence and difficulties with adaptive behaviour.¹⁴² The largest series of children and young adults with a Fontan circulation to be studied to date underwent formal testing at Children's Hospital in Boston.⁹ The results in these patients reflect the management of the 1970s and 1980s, with an average age at conversion to the Fontan circuit of 7.3 years. Intermediate superior cavopulmonary connections were performed in only a minority of the patients, as were fenestrations of the baffle. Over the duration of the study, a number of different surgical modifications were undertaken, hospital mortality was high, and prolonged pleural effusions were common in the survivors.¹⁴³ Thus, the generalisability of these outcomes to current patients may be questioned, the more so since only five patients had been included with hypoplastic left heart syndrome. Given these limitations, the majority of these patients had intelligence quotients and scores for achievement in the normal range, although the group performed lower than expected compared to their peers in the normal population. Risk factors for adverse outcomes in cognitive function included lower socioeconomic state, anatomical diagnosis, and the prior use of circulatory arrest. The risk factors for worse performance on testing for achievement included lower socioeconomic state, diagnosis, and circulatory arrest, as well as a number of post-operative factors such as the need for an early reoperation, longer length of stay, and higher right atrial pressures on the first post-operative day. Duration of hypoxaemia, that is the age at conversion to the Fontan circuit, in contrast, was not associated with adverse outcomes. The cohort has now been expanded to include patients from a more recent era, specifically with more patients who had undergone an interim superior cavopulmonary connection, as well as more patients with hypoplastic left heart syndrome.⁷ These patients were considerably younger at the time of the Fontan procedure, and had scores slightly lower than the previously reported cohort. Longer total duration of circulatory arrest was significantly associated with lower scores. If one patient with a cumulative duration of 158 minutes was excluded from the analysis, however, the relationship was no longer significant. Interestingly, socioeconomic state was not associated with scores for intelligence. The conclusion reached was that the current approach to children with functionally univentricular hearts, with increasingly complex patients and a planned three-stage approach in most patients, has not significantly adversely affected outcomes compared to the historical cohort.

A contemporary cross sectional study has also been performed of patients who underwent a Fontan operation at The Children's Hospital of Philadelphia between 1992 and 1999.¹⁴⁴ Median age at follow-up was 8 years, and over half of the cohort included patients with hypoplastic left heart syndrome. A majority of children had required additional hospitalisations, and yet 9 out of 10 parents still rated the health of their child as excellent or good. Although standard testing for achievement was not performed in this cohort, two-thirds of parents rated school performance of the children as average or above average. Furthermore, there were no significant peri-operative predictors of poor school performance, including the diagnosis of hypoplastic left heart syndrome.

The increasing number of survivors among children with hypoplastic left heart syndrome undergoing staged reconstruction is one of the significant advances in paediatric cardiology and cardiac surgery in the past two decades. The oldest survivors from The Children's Hospital of Philadelphia have now been studied.⁶⁹ Mean scores on standardised testing were significantly lower than that in normative populations, two-thirds were thought to have attention deficit-hyperactivity, and one in five had clinically important scores for anxiety and depression. On multivariate analysis, it was the pre-operative state of the patient that most strongly predicted outcome, and intra-operative variables, such as duration of cardiopulmonary bypass or circulatory arrest, were not found to be associated with poorer scores. The authors argued that, with recent prenatal, intra-operative and post-operative advances, current results were likely to be better. This has now been confirmed by a recent study showing the average intelligence quotient to be 94 in the setting of hypoplastic left heart syndrome.¹⁴¹

It is of interest to examine the developmental abnormalities seen in groups of children with hypoplastic left heart syndrome, and compare them to the findings following infants undergoing transplantation for the same disease.^{145,146} The patterns of dysfunction are remarkably similar, despite the markedly different therapeutic strategies. This suggests that factors other than the surgical approach and intra-operative support, such as congenital

cerebral disease and abnormal fetal physiology, may play a more significant role in long-term outcome.

FUTURE DIRECTIONS

While advances in the medical and surgical fields have allowed the ability to mend children born with congenital cardiac disease, the increasing number of survivors has created a growing cohort of children with potential academic difficulties. The causes are clearly multi-factorial, additive, and incompletely understood. Much has been learned about cardiopulmonary bypass and the relatively short period of time these children spend in surgery. Much more work needs to be done to understand the modifiable risk factors in the peri-operative period, the influences of the timing of surgery, and whether or not improved monitoring of the central nervous system in the intensive care unit setting will improve neurological and developmental outcomes.

CONCLUSIONS

In Figure 64-4, we show some of the current understanding regarding the multiple factors which may adversely affect the central nervous system in children with complex congenital cardiac disease. There is a growing body of literature showing suboptimal outcomes in school age children, particularly with respect to attention, behaviour, higher order executive function, handwriting and school performance. Many of the

Figure 64-4 Currently identified factors that, in total, adversely affect long-term neurological and developmental outcomes in children with complex congenital cardiac disease. ICU, intensive care unit; PVL, periventricular leucomalacia. (From Wernovsky G: Current insights regarding neurological and developmental abnormalities in children and young adults with complex congenital cardiac disease. *Cardiol Young* 2006;16[Suppl 1]:92-104.)

risk factors for adverse outcomes are interrelated, such as abnormalities of the fetal circulation, the need for prolonged intensive care, complex operations with cardiopulmonary bypass with or without deep hypothermia and circulatory arrest, prolonged hypoxaemia and multiple reoperations. Thus, it is difficult to conclude which, if any, are most explanatory. Many of the reports on the effects of cerebral consequences of cardiopulmonary bypass in particular are conflicting, and there is a need for ongoing laboratory experiments and controlled clinical trials before sweeping changes to intra-operative management are undertaken, with particular attention to long-term outcomes in school age children. Neurodevelopmental abnormalities are widely prevalent, and are major contributors to adverse health-related outcomes concerning quality of life. Further research must continue, in the laboratory, inpatient, and outpatient settings.

ANNOTATED REFERENCES

- Bellinger DC, Bernstein JH, Kirkwood MW, et al: Visual-spatial skills in children after open-heart surgery. *J Dev Behav Pediatr* 2003;24:169–179.
This study is part of the series of reports from the Boston Circulatory Arrest Study group, in which a total of 171 children born with transposition were randomised to undergo the arterial switch operation with either low-flow cardiopulmonary bypass or a predominant deep hypothermic circulatory arrest strategy between 1988 and 1992. The cohort has been followed prospectively, and various aspects of the 8 year follow-up data are published. In this report, Bellinger and colleagues have explored the clinical significance of visual-spatial deficits, which were not only found in this population of patients with transposition from the Boston Circulatory Arrest Study, but are patterns reported for other forms of congenital cardiac disease as well. The authors used the Rey-Osterrieth Complex Figure, which is a standardised design-copy task developed to elicit more complex processes required for visual-perception and visual-motor skills. Additional testing was performed in order to delineate the neuropsychological origins of poor performance on the copy task. The results revealed that over one half of the children in the cohort scored at the lowest level, which is twice as many as expected in a normal population of 8-years-olds. Impaired visual-perception skills, rather than motor or cognitive skills, were implicated as the primary contributor to the poor performance on the Rey-Osterrieth Complex Figure test. Of note, neither peri-operative events nor intra-operative strategy were significantly associated with poor performance. Visual-spatial deficits and specifically visual-perception deficits are associated with difficulties in specific academic areas, such as mathematics. This study provides unique insight into the practical implications for children and their families, and the findings from the adolescent follow-up of this cohort should present even more information about how visual-spatial deficits identified in the early school years affect later academic achievement and social integration.
- Limperopoulos C, Majnemer A, Shevell MI, et al: Predictors of developmental disabilities after open heart surgery in young children with congenital heart defects. *J Pediatr* 2002;141:51–58.
This study is part of a series of published reports from Montreal Children's Hospital describing ongoing follow-up of a cohort of children who underwent cardiac surgery requiring cardiopulmonary bypass, with or without deep hypothermic circulatory arrest, before the age of 2 years. Neurodevelopmental evaluations were performed prior to surgery, and follow-up occurred at 12 to 18 months after surgery. Of note, patients with hypoplastic left heart syndrome were excluded. The authors found that fine and gross motor deficits were present in two-fifths of the tested cohort, and significant deficits in language, eye-hand coordination, practical reasoning, locomotor, and personal social difficulties were also present. Microcephaly was present in three-tenths of the group, and global developmental delays were identified in nearly one quarter. The pre-operative neurological status was found to be predictive of delay at the follow-up, and specifically the presence of pre-operative microcephaly was a strong predictor of adverse outcomes. A longer duration of deep hypothermic circulatory arrest time was associated with worse outcomes. In addition, prolonged length of stay and need for intensive care was associated with worse outcomes. The findings from this study add to the growing body of data outlining the potential deficits facing survivors of early cardiac surgery, while also highlighting the importance of identifying patients in the peri-operative period who are at higher risk of later neurodevelopmental impairment, which will ultimately prove valuable for educating and counseling families.
- Creighton DE, Robertson CM, Sauve RS, et al: Neurocognitive, functional, and health outcomes at 5 years of age for children after complex cardiac surgery at 6 weeks of age or younger. *Pediatrics* 2007;120:e478–e486.
Creighton and colleagues from Alberta Children's Hospital report the 5-year follow-up of 85 infants who underwent cardiac surgery prior to 6 weeks of age between 1996 and 1999. Of the initial infants enrolled, 61 were available for assessment, and represented five surgical groups: arterial switch operation, arterial switch operation with ventricular septal defect closure, Norwood procedure, simple total anomalous pulmonary venous repair, and a miscellaneous group. The Norwood patients scored lower than both the arterial switch operation groups and the total anomalous pulmonary venous return repair group for full scale intelligence quotient and verbal intelligence quotient. The duration of deep hypothermic circulatory arrest and cardiopulmonary bypass did not correlate with cognitive outcomes. The authors previously published the results of developmental assessments at 2 years of age from this cohort, and were able to demonstrate that subjects receiving normal assessments at 2 years of age continued to do well at 5 years of age. In addition, fewer subjects had impaired cognitive scores at 5 years than at 2 years. An important strength of this study is that multiple forms of cardiac defects are represented, and therefore allows for comparison of differences between cardiac defects in the setting of relatively standardised peri-operative management.
- Uzark K, Jones K, Slusher J, et al: Quality of life in children with heart disease as perceived by children and parents. *Pediatrics* 2008;121:e1060–e1067.
Uzark and colleagues from Cincinnati administered the Pediatric Quality of Life Inventory Generic Core Scales and Cardiac Module to 475 families and 347 school age children with varying levels of cardiac disease. Overall, children self-reported significantly lower scores for psychosocial and physical functioning compared to normal healthy populations. While subscale scores for emotional and social functioning were also lower than normal children, the most dramatic differences were for school function. Children with more severe cardiac disease reported lower scores for physical functioning, but there were only small differences in psychosocial scores among disease severity. In contrast, parental reports of quality of life varied based on the age group of the child. Total quality of life scores in the toddler and child age group were not significantly different compared to the normal children, while reports from parents of teenagers did reveal a significant difference. Moreover, lower scores from parents correlated with more significant cardiac disease. This extensive evaluation in a large sample provides a contemporary review of how cardiac disease affects children as they progress through school and provides compelling evidence for ongoing assessments not only of physical health, but also school performance and social functioning. In addition, the discrepancy between parental and child reports suggests that children with cardiac disease may have more impairment than parents realise.
- Moons P, Van Deyk K, De Bleser L, et al: Quality of life and health status in adults with congenital heart disease: A direct comparison with healthy counterparts. *Eur J Cardiovasc Prev Rehabil* 2006;13:407–413.
Moons and associates from Leuven, Belgium, have published several reports challenging the notion that adults with congenital cardiac disease universally have a poor quality of life. The authors propose that traditional measures of quality of life have concentrated too heavily on functional outcomes such as employment or education level, rather than focusing on the individual's perception of life satisfaction. In this study, 404 adult patients with varying forms of congenital heart disease and 404 healthy matched controls were recruited to participate in a questionnaire study to assess both quality of life and perceived health status (three different standardised scales were used and are described in detail in the manuscript). Overall, the patients reported high scores for subjective health status. Patients reported that the most important determinant of quality of life was 'feeling that one's body is less capable than one would wish'. When compared to the healthy controls, the patients actually reported a better quality of life, while there was no significant difference for self-perceived health status between the groups. The authors note that the adults with congenital heart disease may have different values or coping skills with respect to quality of life perceptions compared to the general population and thus measures of quality of life should not be limited to functional outcomes only. As the number of adult patients with congenital heart disease increases, outcome evaluations will become increasingly important. Moons and colleagues have shown that the quality of life for this population is not significantly different from the general population if the assessment is based on the individual's perceptions.
- Miller SP, McQuillen PS, Hamrick S, et al: Abnormal brain development in newborns with congenital cardiac disease. *N Engl J Med* 2007;357:1928–1938.
The authors from University of California, San Francisco utilised advanced techniques, such as magnetic resonance spectroscopy and diffusion tensor imaging, to analyse the brains of 41 newborns with either transposition or functionally single ventricle prior to cardiac surgery. One-third of the cohort had evidence of pre-operative neurological injury in the form of white matter injury, stroke, or haemorrhage, while new post-operative injuries were identified in an additional three-tenths of the cohort. Abnormalities were identified using both techniques indicative of immature brain metabolism and microstructural development. The findings suggest that full-term infants with complex congenital cardiac disease have impaired cerebral development with patterns that are similar to preterm infants at birth. Since the neurodevelopmental outcomes in congenital cardiac disease are strikingly similar to those described in premature infant follow-up studies, the finding of brain immaturity is congruent. Moreover, the studies were performed in pre-operative infants, and thus the brain abnormalities are presumably related to impaired fetal central nervous system development. Understanding patterns of cerebral blood flow and delivery of oxygen to the fetal brain will be an important area of research in light of the findings from this study.
- Rosenthal GL: Patterns of prenatal growth among infants with cardiovascular malformations: Possible fetal hemodynamic effects. *Am J Epidemiol* 1996;143:505–513.

Geoffrey Rosenthal examined newborn infants with four types of congenital cardiac disease who had been enrolled in the Baltimore–Washington Infant Study, which was a population based case-control study designed to explore environmental and genetic risk factors for congenital cardiac disease. Eligible subjects included full-term infants without associated extracardiac abnormalities and comprised 69 patients with transposition, 66 patients with tetralogy of Fallot, 51 patients with hypoplastic left heart syndrome, 65 patients with coarctation of the aorta, and 276 controls. Anthropometric measurements, as well as the ponderal index, a measure of relative thinness, were abstracted from patient records. Potential confounders such as maternal weight gain, smoking, pre-pregnancy weight gain and diabetes mellitus, as well as infant sex, race, and gestational age were also included in the statistical model. Compared to controls, infants with transposition had a smaller head circumference, shorter birth length, and greater birth weight given birth length, as well as a smaller head volume relative to birth weight. Thus these infants tended to have smaller head circumference, but greater birth weight. Infants with tetralogy of Fallot had lower birth weight, shorter birth length, and smaller head circumference compared to controls. Infants with hypoplastic left heart syndrome similarly had smaller head circumference, lower birth weight, and shorter birth length, with a more striking difference in the head volume relative to birth weight. Thus infants with hypoplastic left heart syndrome were small in all dimensions, but the head size was relatively smaller compared to the other dimensions. Infants with coarctation were found to have larger head volume relative to birth weight, but overall lower birth weight and shorter birth length. This study is an eloquent demonstration of variances of patterns of fetal growth among four different forms of congenital cardiac disease that presumably maintain unique alterations of fetal circulatory patterns which affect cerebral blood flow. More information is needed regarding fetal brain development in congenital cardiac disease in order to correlate the observations from this study with later neurological impairment.

- Hoffman GM, Mussatto KA, Brosig CL, et al: Systemic venous oxygen saturation after the Norwood procedure and childhood neurodevelopmental outcome. *J Thorac Cardiovasc Surg* 2005;130:1094–1100.

Hoffman and associates from Children's Hospital, Wisconsin investigated the neurodevelopmental status of 13 patients with hypoplastic left heart syndrome at a mean age of 4.5 years after a Fontan completion. The specific aim of this study was to assess the influence of systemic venous saturation of oxygen in the post-operative period as a measure of systemic delivery of oxygen. In other words, is there a correlation between post-operative hypoxaemia and later neurodevelopmental outcome. Mean scores for all developmental measures (McCarthy Scale of Children's Abilities–Motor and General Cognitive, Beery Test of Visual-Motor Integration, and Achenbach's Child Behaviour Checklist) in this cohort were within the normal range, but overall lower than expected in the normal population. Statistically significant differences were observed for the McCarthy scale of Children's Abilities–Motor and the Composite score. Of the peri-operative variables assessed, only systemic venous saturation of oxygen correlated with abnormal outcomes significantly. Moreover, a longer duration with a low systemic venous saturation of oxygen was associated with a greater relative risk of abnormal outcome. Although a significant limitation of this study is the small sample size, the data suggests a valid link between the post-operative state and later neurodevelopmental outcomes, as well as suggests the benefits of non-traditional monitoring in the post-operative period.

- Hovels-Gurich HH, Konrad K, Skorzinski D, et al: Long-term neurodevelopmental outcome and exercise capacity after corrective surgery for tetralogy of Fallot or ventricular septal defect in infancy. *Ann Thorac Surg* 2006;81:958–966.

Hovels-Gurich and colleagues from Aachen University of Technology have published a series of follow-up studies in children who underwent cardiac surgery in infancy in order to investigate the longer-term effects of pre-operative hypoxaemia compared to infants without pre-operative hypoxaemia, but with pre-operative symptoms of cardiac failure due to pulmonary over-circulation. No subject had an identifiable chromosome abnormality or genetic syndrome. One-third of the total cohort had evidence of central nervous system abnormalities, but there was not a statistically significant difference between those with tetralogy of Fallot or ventricular septal defect. The total group also had significantly worse scores compared to age-matched published controls. Gross motor dysfunction was higher for those with tetralogy of Fallot compared to ventricular septal defect, but there were no differences between the groups for the other domains. Exercise capacity was not significantly different compared to the normal population. Although the cohort is relatively small in this study, the conformity of the peri-operative management between the two groups provides a basis for assessing the impact that prolonged hypoxaemia may have on outcomes. Additional published reports from this group have investigated behaviour, quality of life, and speech and language outcomes. There continues to be a trend toward those with tetralogy of Fallot scoring worse than those having a ventricular septal defect, although the effects on behavioural outcomes appear to be more related to attention problems.

- Gaynor JW, Gerdes M, Zackai EH, et al: Apolipoprotein E genotype and neurodevelopmental sequelae of infant cardiac surgery. *J Thorac Cardiovasc Surg* 2003;126:1736–1745.

Gaynor and associates enrolled 368 infants, who underwent cardiac surgery before 6 months of age at The Children's Hospital of Philadelphia between 1998 and 2001. Pre-operative data was obtained on all subjects, and 1-year neurodevelopmental evaluations were performed in 244 of the survivors. The primary aim was to evaluate whether genetic polymorphisms are associated with longer-term outcomes. Apolipoprotein E is a regulator of cholesterol metabolism and specifically involved in lipid transport in the central nervous system. In adults, specific isoforms of apolipoprotein E have been associated with Alzheimer's disease, as well as recovery after neurological injury. The results of this study revealed a significant association between the presence of the APOE $\epsilon 2$ allele and a lower Psychomotor Development Index from the Bayley Scales of Infant Development. The implications of this association suggest that infants at risk for more significant neurological injury may be identified pre-operatively or even antenatally based on genetic testing, and these findings may impact counseling as well as management techniques in the future. However, more definitive evaluations in older children will provide valuable information. The 4-year follow-up of this cohort is underway.

Communication with the Referring Teams Providing Health Care

PAUL STEPHENS, Jr., TYRA BRYANT-STEPHENS, and GIL WERNOVSKY

Communication between the cardiologist and providers of primary care is an essential component of the medical care of the patient, and is of increasing importance in the current era, which is marked by increased complexity of medical testing and polypharmacy. Breakdowns in this vital area of communication can result in delayed or missed diagnoses, repeated or unnecessary testing, and increased risk of litigation.¹ The challenges that face patients with congenitally malformed hearts go beyond their particular pathophysiology. All patients with important cardiovascular defects require healthcare delivered by multiple teams. The providers of primary care, general practitioners, and general paediatricians, are usually the first line of defense against morbidity and mortality for these patients, and usually are based close to the area of residence of the patient. The cardiac specialist may be located a great distance from the patient, and therefore must maintain constant and consistent interaction with the team providing primary services in order to optimise the delivery of healthcare. Difficulties in communication between generalists and specialists have been extensively documented. Many physicians learn how to perform effective consultations through trial and error, resulting in considerable variability in consultation skills² and frustrated referring physicians. Paediatricians have generally been slow in developing an infrastructure for effective consultation, and most of the landmark literature in this area comes from experience with adult patients. Explicit instructions have been developed for internists in how to perform effective consultations.² In this chapter, we review some of the challenges encountered when multiple teams care for a mutual patient. Some common problems are highlighted by making reference to hypothetical cases. We also offer some thoughts on potential solutions.

CASE I

Dr. John has referred a patient to you. On completing your evaluation, you feel sure that the patient has a small haemodynamically insignificant ventricular septal defect that does not require surgical intervention. At the consultation with the parents, you assured them that their child was well, required no intervention or restrictions of exercise, and recommended reassessment in from 2 to 3 years. Now the child wants to participate in competitive athletics, and the parents are concerned about the cardiac defect, and

if the child should be allowed to compete at a level of high intensity.

Whose Patient Is This?

The overall health of the child is, first and foremost, the responsibility of the team providing primary healthcare, and consultants must recognise their subsidiary role.² This is always the case, irrespective of whether the cardiac disease is trivial or complex. Prolonged stays in hospital, particularly soon after birth in the neonatal intensive care and step-down units, often result in the accumulations of multiple problems. The complexity of those problems facing the parents makes the assimilation of medical information a difficult task for hospital-based specialists, let alone the provider of primary care, who must eventually assume this responsibility after the patient is discharged from the hospital. In the present era of improved surgical outcomes, and higher rates of survival, a common scene experienced by the generalist is the follow-up visit subsequent to the hospitalisation of the infant with complex congenital cardiac disease. After appropriate visits with the supervising cardiologist, these infants require visits with their providers of primary care for mandatory immunisations, anticipatory guidance for young and new parents, as well as surveillance of other organ systems that are critical for normal growth and development. Complex medical problems can be intimidating for any caregiver, but the team providing primary healthcare typically possesses a very balanced fund of medical knowledge and expertise in a number of areas, enabling those persons to be the most qualified medically to supervise the child subsequent to discharge. The potential disconnection between those providing primary care and the patient subsequent to prolonged hospitalisations, nonetheless, may lead to a lack of confidence on the part of the primary caregiver. In consequence of this disconnection, the needs of the patient, with the exception of immunisations, may be left in part to the specialist, who cares for the most complex, or most potentially life-threatening, of the medical problems. This relinquishment of the overall care of the patient to the specialist should be avoided. The specialist team can play a major role in ensuring that the generalist remains the confident primary provider of healthcare. Timely, and collegial, communications from the specialist in paediatric cardiology, including details of the precise diagnosis and plans for treatment, may help the

team providing primary healthcare to feel empowered to provide ongoing care for the patient.³

In the hypothetical situation outlined above, the provider of primary care, with guidance from the paediatric cardiologist, should make the decision regarding participation in sports. The cardiologist, for example, may not be aware of other conditions, such as absence of, or damage to, one of paired organs that may preclude participation in certain competitive sports. Because of this, the specialist may give inappropriate approval for the patient to participate in activities that could be detrimental to health in the event of injury. The team providing primary services is most important in this framework of a tiered approach to comprehensive provision of health care. Dysfunction may ensue if roles and responsibilities are not appropriately assumed.

Parental Concerns: Who Should I Call to Discuss a Medical Problem?

Although the paediatric cardiac specialist knows that the overall surveillance of the health of the child is primarily the responsibility of the team providing primary care,⁴ parental confusion, and at times unrealistic expectations, are occasionally encountered by the cardiac specialist. The dilemma of which specialist to call for symptoms and signs of illness may be a problem even for physicians. Parents, who for the most part have no formal medical training, also share in this dilemma. Telephone calls, and increasingly, email correspondence to cardiac specialists that should be directed toward the primary team, and communications in the opposite direction, are not uncommon events, particularly when made by parents who have children with newly diagnosed cardiac disease. A substantial number of parents of children with serious cardiac disease may believe that the provider of primary care is unable to meet many of the needs of their child.⁵ It is important for the cardiac specialist to have patience with the parents, grandparents, and guardians of children with cardiac disease when family concerns result in what can seem to be endless or inappropriate telephone calls, and frequent visits.

Many times, it is the level of parental anxiety, rather than the complexity of the cardiac disease, which is the determining factor for frequent contact with the specialist. The number of telephone calls and visits expressing anxiety correlate inversely with the length of experience that the parents have in managing their child with cardiac disease. The number of telephone calls, however, does not appear to vary directly with the complexity of the cardiac conditions. In our experience, even simple congenital cardiac malformations not requiring surgical treatment have produced high levels of anxiety in family members, who have needed constant reassurance regarding the well-being of the child. More parental experience with children with congenital cardiac disease appears to translate into a lower level of anxiety, and fewer telephone calls to the cardiac specialist. The majority of parents of teenagers with congenital cardiac malformations preferred using their provider of primary care rather than their paediatric cardiologist as a point of first contact for all concerns relating to general health, as well as for many potential concerns relating to the heart.⁶

Parental anxieties seem to escalate whenever a sudden unexpected, or unsolved, death occurs in the community or nationally, and gains significant attention in

the media. The cardiac specialist should not be surprised when urgent referrals are needed to rule out cardiac disease, particularly after the unexpected death of a local or well-known athlete prior to the start of the school season when pre-participatory evaluations for sport are in full swing in the offices of providers of primary care. A plethora of referrals to the cardiac specialist typically follows for a short period of time whenever such an event occurs. The ebb and flow of such referrals are, and will likely always be, a part of the practice of the primary team, as well as the cardiac specialist. These physicians can take advantage of available ancillary tests in the face of such an epidemic of the need for cardiac consultation. Many families are very uncomfortable waiting for the elective appointment to rule out cardiac disease, and can be reassured if preliminary tests are normal. The cardiac specialist can advise the primary team so as to alleviate some of these concerns by taking advantage, in this particular situation, of the availability of an electrocardiogram. A normal electrocardiogram makes unlikely the diagnoses of hypertrophic cardiomyopathy, this being the leading cause of sudden death in competitive athletes in the United States of America. Electrocardiographic testing can be used in many cases transiently to alleviate some parental concerns until the time that the child can be seen by the cardiologist.

CASE 2

A child aged 2 years, having chronic lung disease and stridor, is referred for exclusion of cardiac disease. The parents relate that the paediatric pulmonologist, who had seen the child approximately one week previously, was concerned about a possible vascular ring, and had referred the child for a cardiac consultation. The physician providing primary care had not yet received written correspondence from the paediatric pulmonologist, and did not understand the need for the referral.

Modes of Communication

The nature of the correspondence from the cardiologist should reflect the tiered system of provision of care. Irrespective of who has referred the patient to the cardiac specialist, the primary team should be the primary addressee for all correspondence. The type of correspondence can be variable. Some consultants choose to send a preliminary short communication, delineating the diagnostic impression and suggested therapeutic plan, while others choose to communicate to the referring physician via an electronic medical record. Irrespective of the mode of communication, the paediatric cardiologist is encouraged to have the communication transcribed as soon as possible after the encounter with the patient. Although the busy cardiologist may find time short, and possibly delay the communication to a more convenient time, such an approach results in more time being spent in trying to recall the details of the encounter. Prompt communication is also frequently helpful to the provider and family in the event that cardiac disease is excluded and the patient needs referrals to additional specialists, or requires completion of forms allowing participation in competitive sports. Many studies have documented inadequate feedback from the consulting physicians in rural settings, and also in university medical centres.⁷⁻⁹ A study of the communication between oncologists and general practitioners found problems with the

timeliness of communication and suggested interventions included greater use of telephone or fax, improved secretarial support, the use of email, nurse-led communications, universal patient records, and revisiting the option of patient-held medical records.¹⁰ In one study, referring physicians who enclosed an addressed envelope with the request for consultation increased the percentage of consultant feedback from two-fifths to three-fifths.⁹ In the past, electronic mail had not been widely accepted by specialists or generalists as a preferred method of communication,¹¹ albeit that this pattern may change in the future. Even with the use of electronic correspondence, one study cited the lack of timely information as a major reason for dissatisfaction among providers of primary care.¹² If promptly performed soon after the visit, electronic transfer of information has the potential to induce major cultural changes in the delivery of healthcare.¹³ Although quite difficult to perform for most busy specialists, most referring physicians prefer direct verbal communication, a type of communication for which there is likely no substitute, especially if the consultant thinks that the recommendations are crucial or controversial.^{2,14} Goldman and colleagues,² in their landmark article, stated succinctly 'talk is cheap, and effective'. Despite the previously well-documented observation that direct communication by phone is a highly valued activity by generalists, the minority of specialists shared this opinion.¹¹ In one study, the satisfaction ratings for the referring physicians was found to be highest for referrals involving specialist feedback by both telephone and letter.¹⁵ Consulting physicians are more likely to respond to the referring physician by phone, or in person, if they were directly contacted by the referring physician.⁷ Studies have also shown that attention to these factors influences the choice made by the primary team concerning specialist referral. A comprehensive detailed prompt communication, clearly delineating the plans for treatment, the natural course of disease, and issues related to management, is associated with a greater level of satisfaction for the primary team.¹⁶

The cardiac consultant must also develop a style of communication that suits himself or herself, and that is appropriate for the recipient. A brief informal survey of a clinical practice at the Children's Hospital of Philadelphia revealed that most clinicians prefer communications that are both informative of the particulars of their patient, and also instructional in a general sense. In this survey, the majority of the respondents of this hospital-based centre for primary care reported reading the letter from the consultant in its entirety, both for information about the patient as well as for didactic purposes. The latter point may come as a surprise to many cardiac specialists, who have been under the impression that only the initial impression, and the component relating to therapeutic plans at the conclusion of the letter, are read by the primary team. Although the didactic, instructional, letter requires more time from the cardiac specialist, at least one such letter, among the many which will accrue for a patient with complex cardiac disease, will likely aid and equip the referring provider, which may lead to more confidence in the care of these patients. This concept of teaching with tact, an instructional letter that is not overly simplistic, was one of the original ten commandments for effective consultation.^{2,14} Furthermore, referring letters which have elements of anticipatory guidance, for example listing of the typical symptoms to be

expected for pulmonary over-circulation in patients with an unrestricted ventricular septal defect, may help the primary provider be on guard for these symptoms, and help to guarantee that certain patients are not lost to follow-up. Generalists and specialists agree that consultation letters should include information about how to manage acute problems in patients with chronic disease.¹¹ Citations of literature in the communication have not generally been felt to be helpful.¹⁴

Additional correspondence detailing results of tests not immediately available on the initial day of consultation day, such as the outcome of 24-hour ambulatory electrocardiographic monitoring, have also been a challenge for the busy cardiac specialist. Every effort should be made, nonetheless, to assure the written completion of the medical record. Well-formulated diagnostic summaries, and plans for treatment, in the medical record also help to eliminate potentially extra work in the form of telephone calls and repeated referrals. There is also less anxiety on the part of both the referring provider and the parents if sufficient information from the consultant is provided in a timely fashion.

Long lists of problems, particularly complex medical problems involving multiple subspecialties, as well as fear of making major, and even minor, errors, may elicit anxiety on the part of providers of primary care. Good communication can minimise this anxiety. The cardiac specialist can play a major role in alleviating the stress associated with managing patients with complex medical problems by frequently updating the primary team during prolonged hospitalisations, and also by prompt communication of the results of outpatient visits. Likewise, the cardiac specialist may feel intimidated when patients are noted to have non-cardiac illnesses that can cause significant morbidity, and or mortality. Asthma, influenza, developmental delay, and complications from neoplastic disorders, are not uncommon medical problems which are encountered in patients with cardiac disease. Although once skilled in the care of these problems, most cardiologists, particular ones furthest away from medical training, may not possess the appropriate skills to manage such medical problems, and may inadvertently place the patient at risk. Parents frequently feel that the cardiologist, particularly those providers who have cared for their child since the diagnosis of the illness, appear to have medical knowledge that extends beyond the discipline of cardiology. The reasons for this sentiment are not entirely understood, but perhaps relate to the recognition by the parents that their cardiac consultant knows their child exquisitely well, which is quite true. This knowledge of the medical history of the child, however, does not always translate into proficiency in managing non-cardiac medical conditions. The cardiac specialist, therefore, should not feel incompetent or inferior when faced with a non-cardiac condition that is perplexing, or even simple, but nonetheless beyond his or her expertise. The specialist should always suggest to the parents to seek the advice of their primary team, rather than potentially to mismanage non-cardiac maladies.

Involvement of the primary team in the entire process of managing complex patients not only should be exercised when non-cardiac problems surface, but should also be a process that occurs early in the care of the patient. A discussion to involve the primary team at an early stage in the process of care is not the usual mode of operation in

large tertiary centres. Furthermore, there can even be arrogance on the part of the subspecialist. Such arrogance may manifest as disparaging remarks made behind doors, or lack of appropriate and timely communications. This type of behavior is probably not rare among today's medical professionals, and runs counter to the first code of ethics of the American Medical Association, which stated in 1847:

A physician who is called upon to consult, should observe the most honorable and scrupulous regard for the character and standing of the practitioner in attendance: the practice of the latter, if necessary, should be justified as far as it can be, consistently with a conscientious regard for truth, and no hint or insinuation should be thrown out, which could impair the confidence reposed in him, or affect his reputation.

Unless there is incompetence that can affect the health of the patient, consulting physicians should avoid denigrating colleagues.⁴

As already discussed, the tension that can occur when providers of primary care are invited into the planning of care at a relatively late stage may result in such a degree of discomfort and difficulty that a critical error can occur in management. Late involvement of the primary team may lead to more work for the cardiologist, and at times less expertise in the care of the patient, thus placing the patient at risk for missed diagnoses or inappropriate treatment. The cardiac specialist should recognise this bias and, although more time costly in the short term, interact with the primary team on a professional level at all times. Ultimately, time, and respect, will be gained with such an approach.

Similar lessons are important for the team providing primary care. Some high-volume general practices may refer patients to the specialist, rather than discuss the case personally, via either phone calls or emails, so as to assess if the referral is necessary. Such an approach may lead to a pattern of over-referral, frequently of relatively non-complex medical problems. Potentially long waiting times for the appointment with the specialist may increase the anxiety of both physician and parents, which may have been minimised with a personal communication with, and reassurance from, the cardiac specialist. The cardiac specialist should encourage an open communication with those providing primary care, either by telephone or email, which may potentially reduce unnecessary referrals. A plan for open communication may also facilitate the delivery of results in a timely fashion for patients who require only an electrocardiogram, and who do not require a formal complete cardiac assessment, such as children who are medicated with drugs having cardiac side-effects requiring serial electrocardiographic monitoring. Some patients enter the office of the cardiac specialist with a collection of reports from recent tests aimed at diagnosing the problem at hand. The cardiac specialist is occasionally faced with weeding through the results of tests that may have not been necessary. Rather than perseverating over the necessity of the tests, and even perhaps the referral itself, an available cardiac specialist can play a role earlier in the process of referral.

Increasingly, written correspondence from the specialist to those providing primary care is also sent to the families of the patient. Possession of the relevant letters by the parents, or even the patient him or herself, may improve

the overall care, and involve the patient and their families in their own healthcare. Written correspondence serves to reinforce what was discussed in the office visit, and may not have been remembered or was misinterpreted.¹⁷ In a recent study, patients appreciated receiving a copy of the letter sent to the team providing primary care.¹⁸ Although patients do not always understand fully the content of the letter,^{19,20} a certain level of understanding is nevertheless achieved, and comprehension is improved when a second, less complex, letter is sent directly to the patient from the specialist. This letter also opens up dialogue between the parent and physician by triggering questions about things that might not have been understood. Many times, it is hard for parents to comprehend all of the information and instructions that are given to them at the first visit with the specialist. By receiving a copy of the letter, they are able to review the diagnosis and instructions, as well as ask questions for clarification. This interpretation is confirmed by studies concluding that most parents of children were satisfied when they received a copy of the letter that was sent to their general practitioner,²¹ although it did not necessarily improve compliance with future visits.²² Fewer errors in information have occurred when the letter was dictated in the presence of the patient.¹⁹ The letter allows families to carry a copy of the cardiac details when travelling, so that all of the details of complex disease do not need to be remembered. Despite evidence that satisfaction amongst patients is improved when they receive a copy of the correspondence from the specialist to the generalist, physicians remain largely resistant to performing it.

CASE 3

A generalist desires an appointment for an infant of 6 months, who was noted to have a murmur during a regular check up. The parents have become more anxious after learning that the earliest available appointment with the cardiac specialist requires a waiting time of 2 months. The parents request that the paediatrician intervene.

How Long Is Too Long?

Generally speaking, most referrals to the cardiac specialist do not represent emergencies, while few are urgent. Truly emergent referrals are quite rare. One of the more common dilemmas for the team providing primary care involves determining the appropriate waiting time for referrals to subspecialists. The team may not feel qualified to ascertain if a few months of waiting time is too long. The cardiac specialist can play a key role in helping to solve this problem. Cardiac specialists, and providers of primary care, agree that a child who is failing to thrive, and has evidence of pulmonary over-circulation, requires an urgent referral, whereas an undiagnosed cyanotic patient, or one who is desaturated, needs to be seen immediately. Asymptomatic patients who have femoral pulses that are difficult to palpate, or absent, usually require urgent consultation. Patients with tachyarrhythmias or significant bradyarrhythmias usually require direct treatment in the emergency room, while those with arrhythmias and haemodynamic instability require immediate treatment in the office.

In our experience, infants who are not cyanosed, are gaining weight appropriately, and have strong femoral

arterial pulses by palpation, rarely have immediately life-threatening congenital cardiac disease. In the hypothetical case highlighted above, the cardiac specialist can reassure the family and those providing primary care, that, in the absence of the above findings, the probability for significant cardiac disease is low. The patient can be given a routine appointment, and the family can be given the option of an earlier appointment in the event that another family cancels their appointment. The level of anxiety suffered by the parents, nonetheless, despite the reassurance of those providing primary care, needs to be factored in to the timing of the appointment.

There are a few helpful adjustments or modifications in the arena of rapid accessibility that the cardiac specialist may offer to the providers of primary healthcare. The availability of satellite clinics may give the generalist more options in securing an appointment for their patients, especially when these visits can be arranged during non-traditional hours, such as appointments in the evening, or at week-ends. The outpatient physicians at the centres organised by Children's Hospital of Philadelphia saw 22,839 patients during the past academic year. Of these, one-third of the encounters occurred in satellite clinics closer to the homes of the patients. A significant increase in the outpatient visits during the past few years was a direct result of encounters at satellite clinics. Increased availability of appointments has resulted in improved satisfaction for both the patients and the referring physicians.²³

THE CARDIOLOGIST AS A RESOURCE OF THE COMMUNITY, AND AN ADVOCATE FOR THE PATIENT

Barriers to communication can be chipped away when the cardiac specialist serves more than just a consulting role in the direct care of patients, but also as a resource for the community. Making the generalist, parents, and community-at-large aware of available professional resources specifically designed for the patient with cardiac disease has proven to be helpful at the Children's Hospital of Philadelphia, which regularly sponsors seminars providing information about the cardiac problems for parents, and conferences providing continuing medical education for professionals. Sponsoring the patients with complex malformations for the Make-a-Wish Foundation, a benevolent organisation that attempts to deliver the once in a lifetime experience for terminally ill children, is a worthwhile activity. The cardiac specialist can also make parents aware of other resources, including summer camps for patients with cardiac disease, internet chat sites, or web logs for parents and patients with congenitally malformed hearts, along with other resources which have helped the child to reintegrate back into his or her community after cardiac interventions. Our group has brought attention to the neurological and psychological issues faced by patients with cardiac disease. Studies on hyperactivity attention deficit disorder in patients with palliated or repaired defects have revolutionised the need for early intervention, prompting teachers, parents, and communities to recognise the potential need for remedial services for this vulnerable population.²⁴ A programme has been established for surveillance in the home that reduced interstage mortality and improved the survival of patients with functionally single ventricles.^{25,26} Efforts have been

made to place automated external defibrillators in schools in an attempt to reduce the risk of sudden catastrophic events in high school athletes.²⁷ Programmes such as these, which go into the community for the provisions of service, have redefined the notion of how large hospitals providing tertiary care can provide for their patients. These ventures, and others, have helped to forge alliances among providers of primary care, cardiac specialists, and community-based workers.

CONCLUSIONS

Optimal care involves a collaborative approach between the team providing primary care and the specialist. Open lines of communication are the cornerstone of this approach, and should optimally involve various combinations of direct, written, faxed and electronic forms. All parties benefit when the provision of healthcare is shared amongst the providers. The teams providing primary care usually gain a higher level of professional satisfaction and confidence when intricately involved in the making of decisions involving their medically complex patients. Most importantly, the patients derive the most benefit when communication is timely, complete, and neither overly simplistic nor pedantic. When lines for communication are firmly in place, it is possible to maximise satisfaction for both the provider, the patients, and the families.

An opinion article promoting the general principles which should guide the interaction between the specialist and generalist. Duties of the referring and consulting physicians, joint duties and responsibilities of healthcare plans in supporting this relationship are discussed.
- McPhee SJ, Lo B, Saika GY, Meltzer R: How good is communication between primary care physicians and subspecialty consultants? *Arch Intern Med* 1984;144:1265–1268.
Prospective study of 464 consecutive patient referrals from 27 practitioners of a general internal medicine group at a university medical centre in San Francisco, California. Despite referring physicians provision of background information in 98% of the cases, communication of the findings by the consultants occurred in only 55% of the consultations.
- Cummins RO, Smith RW, Inui TS: Communication failure in primary care. *JAMA* 1980;243:1650–1652.
Survey of 233 referrals to specialists from a two-physician practice within 80 km of two university medical centres. The overall rate of receiving follow-up information was 62%. Private specialists provided more follow up information (78%) than either university affiliated emergency rooms (48%) or university affiliated specialty clinics (59%).
- Curry RW, Crandall LA, Coggins WJ: The referral process: A study of one method for improving communication between rural practitioners and consultants. *J Fam Pract* 1980;10:287–291.

Randomised prospective study of 235 patient referrals from three rural primary care clinics to a university medical centre in Gainesville, Florida. Receipt of specialist feedback occurred at a higher percentage (60%) when a mailer was included in the consultation request than with patient referrals in which a request for feedback and a return mailer was not included (39%). Private specialists were also more likely to provide feedback.

- Farquhar MC, Barclay SI, Earl H, et al: Barriers to effective communication across the primary/secondary interface: Examples for the ovarian cancer patient journey. *Eur J Cancer Care (Engl)* 2005;14:359–366.

This study explored the views of general practitioners regarding the process of communication from specialists in patients with ovarian cancer. Nine general practitioners experienced in the care of patients with ovarian cancer from predominantly semi-rural regions in the United Kingdom participated in a structured interview process within 6 months of the death of their patient. The main challenge of communication reported by the practitioners was the tardiness of the written or oral communication which led to handcuffing of the general practitioners in their ability to provide appropriate care. General practitioners reported inadequacies in their knowledge of test results and felt out of touch with the state of the patient. Subsequent to the insufficient communication, the practitioners reported feeling inadequate in their ability to provide moral support, crisis management, patient advocacy, and end of life care. Suggested communication improvements are reported in the text. General practitioners as a group welcomed calls from doctors or nurses.

- Stille CJ, Primack W, Savageau JA: Generalist-subspecialist communication for children with chronic conditions. *Pediatrics* 2003;112:1314–1320.

A survey of 403 paediatricians, specialists and generalists, in New England identifying target areas to improve communications between the two groups when sharing care of chronically ill patients. Differences in perception about the adequacy, timing and type of the communication were found. Suggestions for targeted interventions are given.

- Gandhi TK, Sittig DF, Franklin M, et al: Communication breakdown in the outpatient referral process. *J Gen Intern Med* 2000;15:626–631.

A survey of providers of primary care and specialists at a major teaching hospital in Boston, Massachusetts. Of the providers of primary care, 63% were dissatisfied with their current referral process, citing the major problems of communication being the lack of timeliness of information and inadequate referral letter content. Two weeks after the referral visit, two-fifths of the providers of primary care had received no information from the specialists and 4 weeks after the referral visit, one-quarter still had yet to receive written correspondence.

- Salerno SM, Hurst FP, Halvorson S, Mercado DL: Principles of effective consultation. *Arch Intern Med* 2007;167:271–275.

An anonymous survey of 323 providers of adult medicine in the United States of America exploring the ideal relationships between referring and consulting physicians. Specialty-dependent differences in referring and consulting practices were noted. A modified ten commandments for effective consultation is proposed.

- Forrest CB, Glade GB, Baker AE, et al: Coordination of specialty referrals and physician satisfaction with referral care. *Arch Pediatr Adolesc Med* 2000;154:499–506.

A survey of 122 pediatricians located in 85 practices throughout 34 states in the United States of America conducted by the Pediatric Research in Office Settings, a research based network established by the American Academy of Pediatrics. This survey examined the bidirectional transfer of information between referring and specialist physicians. Referring physicians were most satisfied when specialists communicated results by both telephone and letter, however this occurred in only 7% of the 964 referrals. Only 51% of the referrals were completed (defined as when the referring physician received written feedback from the specialist) within 3 months after the specialist visit.

- Kinchen K, Cooper L, Levine D, et al: Referral of patients to specialists: Factors affecting choice of specialists by primary care physicians. *Ann Fam Med* 2004; 2:245–252.

This was a national cross sectional study of primary care physicians in the United States via questionnaire. Respondents identified factors of major importance when choosing a specialist, with a response rate of 59%. The medical skill of the specialist was identified as the most important variable when choosing a specialist. Timeliness of the appointment, prior experience with the specialist and the quality of the specialist communication to the primary care physician were also deemed to be of major importance.

- Cowper DM, Lenton SW: Letter writing to parents following paediatric outpatient consultation: A survey of parent and GP views. *Child Care Health Dev* 1996;22:303–310.

A survey of parents and general practitioners of paediatric outpatient clinic patients at a major teaching hospital in Bath, United Kingdom. All 103 parents were in favor of receiving a letter from their child's specialist and most general practitioners considered that the letters would improve parental satisfaction and compliance.

- Saunders NC, Georgalas C, Blaney SP, et al: Does receiving a copy of correspondence improve patients' satisfaction with their outpatient consultation? *J Laryngol Otol* 2003;117:126–129.

A cohort of 200 patients in the United Kingdom were randomly assigned to receive a copy of the letter that was sent from the specialist providing treatment of diseases of the ear, nose, and throat to their general practitioner and were asked to complete a satisfaction survey. Compared to those that did not receive a copy of the letter, recipients had a higher satisfaction score. The only other factors predictive of a higher level of satisfaction were spending more time with the doctor or having a detailed explanation of the problem.

- Roberts, NJ, Partridge, MR: How useful are post consultation letters to patients? *BMC Med* 2006;4:2.

This study was performed in the United Kingdom involving 62 patients and the aim was to assess the utility of letters sent from the specialist to both the general practitioner and patient. Separate letters which summarised the encounter between the specialist and the patient were sent to both the general practitioner and the patient. The recipients were asked to evaluate these letters in terms of readability and accuracy of content. The majority of the patients expressed satisfaction about receiving a letter at their reading level, while the minority of patients preferred receiving copies of both letters. Few general practitioners desired receiving both letters, reporting that there was an increased workload, having to read both. Patients and general practitioners were also asked to circle items that were not comprehensible or inaccurate. Very few letters had inaccuracies, and as expected, most patients circled more items that were not comprehensible on the general practitioner's letters compared to the letters sent specifically to them. The article concluded that patient satisfaction improved when they received letters from the specialist despite the lack of full comprehension of the letter.

- O'Reilly M, Cahill M, Perry I: Writing to patients: A randomized controlled trial. *Clin Med* 2006;6:178–182.

This is a randomised controlled study of 150 patients in a general hematology clinic in Limerick, Ireland, to determine whether a brief letter of thanks for attending the clinic visit versus a detailed letter from the consultant recounting the visit would enhance recall of the visit. The majority of the patients were more satisfied with the detailed letter from the consultant, but there was no substantial difference in recall of information among the two groups.

- Waterson T, San Lazaro C: Sending parents outpatient letters about their children: Parents' and general practitioners' view. *Qual Health Care* 1994;3:142–146.

The study assessed the impact of letters from the general paediatric specialist to the families of the referred paediatric patient and also to the general practitioner. The majority of the families reported that the letter from the specialist improved their understanding of the medical problem and they were happy to have received a letter. The majority of the general practitioners favored the idea, however many of the general practitioners expressed reservations about direct communication between the specialist and the parents of the patient.

Growth and Nutrition

LISA M. KOHR and NANCY J. BRAUDIS

Nutrition is fundamental for ensuring adequate energy for basal metabolism, growth, and physical activity. Infants and children possess high metabolic rates and limited reserves of endogenous substrates at baseline, and are at risk for developing deficiencies of energy during episodes of acute or chronic illness.¹ Infants and children with congenitally malformed hearts are at significant risk for developing such energetic imbalance due to increased expenditure of energy, and poor or inadequate nutrition.² Energetic imbalance leads to the development of malnutrition, which can adversely affect somatic growth, along with cognitive and motor development.³ Failure of growth alters the metabolic response to injury and, for children with congenitally malformed hearts, increases the risk of post-operative morbidity and mortality, contributing to longer lengths of hospitalisation and times needed for recovery.¹

MALNUTRITION

Malnutrition is defined as a state of poor nutrition and failure of growth (Table 66-1). Failure of growth exists when weight, or weight for height, is less than 2 standard deviations below the mean for sex and age, weight is less than the third centile, or weight for age has a *z* value of less than -2.0.⁴ Criteria for the diagnosis of malnutrition also apply to children whose curve for gain in weight crosses more than 2 centiles from baseline on the growth charts created by the National Center for Health Statistics after having previously achieved a stable pattern. The baseline centile is the maximum weight achieved between 4 and 8 weeks of age, as studies have shown that the gain in weight during this time period correlates with the weight at the age of 12 months.⁴

Malnutrition is a well-known consequence of congenital cardiac disease. It is estimated that four-fifths of hospitalised infants with congenitally malformed hearts suffer from acute or chronic malnutrition.⁵ Prior to the 1980s, when such children underwent surgical correction at an older age, those with acyanotic and cyanotic lesions exhibited failure of growth at birth that persisted well into childhood.⁶ In the current era of neonatal surgery, there has been a shift in the severity of pre-operatively delayed growth from the infants with cyanotic lesions to those having congestive cardiac failure. This is due primarily to the earlier age at surgical intervention.⁷ The cause of malnutrition in these children is multi-factorial, albeit that the

magnitude of the disturbed growth appears to be related to the anatomical lesion.¹

Significance of Malnutrition in Those with Congenitally Malformed Hearts

Malnutrition, specifically failure of growth, has been reported in more than half the children with congenitally malformed hearts.² The amount and type of retardation in somatic growth varies depending on the haemodynamic impact of the defect. In one study,⁸ factors impacting on the extent of malnutrition included gender, the type of cardiac disease, weight at birth, thickness of the subscapular and triceps muscles, and cephalic circumference. The index of weight for length was found rapidly to decrease in those with cyanotic lesions, albeit that no differences in anthropometric measurements were noted between those having cyanotic and acyanotic lesions. Boys showed greater deterioration in weight for age, suggesting more acute malnutrition, while girls had lower linear growth for age, indicative of more chronic malnutrition. In another study,⁹ somatic growth was shown to be most affected in patients with large ventricular septal defects and tetralogy of Fallot, improving after operative repair, but failing to normalise. Catch-up growth for length was strongly correlated with severity of pre-operative growth failure, but not with age at operation.⁹ In yet another study,¹⁰ weight was found to be below the third centile in half of those studied, height in one-third, and skin fold thicknesses in from one-eighth to one-fifth, thus endorsing the findings of Chen and colleagues.²

MECHANISMS OF FAILURE TO GROW

Congenital Cardiac Disease

As discussed already, at birth, infants with both cyanotic and acyanotic cardiac lesions are more likely to have low weight.^{2,8} The Baltimore-Washington Infant Study¹¹ found that infants with tetralogy of Fallot, atrioventricular septal defects, ventricular septal defects, and hypoplastic left heart syndrome had the lowest weights at birth, even when corrected for gestational age, findings endorsed in another study, this one showing also that those with transposition had normal weights at birth.¹²

Failure to grow after birth is dependent on the haemodynamic effects of the cardiac lesion. The growth curve of neonates with mild malformations may be minimally affected, while those with severe cyanotic disease are at

TABLE 66-1

WATERLOW CLASSIFICATION OF MALNUTRITION

Range	Acute Malnutrition (Wasting) (% Median of Weight for Height)	Chronic Malnutrition (Stunting) (% Median of Height for Age)
Normal	>90	>95
Mild	80–90	90–95
Moderate	70–80	85–90
Severe	<70	<85

Adapted from Waterlow JC: Classification and definition of protein-calorie malnutrition. *Br J Med* 1972;3:566–569.

highest risk for malnutrition.¹³ Pulmonary hypertension appears to be an important risk factor for failing growth in those with both acyanotic and cyanotic lesions, such children tending to suffer severe growth failure.¹⁴

Congestive cardiac failure causes a hypermetabolic state and subsequent growth failure.¹ Cardiac lesions commonly resulting in congestive cardiac failure include hypoplastic left heart syndrome, patency of the arterial duct, totally anomalous pulmonary venous connection, critical valvar aortic stenosis, coarctation of the aorta, and ventricular septal defects.^{15,16} With large and unrestrictive left-to-right shunts, excessive flow of blood to the lungs causes increased pulmonary and left heart pressures, along with elevated left ventricular end-diastolic pressures, resulting in a high-output state and failure to grow.¹⁴

Children with cyanotic defects frequently have decreased weight and height compared to healthy infants.¹⁵ Cyanotic lesions such as transposition and tetralogy of Fallot with and without pulmonary atresia usually have right-to-left shunting resulting in hypoxaemia. The duration of hypoxaemia in years is directly related to the retardation of growth.² Children who are both hypoxaemic and have congestive cardiac failure are more severely affected.²

Children with multiple anomalies, in addition to congenital cardiac disease, are at the highest risk for acute and chronic malnutrition.² Genetic syndromes frequently associated with congenital cardiac disease, including trisomies 21, 13, and 18, Turner's syndrome, Williams syndrome, Noonan's syndrome, and DiGeorge syndrome, may also impact the rate of growth due to alterations in caloric intake, gastrointestinal absorption, metabolism, and expenditure of energy.^{1,2}

Inadequate Caloric Intake

Inadequate caloric intake is believed to be the main cause of infants with congenital cardiac disease failing to grow. The feeding patterns of such children have been compared to matched subgroups of normal infants.^{1,17} For infants with congenitally malformed hearts, feeding is equivalent to an exercise test, demanding increased amounts of energy. Intolerance of feeding can be attributed to an inability to expend sufficient energy on feeding, as exhibited by tachycardia, tachypnoea, shortness of breath, and vomiting. Other contributing factors include early satiety, decreased gastric capacity caused by hepatosplenomegaly, delayed gastric emptying time secondary to low cardiac output and an uncoordinated suck, and abnormal patterns of swallowing and breathing due to tachypnoea.

Additionally, fluid restrictions and diuretic therapy as part of the medical management may limit caloric intake.

Hypermetabolism

Energetic imbalance is a major contributing factor to failure of growth and malnutrition in children with congenitally malformed hearts.¹⁸ The energy available for metabolism is the sum of total energy expenditure and energy stored. Basal metabolic rate represents the major component of total energy expenditure and metabolisable energy. In general, children have a higher metabolic rate, placing them at high risk for energetic deficiencies during episodes of acute illness.¹ The basal metabolic rate of infants is almost twice that of an adult per kilogram of body weight.

Children with congestive cardiac failure have been reported to have up to five times higher basal metabolic rates than children without cardiac disease.¹⁸ The elevated basal metabolic rate may be due to the increased workload of the cardiac and respiratory systems. Resting expenditure of energy represents consumption of oxygen per kilogram of body weight, and has been shown to be increased in malnourished infants with congestive cardiac failure.¹ This increase has been attributed to a dilated or hypertrophied cardiac muscle, which can use up to one-third of the total oxygen consumed by the body, compared to one-tenth used by the healthy child.¹⁰ Other conditions which have been attributed to an elevation in the total body metabolic rate in children with congestive cardiac failure include increased activity of the sympathetic nervous system, haematopoietic tissue, and respiratory muscles.¹

Frequent respiratory infections and fever will also contribute to a state of hypermetabolism and failure of growth. In infants, total expenditure of energy is increased due to an increase in physical activity from 5% of total metabolisable energy intake at 6 weeks of age to 34% at 12 months of age.¹⁹ A marked rise in total energy expenditure relative to resting energy expenditure occurs in 3- to 5-month-olds with left-to-right shunting lesions due to increased cardiac workload, increased work of breathing, diminished myocardial efficiency, and increased stimulation of the sympathetic nervous system.¹

Malabsorption

Malabsorption is another condition which contributes to the malnutrition seen in children with congenitally malformed hearts. This can result from gastrointestinal tissue hypoxia, and causes feeding intolerance, limits caloric intake, and decreases absorption of nutrients.¹³ The presence of hepatosplenomegaly may cause decreased gastric capacity and altered oral intake of nutrients. Those with cardiac lesions resulting in right-sided cardiac failure and increased systemic venous pressure due to right-to-left shunting may develop oedema of the intestinal wall and mucosal surfaces. These changes in the intestinal wall will lead to impaired nutrient extraction and malabsorption, affecting the timing, volume, and caloric density of feedings.¹³

Growth Factor Hormone

Endocrine factors have been investigated as a possible cause for the growth delay in children with congenital heart disease.²⁰ Others found a positive correlation between low

saturations of oxygen and levels of IGF-1 in the serum, indicating that hypoxaemia may be an independent factor contributing to growth failure.^{21–23}

ASSESSMENT OF GROWTH DELAY

Physical Growth

Physical growth is a direct reflection of nutritional well-being and is the single most important parameter used in assessing nutritional growth. Periodic assessments should be made to determine whether weight, height, length, and head circumference are within normal limits for age and gender. Anthropometric measurements can assess the longitudinal speed of growth. Length is the most useful indicator, and is most reliable after 2 years of age due to the difficulty in obtaining accurate measurements in infants.⁴ Weight for height, the ratio of true weight to the ideal weight for height, is used to differentiate stunted growth from wasting independent of age. Stunting caused by chronic malnutrition, chronic illness, and genetic or endocrine abnormalities results in a child who is small for age but proportional for weight to height.⁴ Body mass index is the best indicator of excess weight and obesity in children and adolescents. Children with an index between the 85th and 95th centiles are considered at risk for being overweight, whilst those with an index greater than or equal to the 95th centile are considered obese.²⁴ Head circumference is a useful tool until the child reaches 3 years of age. It is particularly important for children who have undergone a bidirectional Glenn procedure, and may provide information regarding the patency of the shunt. Measurements of the skinfolds at the triceps and the supriliac crest are useful for estimating total body fat. Their application is limited in infants and young children, however, due to their lack of validity.⁴ Other tools exist, but are rarely used routinely in children, again due to lack of validity, coupled with lack of accessibility, invasiveness, or cost.

Anthropometry

For children who are hospitalised, anthropometry may occur on a daily or biweekly basis to track tolerance of oral feedings, or effectiveness of breast-feedings, high-calorie diet, or anti-congestive therapy. Standard guidelines point to a target gain of weight of 10 to 35 grams per day for infants, depending on their age in months²⁵ (Table 66-2). Infants who are undernourished have weights that plot at 2 standard deviations below the mean for gender and age on the growth charts compiled by the National Center for Health Statistics.⁴ The rate of gain in weight of children with congenitally malformed hearts is typically affected more than the height. If the nutritional deficit is severe and long term, weight and height are equally affected.⁸ Currently, there are no standard measurements which have been established for the population with congenitally malformed hearts. Interpreting data collected for this population, and evaluating any delayed growth on the basis of standards derived from healthy children, therefore, may exaggerate the degree of malnutrition.

Prealbumin

Prealbumin, also known as thyroxine-binding prealbumin, or transthyretin, is a sensitive marker for assessing the severity of illness in children who have critical or chronic disease,

TABLE 66-2

EXPECTED GAINS IN WEIGHT FOR INFANTS AND OLDER CHILDREN

Age	Weight (g/day)	Length (cm/mo), Crown to Heel
Newborns (gestational age)		
31 wk	24	3.2–4.4
34 wk	35	
>36 wk	30	
Infants		
0–3 mo	25–35	2.6–3.5
4–6 mo	15–21	1.6–2.5
7–12 mo	10–13	1.2–1.7
Children		
1–3 yr	4–10	0.7–1.1
4–6 yr	5–8	0.5–0.8
7–10 yr	5–12	0.4–0.6

and correlates with outcomes and recovery.²⁶ Specifically, levels of prealbumin have been shown to be a sensitive indicator of protein-calorie nutrition. The marker is more sensitive than either albumin or transferrin in measuring intake of protein and calories.²⁶ Being a negative acute phase reactant, its levels will decrease in presence of inflammation. It also decreases in the presence of hepatic dysfunction, since it reflects the ability of the liver to synthesise protein. Due to the accessibility of the test, and the rapid turnover in results, measuring levels of prealbumin allows for a more accurate and timely assessment of change in diet.²⁶ Serial levels obtained once or twice a week can assist in identifying nutritional adequacy.²⁷ The test should be used when there is suspicion of subclinical or marginal levels of protein-calorie nutrition, to assess the nutritional response to diet, including parenteral nutrition, and as a biochemical marker of nutritional adequacy in premature infants.

NUTRITIONAL MANAGEMENT

Requirements of Nutrients in Infancy

There are six classes of nutrients that influence the patterns of growth in infants and children: carbohydrates, fats, proteins, vitamins, minerals, and water, which in combination provide optimal nutrition and allow somatic growth (Table 66-3). Nutritional options in infancy include breast-feeding along with a host of commercial formulas prepared specifically for premature and term infants, as well as for specific medical conditions. For healthy infants up to 6 months of age, the recommended dietary allowance in terms of calories is from 108 to 117 kilocalories per kilogram of body weight (kcal/kg) per day.²⁵ The need for protein during early infancy is high, due to rapid muscular and skeletal growth, and approximately 2.2 grams per kilogram of body weight⁴ (see Table 66-3). Neonates with haemodynamically significant congenital cardiac malformations require substantially more nutritional support to sustain and catch up growth than do their healthy counterparts.¹ Those with mild to moderate disease may require from 130 to 150 kcal/kg per day, while those having moderate to severe lesions may require as much as 175 to 180 kcal/kg

TABLE 66-3

RECOMMENDED MACRO AND MICRO NUTRIENTS FOR GROWTH

Component	Function	Recommended Daily Intake	Special Considerations for CHD
Calories	Provides energy for all metabolic processes and to support growth.	Calorie levels based on EER and activity levels from the Institute of Medicine, Dietary Reference Intakes (DRI) Macronutrient Report, 2000. <i>Premature infant</i> 110–130 kcal/kg <i>RDA</i> 0–6 mo, 108 kcal/kg 7–12 mo, 98 kcal/kg 1–3 yr, 102 kcal/kg 4–6 yr, 90 kcal/kg Females 11–14 yr, 47 kcal/kg; 15–18 yr, 40 kcal/kg Males 11–14 yr, 55 kcal/kg; 15–18 yr, 45 kcal/kg	Children with CHD may require up to 50% more calories due to increased metabolic needs. Catch-up growth in children with growth failure is determined by ideal body weight for height and using indirect calorimetry or calorie levels based on EER. Caloric requirement for infants with poor growth: kcal/kg = RDA for age (kcal/kg) × ideal weight for height divided by actual weight Supplementation may be required with calorie-dense formula, supplemental NGT/GT feedings, or high-calorie diet.
Protein	Major structural component of all cells, acts as transport carrier.	Protein requirements are based on metabolic needs. Preterm infant 1.1–1.5 g/kg <i>RDA</i> 0–6 mo, 1.52 g/kg 7–12 mo, 1.2 g/kg 1–3 yr, 1.05 g/kg 4–6 yr, 0.95 g/kg Females 11–13 yr, 0.95 g/kg; 14–18 yr, 0.85 g/kg Males 11–13 yr, 0.95 g/kg; 14–18 yr, 0.85 g/kg	Children with CHD may require twice the recommended amount of protein due to malnutrition and severe protein losses. When protein modular is used for caloric supplementation, monitor for increased solute load.
Carbohydrate	Calorie source to maintain body weight. Primary source of energy for the brain.	RDA 55%–60% of total calories Children and adults, 130 g/day Added sugars should not exceed 25% of total calories consumed.	Carbohydrate modular use for caloric supplementation may cause increased fecal output due to high osmolality.
Fat	Increases absorption of fat soluble vitamins. Source of n-3 and n-6 polyunsaturated fatty acids (essential component of cell membrane, involved in cell signaling).	<i>AMDR</i> <i>Children</i> 1–3 yr, 30–40 g 4–8 yr, 25–35 g Males and females >9 yr, 25–35 g	Fat modular use may cause delayed gastric emptying and decreased appetite. Use with caution in patients with history of gastroesophageal reflux or aspiration.
Fluids/Water	Essential for maintaining vascular volume.	Fluid (volume/24 hr) <i>Premature infant</i> 80 mL/kg/day on day 1 of life Increase by 10–20 mL/kg/day as infant matures. Weight ≤10 kg = 100 mL/kg Weight ≤20 kg = 1000 mL + 50 mL/kg for each kg above 10 kg Weight >20 kg = 1500 mL + 20 mL/kg for each kg above 20 kg	Preterm infants have increased fluid requirements (up to 130–150 mL/kg/day depending on birth weight). Neonates and children with unrepaired CHD may require fluid restrictions. Following complete repair, fluid may be liberalized as tolerated.
Vitamins			
Vitamin A	Antioxidant, important in protecting mitochondria and cells from reactive oxygen intermediates. Essential for normal vision, gene expression, embryonic development, growth and immune function.	0–6 mo, 400 µg 7–12 mo, 500 µg 1–3 yr, 300 µg 4–8 yr, 400 µg Females 9–13 yr, 900 µg; 14–18 yr, 600 µg Males 9–13 yr, 600 µg; 14–18 yr, 900 µg	Children with heart failure may require higher amounts of certain micronutrients to optimize cardiac function. Serum levels of micronutrients may not reflect adequacy of nutrients at the tissue level.
B ₁ , thiamine	Coenzyme for carbohydrate metabolism and maintenance of myelin for nerve and muscle function.	0–6 mo, 0.2 mg 7–12 mo, 0.3 mg 1–3 yr, 0.5 mg 4–8 yr, 0.6 mg 9–13 yr, 0.9 mg Females 14–18 yr, 1.0 mg Males 14–18 yr, 1.2 mg	Endogenous antioxidants include enzymatic antioxidants (zinc in superoxide dismutase or selenium in glutathione peroxidase), free radical scavengers (vitamins A, C, and E) and metal chelators.
B ₃ , niacin	Functions in intracellular respiration, fatty acid synthesis, and glucose oxidation. Decreases cholesterol and lipoprotein levels.	0–6 mo, 2 mg 7–12 mo, 4 mg 1–3 yr, 6 mg 4–8 yr, 8 mg 9–13 yr, 12 mg Females 14–18 yr, 14 mg Males 14–18 yr, 16 mg	During stress, free radical production exceeds normal clearance. Antioxidants limit deleterious effect of free radicals.

TABLE 66-3—CONT'D

RECOMMENDED MACRO AND MICRO NUTRIENTS FOR GROWTH—CONT'D

Component	Function	Recommended Daily Intake	Special Considerations for CHD
B ₆	Reduces homocysteine levels and improves endothelial function	0–6 mo, 0.1 mg 7–12 mo, 0.3 mg 1–3 yr, 0.5 mg 4–8 yr, 0.6 mg 9–13 yr, 1 mg Females 14–18 yr, 1.2 mg Males 14–18 yr, 1.3 mg	
B ₁₂	Improves endothelial function by reducing homocysteine levels.	0–6 mo, 0.4 µg 7–12 mo, 0.5 µg 1–3 yr, 0.9 µg 4–8 yr, 1.2 µg 9–13 yr, 1.8 µg 14–18 yr, 2.4 µg	
Vitamin C	Antioxidant. Helps maintain tissue levels of vitamins A and E.	0–6 mo, 40 mg 7–12 mo, 50 mg 1–3 yr, 15 mg 4–8 yr, 25 mg 9–13 yr, 45 mg Females 14–18 yr, 65 mg Males 14–18 yr, 75 mg	
Vitamin D	Essential for calcium absorption from the intestine.	0 mo–18 yr, 5 µg	
Vitamin E	Antioxidant working to prevent propagation of lipid peroxidation.	0–6 mo, 4 mg 7–12 mo, 5 mg 1–3 yr, 6 mg 4–8 yr, 7 mg 9–13 yr, 11 mg 14–18 yr, 15 mg	
Vitamin K	Promotes liver synthesis of clotting factors (II, VII, IX, X).	0–6 mo, 2 µg 7–12 mo, 2.5 µg 1–3 yr, 30 µg 4–8 yr, 55 µg 9–13 yr, 60 µg 14–18 yr, 75 µg	
Folate	Necessary for DNA synthesis and replication.	0–6 mo, 65 µg 7–12 mo, 80 µg 1–3 yr, 150 µg 4–8 yr, 200 µg 9–13 yr, 300 µg 14–18 yr, 400 µg	Inadequate concentrations may decrease circulating levels of homocysteine.
Minerals			
Calcium	Essential for bone metabolism and muscle contraction.	<i>Preterm infant:</i> 0–6 mo, 210 mg 7–12 mo, 270 mg 1–3 yr, 500 mg 4–8 yr, 800 mg 9–18 yr, 1300 mg	
Chromium	Potentiates the action of insulin. Plays role in protein and lipid metabolism. Required for growth.	0–6 mo, 0.2 g 7–12 mo, 5.5 µg 1–3 yr, 11 µg 4–8 yr, 15 µg Females 9–13 yr, 21 µg; 14–18 yr, 24 µg Males 9–13 yr, 25 µg; 14–18 yr, 35 µg	Decrease intake in presence of renal dysfunction.
Copper	Functions in iron metabolism.	0–6 mo, 200 µg 7–12 mo, 220 µg 1–3 yr, 340 µg 4–8 yr, 440 µg 9–13 yr, 700 µg 14–18 yr, 890 µg	

(Continued)

TABLE 66-3—CONT'D

RECOMMENDED MACRO AND MICRO NUTRIENTS FOR GROWTH—CONT'D

Component	Function	Recommended Daily Intake	Special Considerations for CHD
Iron	Necessary for ATP to be synthesized.	0–6 mo, 0.27 mg 7–12 mo, 11 mg 1–3 yr, 7 mg 4–8 yr, 10 mg 9–13 yr, 8 mg Females 14–18 yr, 15 mg Males 14–18 yr, 11 mg	
Magnesium	Active component of antioxidant enzymes.	0–6 mo, 30 mg 7–12 mo, 75 mg 1–3 yr, 80 mg 4–8 yr, 130 mg 9–13 yr, 240 mg Females 14–18 yr, 360 mg Males 14–18 yr, 410 mg	
Manganese	Cofactor in many enzyme functions. Stimulates synthesis of cholesterol and fatty acids in liver. Influences mucopolysaccharide synthesis.	0–6 mo, 0.003 mg 7–12 mo, 0.6 mg 1–3 yr, 1.2 mg 4–8 yr, 1.5 mg Females 9–13 yr, 1.6 mg Males 9–13 yr, 1.9 mg; 14–18 yr, 2.2 mg	
Phosphorus	Antioxidant that works in concert with vitamin E to protect cells from peroxidase damage. Required in all cellular reproduction and protein synthesis.	0–6 mo, 100 mg 7–12 mo, 275 mg 1–3 yr, 460 mg 4–8 yr, 500 mg 9–18 yr, 1250 mg	Vital to the structure of bones and teeth. Primary constituents of cellular membranes. Required for the production of ATP, the major physiologic molecule used in the storage and transport of energy. Key buffering system used to ensure acid-base balance.
Selenium	Antioxidant component of glutathione peroxidase that protects cell components from oxidative damage.	0–6 mo, 15 µg 7 mo–3 yr, 20 µg 4–8 yr, 30 µg 9–13 yr, 40 µg 14–18 yr, 55 µg	
Zinc	Needed for DNA and RNA synthesis and other enzyme functions. Necessary for optimal wound healing.	0–6 mo, 2 mg 7 mo–3 yr, 3 mg 4–8 yr, 5 mg 9–13 yr, 8 mg Females 14–18 yr, 9 mg Males 14–18 yr, 11 mg	
Other			
Carnitine	Essential for transport of long-chain fatty acids from cytoplasm to β -oxidation sites within the mitochondrial matrix.	No established RDA	
Taurine	Nonessential amino acid that participates in controlling cellular calcium levels.	No established RDA	
Fiber	Assists in maintaining normal glucose levels and bowel regularity.	1–3 yr, 19 g 4–8 yr, 25 g Males 9–13 yr, 31 g; 14–18 yr, 38 g Females 9–18 yr, 26 g	

AMDR, acceptable macronutrient distribution range; CHD, congenital cardiac disease; EER, estimated energy requirement; GT, gastrostomy tube; NGT, nasogastric tube; RDA, recommended dietary allowance.

per day.² Diets that contain a deficient amount of carbohydrates, fats, and protein will result in poor weight gain, while linear growth is retarded when the dietary intake of protein is deficient.⁴

Fluid requirements for the normal neonate are 120 mL/kg per day for those weighing less than 3 kilograms, and 100 mL/kg per day for heavier neonates.²⁸ Once

intravenous access is secured, intravenous fluids are started at 80 mL/kg per day, and generally advanced to a goal of 100 mL/kg per day over the course of 72 hours for all neonates except those with functionally univentricular circulations, or those with excessive insensible losses, fluids in these latter cases generally being started at 100 mL/kg per hour.²⁹ Neonates with congestive heart failure have losses of fluids

up to one-sixth greater than those of a normal neonate due to their increased work of breathing, vomiting, and diuretics.²⁹ Achieving an optimal fluid balance in children with congenitally malformed hearts, therefore, is challenging, in part because of their insensible losses, but also because of the potential for protein imbalance and the role it plays in the retention of fluid.

Management of In-patients

It is axiomatic that timely nutritional support is needed for patients with congenitally malformed hearts so as to maintain an adequate nutritional state, and to minimise the physiologic consequences of undernutrition. Goals for neonates considered to be at risk, therefore, are to provide adequate nutrition to promote growth, and to correct nutrient deficiency. Goals for children include providing adequate nutrition to meet current metabolic demands, as well as for catch-up growth.³⁰ The challenge is to calculate energy requirements to maintain metabolism, this requiring 40 to 70 kcal/kg per day, as well as synthesis of tissues and storage of energy for growth, requiring an additional 50 to 70 kcal/kg per day, and to cope with routine losses of approximately 20 kcal/kg per day as well as any further expenditures related to illness.²⁸ A compromised nutritional state may delay surgical intervention and increase the risk of post-operative complications. In the neonate, poor nutrition negatively impacts cerebral development, cognitive function, and attainment of motor skills.²⁹

Types of Nutrition

Parenteral Nutrition

Parenteral nutrition and intralipids should be started when the initiation of enteral feedings is not an option for ensuring metabolic needs.²⁸ Due to the high incidence of respiratory problems, limited gastric capacity, and intestinal hypomotility of premature infants, enteral feeds should be initiated and advanced in slow fashion.²⁹ Parenteral nutrition supplements the calories provided by limited enteral feedings to ensure the nutritional needs. The nutritional content of the parenteral supply is limited by the type of vascular access available. The content of dextrose in peripheral parenteral nutrition should not exceed 12.5%, and amino acids should not exceed 2%, because of the potential of producing venous irritation. Lipid tolerance of 20% solutions is superior to that of 10% solutions due to their lower content of phospholipid emulsifiers.²⁸ For term infants born with low weight, parenteral nutrition should be instituted within the initial 3 days of life if enteral feeds are contra-indicated due to concerns of necrotizing enterocolitis or extracardiac anomalies such as tracheoesophageal fistula, duodenal atresia, and gastroschisis.²⁹ In such infants born with low weight, it has been shown that the average retention of nitrogen improved even when the intake of energy was less than 30 kcal/kg per day when protein, 1.15 g/kg per day, was initiated on the first day of life.²⁸

The rate of glomerular filtration, and the distal and proximal tubular function, are decreased in infants of less than 34 weeks of gestation. Premature infants have a decreased ability to concentrate urine compared to those born at term.⁴ This produces a risk for hyperkalaemia during the first few days of life. Electrolytes, therefore, are generally not added

to intravenous fluids for the first 24 hours of life.⁴ Neonates born at term may require supplementation of calcium over the first 24 to 48 hours after birth due to the sudden cessation of placental delivery of calcium, the decreased release of parathyroid hormone, and elevated levels of calcitonin.³⁰ Infants who are premature, infants who required phototherapy or were exposed to anticonvulsants during fetal life, and infants of diabetic mothers or mothers with a history of hyperparathyroidism are all at risk for prolonged periods of hypocalcaemia. Preventative therapy consists of doses of 25 to 75 mg/kg per day of intravenous elemental calcium added to intravenous fluid or parenteral nutrition.³⁰

For children and adolescents, parenteral nutrition and intralipids should be initiated when a delay of up to 1 week is anticipated before enteral feedings can be started.⁴ Parenteral nutrition should be implemented in children who exhibit signs of malnutrition pre-operatively to avoid deficiencies of fatty acids and to promote optimal nutrition.³⁰ If a delay of longer than 1 week is anticipated before the initiation of enteral feedings, consideration should be given to placing a central venous line so as to optimise the caloric density of the parenteral solution.⁴

Prolonged administration of parenteral nutrition is associated with cholestasis, hepatocellular necrosis, and in advanced cases, hepatic disease or cirrhosis.⁴ After 2 to 3 weeks of parenteral nutrition, infants are at risk for developing cholestasis as evidenced by hyperbilirubinaemia and elevated transaminaemia.²⁸ Older children and adolescents develop steatosis and steatohepatitis.³⁰ The severest hepatic pathological changes are found in patients with the poorest enteral intake. Enteral feedings, therefore, should be commenced as soon as possible, even if only as trophic feeds, to minimise the risk of hepatic dysfunction.⁴

Infant Nutrition

Breast Milk

The Department of Health and Human Services of the United States and the American Academy of Pediatrics recommend exclusive breast-feeding during the first year of life.^{31,32} Human milk provides optimal fat, protein, and carbohydrates for the infant born at term. Breast milk possesses anti-infective properties, reducing the incidence of acute illness, pathogenic bacterial faecal flora, necrotizing enterocolitis, otitis media, and infections of the lower respiratory and urinary tracts.³² It has been suggested that immune-mediated diseases, such as diabetes mellitus, Crohn's disease, eczema, asthma, and allergic gastroenteritis, are lower among breast-fed infants.³² The bond between mother and infant is enhanced, and cognitive scores consistently improve in direct relation to the duration of breast-feeding.³³ When the mother is unable to produce sufficient supply, or when breast-feeding is contra-indicated due to maternal health reasons, banked donor breast milk is available. Possible reasons for using donor breast milk may include prematurity, allergies, inborn errors of metabolism, and renal disease. Despite the well-known benefits of breast-feeding, infants with congenitally malformed hearts are often unable to meet their caloric needs by this method. Despite this caveat, parents should be educated about the benefits of breast milk, provided either by bottle or a supplemental device.

Commercial Formulas

Iron fortified formulas are indicated as substitutes for human milk when the mother chooses not to breast-feed or use banked donor breast milk, when breast-feeding is medically contra-indicated, and as a supplement when the intake of breast milk is inadequate.³³ Formulas based on cow's milk contain up to half more protein than does human milk. Fats are derived from vegetable oils, or a mixture of vegetable and animal fat, and the major carbohydrate source is lactose.⁴ Soy-based formulas are indicated when the family is vegetarian or the infant has a history of lactase deficiency, galactosaemia, immunoglobulin E-associated cow milk protein reaction, or suspected intolerance to cow milk-based formula as exhibited by colic, loose stools, and vomiting.⁴ The concentration of protein in soy milk-based formula is supplemented with methionine, and sucrose is the major source of carbohydrates.⁴ Protein hydrolysate formulas are designed for infants who are severely intolerant to intact cow milk or soy proteins, and for those with significant malabsorption due to gastrointestinal or hepatobiliary disease. This type of formula has the advantage that the protein is extensively hydrolysed, resulting in peptides that do not elicit an immunologic response. The disadvantages include taste, cost, and higher osmolality.⁴

Maximizing Calories

Optimizing caloric intake to meet increased hypermetabolic needs of children with cardiovascular disease can be achieved by increasing either the volume or the caloric density of the feeds, and by implementing medical and surgical interventions to manage symptoms associated with their cardiac disease. If the infant with congestive cardiac failure feeds on demand, without change in baseline symptoms and vital signs, limiting feeds is typically not warranted. If restriction of fluids is not a concern, then breast milk, or commercial formula which provides 20 calories per ounce, can be offered at an increased volume. If intake of fluid is a concern, increasing caloric density of either pumped breast milk or commercial formula should be provided (Table 66-4). Studies have reported that weight gains of infants following cardiac surgery are suboptimal and that outcomes are improved by rapid advancement of calories.³⁴ Caution is needed when increasing caloric density, however, since it can lead to decreased free water, increased osmolality, and increased solute load, resulting in an increase in output of stool and disturbed electrolytes.⁴ Renal solute load, that is, excess accumulation of nitrogen due to metabolism of proteins, may also be altered when the concentration of the formula is changed. Dehydration may then occur as the body attempts to compensate, drawing out excess water to dilute the solute load.

Methods for increasing caloric density are based on the type of nutrition. Breast milk can be fortified with human milk fortifier or a commercial formula to increase the caloric density up to the desired concentration. Use of hind milk in the neonate is recommended due to its high content of fat.³² For formulas made from powder or liquid concentrate, calories are increased by decreasing the content of water added per ounce of formula. Caloric density may also be increased by using glucose polymers, microlipid or medium-chain triacylglyceride oil, and protein supplements.

TABLE 66-4

FORMULATIONS OF CALORIE-DENSE ENTERAL NUTRITION

Caloric Density	Liquid Concentrate	Powder (Single Bottle Preparation)
20 kcal/oz	Add 13oz (390 mL) formula to 13 oz water = 780 mL final volume	Add 2 scoops powder to 4 oz water For Neocate only: add 4 scoops powder to 3.5 oz water (105 mL)
22 kcal/oz	Add 13 oz (390 mL) formula to 11 oz (330 mL) water = 24 oz (720 mL) final volume	Add 2 scoops powder to 3½ oz (110 mL) water For Neocate only: add 4 scoops powder to 3 oz water
24 kcal/oz	Add 13 oz (390 mL) formula to 9 oz (270 mL) water = 22 oz (660 mL) final volume	Add 2 scoops powder to 3½ oz water (100 mL) For Neocate only: add 3 scoops powder to 2 oz water
27 kcal/oz	Add 13 oz (390 mL) formula to 6 oz (180 mL) water = 19 oz (570 mL) final volume	Add 2 scoops powder to 3 oz water For Neocate only: add 4 scoops powder to 2.5 oz (75 mL) of water
30 kcal/oz	Add 13 oz (390 mL) formula to 4 oz water = 17 oz (510 mL)	Add 2 scoops powder to 2.5 oz (75 mL) water For Neocate only: Add 3 scoops powder to 1.5 oz (45 mL) water

Glucose polymers, such as polylose, can increase the content of carbohydrate in the feed. Medium-chain triglycerides such as microlipids can be used to optimise the content of fat, with ProMod used as a protein supplement. In order to optimise outcomes, a nutritionist should be consulted to educate families about the recipe required to achieve the prescribed caloric density.

Routes of Feeds

Oral Feeds

Breast-feeding among infants with congenitally malformed hearts, especially in those with functionally univentricular circulations, remains controversial. Several studies have attempted to evaluate how such infants tolerate breast-feeding, and whether the required gain in weight could be achieved, with some showing advantages of breast-feeding.^{35,36} Others, in contrast, have reported that bottle-fed infants gain four times the weight of breast-fed infants.^{37,38}

Difficulties in oral feeding are common in infants following cardiac surgery. Risk factors include injury to the vocal cords, prolonged intubation, low weight at the time of surgery, and surgical intervention on or in proximity to the aortic arc.³⁹ In a recent study,⁴⁰ one-fifth of children required evaluation because of intolerance during feeding, and half had documented aspiration and/or reflux requiring alternative enteral feeding, with almost half of the studied population requiring nasogastric tube feedings at the time of discharge. Risk factors for feeding difficulties included the severity of the cardiac malformation, and prolonged

post-operative intubation. Neonates with functionally univentricular physiology experienced the longest transition to oral feedings, and those with systemic-to-pulmonary shunts required alternative modalities for feeding.

Nasogastric Tube Feeds

Infants may be unable to take in sufficient calories due to uncoordinated sucking, swallowing, patterns of breathing, lack of energy stores, or the presence of gastroesophageal reflux or other medical conditions producing a risk for aspiration. These conditions warrant that feedings be provided using an alternative route. Indications for tube feedings in children include altered mental state, congenital anomalies, dysphagia, prematurity, increased metabolic needs, and failure to grow.⁴¹

Trophic feeds are defined as a small volume of enteral nutrition given at a slow continuous rate over a minimum of 5 days, usually in conjunction with parenteral nutrition.⁴² Such trophic feeds should be initiated as soon as possible to prevent bacterial translocation. Rates of infusion as low as 0.5 to 1 mL/kg per hour can prevent intestinal mucosal atrophy and loss of the functional intestinal barrier.⁴³ A systematic review of the literature⁴² showed that infants at high risk receiving trophic feeds could achieve full feedings significantly faster than a comparison group, and had a reduction in length of hospital stay, albeit that a noted slight increase in the incidence of necrotizing enterocolitis questioned the benefits of minimal enteral nutrition over the risk of developing the enterocolitis.

There is currently uncertainty regarding the use of continuous nasogastric feedings compared to bolus tube feedings. Some promote continuous tube feeding, reporting that continuous nasogastric tube feeding is associated with lower amounts of expended energy, less abdominal distention and respiratory compromise due to abdominal competition, and the ability more rapidly to achieve desired caloric intake.⁴ Proponents of bolus feedings contend that it has the advantage of normalizing the pattern of feeding and the transition to oral feeds. A randomised study comparing continuous and intermittent nasogastric feeding produced similar outcomes, with no difference in gastric distress.⁴⁴

Transpyloric Tube Feeds

Controversy also exists as to whether enteral nutrition should be delivered via the gastric or transpyloric route. Transpyloric enteral nutrition is an option when there is gastric distress, delayed gastric emptying, or an increased risk of aspiration.⁴¹ A study in adults undergoing intensive care showed that those fed by the nasojejunal route achieved a significantly higher proportion of calories, and had a lower incidence of pneumonia, when compared to those fed nasogastrically.⁴⁵ A randomised controlled trial of ventilated children showed that those receiving feedings through the small bowel achieved a greater amount of daily calories than those fed via the gastric route.⁴⁶ On the other hand, transpyloric feeds have been shown to be well tolerated, achieve the required caloric intake more quickly, and produce fewer interruptions in the regime of feeding. However, these investigators⁴⁷ noted that transpyloric feedings did not reduce complications associated with tube feedings, including gastric distress and aspiration, as well as being associated with a significant increase in necrotizing enterocolitis in cyanotic patients.

Another group⁴⁸ evaluated the efficacy of continuing enteral feedings via the transpyloric route throughout the process of weaning and extubation in the paediatric intensive care unit. This trial is contrary to the usual practice of withholding feedings for at least 4 hours prior to extubation to reduce the risk of aspiration and to ensure the airway is protected in case reintubation is required. They showed that continuous transpyloric feedings could safely be administered during the periods of weaning and extubation, permitting the patients to receive more optimal nutrition without interruption.

Feeding via Gastrostomy Tube

Percutaneous endoscopic gastrostomy is indicated to provide nutritional support in those who require long-term nasogastric feeding, display growth failure, or have neurologic impairment.⁴⁹ It is reported by some⁵⁰ to produce increased gain in weight in the majority of patients, with improved oral intake and no major complications, albeit that others observed severe complications in one-twentieth of their series of children and adolescents receiving feeding through a percutaneous gastrostomy.⁴⁹ Taken overall, nonetheless, the current data suggests that, when required, percutaneous gastrostomy is a safe and effective method of improving nutritional outcomes.^{49,50}

Delayed Enteral Feeds

The aetiology of poor gain of weight, or weight loss, in children who have undergone either corrective or palliative surgery for congenital cardiac malformations has been well investigated.^{37,51-53} Barriers related to the delivery of enteral nutrition include restriction of fluid, mechanical problems with feeding tubes, residual volumes, haemodynamic instability, and daily care. In a very recent study of 100 patients, almost half with functionally univentricular circulations, admitted to the cardiac intensive care unit, it was found that two-fifths of total enteral feeding days were provided via a nasogastric tube, and just over one-third provided via a combination of oral feeds supplemented by nasogastric tube.⁵⁴ The noted inability to achieve the targeted caloric density and weight was attributed to the frequency of interruptions, amounting to one-fifth of the total enteral feeding days, due to procedures, interventions, or gastrointestinal symptoms.

Post-operative Conditions Limiting Oral Intake

Swallowing Dysfunction

The risk of dysphagia is significantly increased in patients following surgical treatment of congenital cardiac malformations.⁵⁵ Post-operative dysphagia was diagnosed in almost one-fifth of one cohort of children studied using transoesophageal echocardiography,⁵⁶ with age less than 3 years, increased severity of illness, prolonged intubation, the size of the probe, and surgical intervention for left-sided obstructive lesions identified as risk factors. Another study⁵⁷ reported abnormal swallowing in almost half of patients following the Norwood procedure for palliation of functionally univentricular physiology.⁵⁷ The characteristics and severity of the dysfunction in swallowing can be evaluated by video fluoroscopic studies.⁵⁸ A multi-disciplinary approach, with early identification of risk factors and prompt intervention, has been suggested to lower associated morbidity and reduce length of hospital stay.⁵⁹

Paralysis of the Vocal Cords

Paralysis of the vocal cords has been reported in 2% of children under the age of 1 year undergoing cardiac surgery.⁶⁰ Such paralysis is a significant post-operative complication because it can compromise the ability of the infant to effectively swallow and increase the risk of aspiration.⁶¹ Dysfunction may be related to operative injury to the recurrent laryngeal nerve, or direct trauma from prolonged intubation.⁶⁰ The most common presenting symptom of unilateral paralysis is a weak cry following extubation. Diagnosis is made by bedside fiberoptic laryngoscopy.⁶⁰ In one series involving patients less than 12 months old, all infants had paralysis on the left side, consistent with the anatomical position of the laryngeal nerve.⁶² Strategies for management include study of swallowing to evaluate for aspiration, thickened oral feedings, and in severe cases the implementation of nasogastric or gastrostomy feedings.⁶¹

Gastroesophageal Reflux

Gastroesophageal reflux is commonly seen in children with congenitally malformed hearts, especially during the immediate post-operative period.⁴ It is characteristically seen in neonates with haemodynamically significant lesions in the setting of delayed gastric emptying. The impact of any non-cardiac factors must be identified early in life in order to institute appropriate interventions and optimise the nutritional state.⁶³ Children with congenitally malformed hearts are known to have a high rate of gastroesophageal reflux, primary aspiration, and growth failure.⁶⁴ Clinical signs include recurrent vomiting, poor weight gain, dysphasia, abdominal pain and persistent respiratory symptoms.⁶³ Diagnosis is made based on history and physical examination, study of the upper gastrointestinal tract, and monitoring of oesophageal pH, or by endoscopy and, occasionally, biopsy.⁶³

Options for treatment include prone positioning after the age of 12 months, supplementation with tube feeding, pharmacological therapies, and surgical interventions.⁶³ The use of thickened feedings, either commercially prepared or by adding cereal, remains controversial. Fewer episodes of emesis have been reported with the use of such thickened feeds, albeit that data suggests that thickened feeds may contribute to longer episodes of reflux.^{65–67} The so-called reflux index was significantly reduced when infants were placed in the prone rather than the supine position.⁶⁸

Pharmacological agents used for treatment are suppressants of acid and prokinetic agents.⁶³ The most common surgical intervention for severe and persistent symptoms is the Nissen fundoplication.⁶³ Surgical repair has been shown to be safe and effective, resulting in greater weight gain and improved oral intake.⁶⁴ Occasionally, these interventions do not alleviate the condition. In such circumstances, the patient may require supplemental feedings through a nasogastric, gastrostomy, or jejunostomy tube to achieve adequate caloric intake and growth.

When to Feed: Myths and Realities**Umbilical Arterial Catheters**

The practice of using umbilical arterial catheters is widespread, although the evidence to support the safety of concurrently introducing enteral nutrition remains controversial. A survey of neonatal intensive care directors showed

that one-sixth of neonates with such catheters in place received enteral feedings most of the time, one-third for some of the time, and half never.⁶⁸ No difference has been shown in flow through the superior mesenteric artery in neonates with or without such catheters,⁶⁹ and others have found no increased incidence of problems with feeding.⁷⁰ Despite the preliminary evidence supporting the use of enteral nutrition in premature infants with these catheters, nonetheless, the practice remains unclear.

Prostaglandin E₁

In one study, evidence of increased difficulties in feeding was observed in neonates receiving prostaglandin E₁ as a continuous intravenous infusion for longer than 2 weeks.⁷¹ Persistent gastric distention has been documented with short-term treatment at high doses, albeit that the problem resolved once the infusions were discontinued.⁷² Prolonged duration and dosing, nonetheless, is associated with an increased risk of developing obstruction of the gastric outlet.^{71–74} Neonates receiving prostaglandin E₁ therefore, should be closely monitored for signs of intolerance in feeding.

Neuromuscular Blockade

Although gastric emptying is often delayed in critically ill patients, the capacity of the gut to absorb is not reduced by the effects of neuromuscular blockade.⁷⁵ Such treatment is held by some to produce only a slight increase in abdominal distention in post-operative patients,⁷⁶ albeit that others observed abdominal distention or excessive gastric residuals in one-third of patients, with most feedings having to be discontinued.⁷⁷ The decision to provide enteral nutrition to patients receiving neuromuscular blockade, therefore, remains uncertain, as does the debate over the usefulness of gastric residuals as an indicator of feeding intolerance.

Post-operative Nutritional Challenges**Necrotizing Enterocolitis**

Infants with congenitally malformed hearts are at much greater risk for developing necrotizing enterocolitis.^{78,79} The overall incidence is reported at around 3%, but was doubled in infants with functional single ventricles.^{80,81} The aetiology is thought to reflect hypoxia and hypoperfusion of the gut.⁸² Cardiopulmonary bypass alters the intestinal barrier and increases permeability.⁸³ Reduced splanchnic flow may also contribute to its development in the post-operative period.⁸³ Infants who developed the complication had at least one other associated risk factor, including prematurity, prostaglandins infused at high doses, multiple episodes of poor systemic perfusion, and shock.⁸⁰ Medical management involves antibiotic therapy and parenteral nutrition. Surgical intervention is indicated when there is necrosis of the bowel or perforation.^{84,85}

Chylothorax

The incidence of chylothorax following surgery for congenital cardiac lesions ranges from 0.85% to 3.8%,^{86–90} and is usually the consequence of direct injury to the thoracic duct, this being the leading cause,⁸⁶ or an alteration in lymphatic flow.^{87,88} The proximity of the thoracic duct to important anatomical structures such as the aorta renders the duct vulnerable to injury during surgical procedures. Higher rates of chylous effusions occur in patients requiring the more complex surgical repairs. Strategies for

TABLE 66-5

LOW LONG-CHAIN TRIGLYCERIDE FORMULAS

Formula	Supplier	Percentage of Calories from Fat	MCT:LCT Ratio	Indications for Use
Monogen 20 kcal/oz	Nutricia	25	90:10	Infant formula. Optimal essential fats (omega-6:omega-3 = 4.6:1).
Portagen 20 kcal/oz	Mead Johnson	40	86:14	Infant formula. Taste may hinder achievement of goal volume.
Lipisorb 40.5 kcal/oz	Mead Johnson	35	85:14	Must be reconstituted to use as infant formula. Vanilla flavored.
Pregestimil 20 kcal/oz	Mead Johnson	50	55:45	Infant formula. Hypoallergenic with low renal solute load. Lactose and sucrose free.
Vivonex Pediatric 24 kcal/oz	Nestle	25	68:32	For infants and toddlers requiring hydrolyzed protein source. Lactose free.
Tolerex 30 kcal/oz	Nestle	1	0:10	For children aged 1–10 yr requiring hydrolyzed protein source. Lactose free.
Peptamen Junior 30 kcal/oz	Nestle	33	60:40	For children aged 1–10 yr. Contains 100% hydrolyzed whey peptides. Lactose free.
Vital HN 30 kcal/oz	Ross	9.4	45:55	For older children. Partially hydrolyzed protein source. Low residue and gluten free.

kcal, kilocalorie; LCT, long chain triglyceride; MCT, medium chain triglyceride; oz, ounce.

management include a low-fat diet, medium-chain triglycerides to reduce lymphatic flow, total parenteral nutrition, octreotide therapy, and surgical intervention⁸⁹ (Table 66-5). Most cases resolve with conservative nutritional management. Advanced therapies and surgical interventions are implemented for prolonged chylous drainage.^{87,88}

Special Populations

Infants Born with Low Weight

Almost one-tenth of infants are born weighing less than 2500 grams, and then pose a nutritional challenge for caregivers when also having a congenitally malformed heart.²⁹ A strong association is reported between cardiac disease and a low weight at birth, infants who are small for gestational age, and prematurity.^{11,12} Nutritional management of this group at high risk must take into account the haemodynamic impact of the congenital cardiac lesion, the degree of prematurity and its associated sequels, intra-uterine retardation of growth, and the presence of anomalies or syndromes.²⁸ Premature infants are at highest risk for developing necrotizing enterocolitis,⁹¹ with hyperosmolality of feeds, bowel ischaemia, infection, and immature intestinal host defenses all identified as potentially causative.²⁹ Studies in infants who are small for gestational age^{70,92} have documented the presence of abnormal flow in the mesenteric or umbilical arteries prior to surgical intervention, providing one explanation for the increased rate of bowel ischaemia in this population when compared to infants born at term.

Patients Requiring Mechanical Support

Parenteral nutrition has historically been the choice of support for critically ill patients on extracorporeal membrane oxygenation.⁹³ Clinicians often withhold enteral nutrition out of concern for decreased gut perfusion, hypoxia, and the vasoconstrictive effects of cardiovascular medications,⁹⁴ albeit that levels of intestinal hormones were shown to be

comparable in neonates supported or not supported with extracorporeal oxygenation.⁹⁵ Several studies of critically ill children and adults supported either with venoarterial or venovenous oxygenation have shown that enteral nutrition is generally well tolerated, producing no serious adverse events.^{95–98}

Patients supported by a ventricular assist device, however, suffer from a variety of conditions associated with cardiac failure, which place them at risk for malnutrition.^{99,100} Conditions include poor pre-operative nutritional state, anorexia, nausea, and early satiety from the weight of the intra-abdominally implanted device as well as delayed gastric emptying.¹⁰¹ The determination of nutritional requirements must take into account their pre-operative nutritional state as well as their current health. The Society of Critical Care Medicine supports use of evidence-based protocols for feeding.¹⁰¹ Such a standardised regime has been developed for adults who require support with a ventricular assist device.¹⁰² In conjunction with the interdisciplinary team that includes a registered dietician, nutritional management for each patient is determined by the score they receive based on severity of illness and a subjective global assessment of the degree of malnutrition. Once a score is assigned, requirements are calculated for calories and proteins, and enteral feedings are started at low levels and advanced while maintaining metabolic stability. Due to the generally poor nutritional state of such patients, enteral nutrition should be started as soon as possible. If enteral feedings are not tolerated, parenteral nutrition should be initiated.¹⁰²

Nutritional Challenges for the Out-patient

Challenges for these patients vary depending on their baseline, their current metabolic needs taking into account the presence of a residual cardiac defect or progression of disease, and the need for catch-up growth.

The latter requirements can be as high as one and a half to two times the daily allowances for age.¹⁶ If optimal nutrition is achieved, steady gain in weight will occur until the desired weight for height is achieved, and then weight and height should increase together at a slower rate. Infants who suffered from malnutrition prior to surgery were found to require nasogastric or nasoduodenal feeds of 140 to 200 kcal/kg per day to allow for catch-up growth.^{3,28} Full-term infants whose nutritional status was optimised pre-operatively may still require 120 kcal/kg per day to meet metabolic needs and for catch up growth.^{1,18} Caloric intake should be adjusted based on the rate of gain in weight, especially in children who undergo biventricular repairs. Older children and adolescents may also require oral or nasogastric nutritional supplementation to their regular diet to achieve targeted caloric intake for catch-up growth.

Infants with functionally single ventricles display the slowest gain despite attempts to optimise caloric intake. Profound disturbance of splanchnic perfusion has been documented in such infants receiving palliation with a systemic-to-pulmonary arterial shunt.⁹² The basal and postprandial flow in the superior mesenteric artery is either absent or reversed in diastole, implying that the resistance of the splanchnic circulation is lowered in attempts to counteract a diastolic steal. This adaptive mechanism may operate at the expense of a reduction in splanchnic flow reserve, and continue to place such patients at risk for intestinal hypoperfusion.⁹²

The prevalence of risk factors for, and the type of delayed growth experienced by, children with congenitally malformed hearts is well studied. One such investigation used retrospective review of charts to determine the prevalence of risk factors for malnutrition after palliative surgery for hypoplastic left heart syndrome.¹⁰³ Adjusting for weight on admission, longer length of hospital stay, longer intensive care unit stay, shorter duration of parenteral nutrition, and higher diuretic doses at discharge were all factors associated with lower weight for age *z* scores at discharge. The risk factors for lack of change in median weight from the admission weight until discharge reflect high patient acuity and therefore, it is not unexpected that this group would experience minimal to no weight gain by discharge. Weight was noted to decrease over time, with the results of this investigation endorsed in a similar study.¹⁰⁴

Special Population: Those with the Fontan Circulation

Although palliation of the child with functionally univentricular physiology by means of staging to the Fontan circulation reduces the adverse effects of hypoxaemia and the prolonged ventricular volume overload, this group of children continue to have poor somatic growth.^{105–107} An accelerated weight gain was noted after conversion to the Fontan circulation prior to the age of 4 years, and while height did improve after conversion, it never normalised.¹⁰⁶ Feeding difficulties were reported in one-third of patients prior to construction of the bidirectional Glenn shunt, in one-fifth prior to conversion to the Fontan circulation, and in one-twentieth even after conversion.¹⁰⁷

Another study, comparing serial measurements of weight and height before and after the Fontan operation, showed significant improvements when compared to pre-operative

measurements.¹⁰⁸ This study found that improved somatic growth was best noted in patients with tricuspid atresia, and did not correlate with either the timing, or the type, of the Fontan circulation. The severity of illness, however, adversely affected somatic growth, with prior atrioseptectomy, construction of a central shunt, and reconstruction of the pulmonary arteries all associated with impaired gains in weight and height.¹⁰⁸

In general, children with congenitally malformed hearts have abnormal skeletal and muscular development compared to healthy children.¹⁰⁹ After corrective surgery, the skeletal mass is normal except for patients with functionally univentricular physiology. This may be due to decreased physical activity that starts from birth and limits stimulation of skeletal development, as well as an alteration in levels of growth hormones.¹⁰⁹

Ensuring optimal nutritional intake for this population is extremely challenging given the developmental stage of the children. This is even more so for children who develop protein-losing enteropathy.¹¹⁰ A host of gastrointestinal symptoms develop from the loss of protein, including diarrhoea, crampy abdominal pain, ascites, and failure to thrive.¹¹¹ For children who develop protein losing enteropathy following the Fontan operation, dietary intake must meet the metabolic demands of the intercurrent illness, provide for catch up growth, and also act as a form of treatment. While a diet high in protein may replenish enteric losses, it will have little impact on levels of protein in the serum.¹¹⁰ A diet low in fat and high in medium chain triglycerides can lead to a reduction in intestinal lymphatic flow and reduce losses of protein. Occasionally, parenteral nutrition must be initiated due to the need to rest the bowel in the setting of severe diarrhoea and intolerance of oral intake. Caution must be taken, nonetheless, for patients who require long-term indwelling venous access for parenteral administration of nutritional needs due to the high risk of venous thromboembolism in this population.¹¹⁰

OBESITY AND CONGENITAL CARDIAC DISEASE

Childhood obesity has become one of the most serious global challenges to health of the 21st century.¹¹² The World Health Organization estimates that, in 2007, 22 million children under the age of 5 were overweight throughout the world.¹¹³ The Centers for Disease Control recently reported an increase of almost half in the prevalence of obese children in the past decade.¹¹⁴ The sequels of obesity have been well documented in the adult literature, and studies in children have revealed similar complications, such as systemic hypertension, inflammation, metabolic syndrome, and type 2 diabetes. Cardiovascular changes include increases in left ventricular mass related to increased workload, endothelial dysfunction, and changes in diastolic function. Childhood obesity is one of the major predictors for obesity, coronary arterial disease, and premature death in adults.¹¹²

The prevalence of overweight and obese children is alarming, and has expanded to children with chronic illness.¹¹² Patients who are overweight or obese add an additional risk for mortality and morbidity on top of the risk associated with progression of their chronic illness.

Overweight or obese children with congenitally malformed hearts are no exception. Limited data exists on the incidence and impact of obesity on such children. In one study, one-quarter of children aged from 6 to 19 years seen in two large paediatric cardiac centers were found to be obese or overweight.¹¹⁵ Rates were significantly less in those with the Fontan circulation. Systolic blood pressures were found to be significantly higher in overweight and obese patients with all forms of congenital cardiac disease. When exploring the associated risks to ongoing health, these investigators noted that coronary arterial and vascular abnormalities could be exacerbated by the endothelial dysfunction and hypertension associated with obesity, with those having manipulation or surgery to their coronary arteries being at increased risk for development of atherosclerosis in adulthood. Those with valvar or ventricular dysfunction who are hypertensive secondary to obesity may also worsen their current haemodynamic status. Obese patients who have been converted to the Fontan circulation may suffer the consequences of having an increased afterload and ventricular mass.¹¹⁵ Another study¹¹⁶ found rates of obesity and increased weight similar to those in normal children, with exercise intolerance greater amongst those who were obese. Patients who were advised to restrict their activity were even more likely to become either overweight or obese. In addition, patients in whom activity was restricted experienced faster growth in body mass index. It was suggested that the reduced activity of these children could be due to caloric storage from an unchanged dietary intake despite the new restriction of activity and lower caloric expenditure.¹¹⁶

Another study examined the medical records of patients listed for cardiac transplantation.¹¹⁷ Of these patients, one-eighth were obese, irrespective of the diagnosis being congenital cardiac disease or cardiomyopathy. The proportion of ideal body weight was found to be a prognostic factor for early survival after transplantation. Surprisingly, wasting, defined as a less than 90% ideal body weight, was associated with the lowest mortality compared to those with normal body habitus. No differences were noted for subsequent morbidities such as acute rejection, infection, or graft vasculopathy.¹¹⁷

Children with cardiac disease, therefore, are at a higher risk for developing cardiovascular complications associated with obesity. Paediatric cardiologists who have traditionally focused on evaluating the adequacy of the surgery and progression of congenital disease are now faced with managing the sequels of a preventable disease. Preventative counseling must be implemented on the basis of age, the degree of excess weight, and the presence of comorbidities. Recommendations should be made for changes in diet and physical activity that can be implemented within the culture, living environment, and socioeconomic state of the family.

The major goals in dietary management are to provide adequate calories and optimal nutrition for normal growth and development, and to sustain healthy eating habits. A well-defined programme for exercise should be developed for each individual patient based on the severity of the cardiac disease. Children with mild forms of disease should be allowed to participate in most sports. Participation in some form of intermediate sport for the child with moderate disease should be based on an individual assessment, as well as exercise testing. For children with severe

forms of disease, specific programmes delineating the type of sport, and limitations, should be developed on an individual basis.

SUMMARY

Malnutrition and failure to grow are major concerns for children with congenitally malformed hearts. The causes of abnormal growth are multi-factorial. Obstacles to providing adequate enteral nutrition include individual variations in practice, underprescription of enteral nutrition, and frequent interruptions in the delivery of feedings,^{65,66} with studies showing that critically ill patients receive only half to two-thirds of their caloric requirements.^{67,68} The population of children with functionally univentricular circulations is at the highest risk for retarded growth.

Recognition of such delayed growth is the first step in optimizing outcomes for children with cardiovascular disease. It is the responsibility of the interdisciplinary team to make nutritional management a high priority in the plan of care for infants and children with congenitally malformed hearts. Medical and nutritional risk factors must be identified for each individual. Evidence-based protocols focusing on initiation of early enteral nutrition can improve clinical outcomes, and reduce barriers to providing optimal nutrition in critically ill children.

Due to the risk factors of inadequate or excessive nutrition in this population, nutritional evaluations should be incorporated into each visit to the out-patient department. Anthropometric measures should be obtained to guide nutritional management. Strategies should be targeted towards identifying caloric goals which account for baseline nutritional state, current metabolic needs, and catch-up growth. Achieving adequate nutrition will ensure optimal outcomes of physical, cognitive, and motor development.

ANNOTATED REFERENCES

- Nydegger A, Bines J: Energy metabolism in infants with congenital heart disease. *Nutrition* 2006;22:697–704.
In this work, Nydegger and Bines reviewed the literature from all researchers investigating energy metabolism and congenital cardiac disease. Despite various methodologies and end points, the majority of studies concluded that energetic imbalance is a major contributor to the retardation of growth exhibited by children with congenitally malformed hearts. The age of the child, and timing of corrective surgery, affects the potential for nutritional recovery.
- Varan B, Tokel K, Yilmaz G: Malnutrition and growth failure in cyanotic and acyanotic congenital heart disease with and without pulmonary hypertension. *Arch Dis Child* 1999;81:49–52.
In this study, the investigators showed that pulmonary hypertension appears to be an important risk factor for delayed growth in children with congenitally malformed hearts. Children with cyanotic lesions and pulmonary hypertension suffered the most significant retardation of their growth. This is the first study to examine the effects of both hypoxia and pulmonary hypertension on growth.
- Li J, Zhang G, Gerridge J, et al: Energy expenditure and caloric and protein intake in infants following the Norwood procedure. *Pediatr Crit Care Med* 2008;9:55–61.
In this study, Jia Li and associates demonstrated that intake of calories and protein was insufficient to meet energy expended during the first 2 days following the Norwood procedure. This deficit is attributed to a hypermetabolic response triggered by cardiopulmonary bypass and requirements for energy following surgical repair.
- Ades A, Johnson BA, Berger S: Management of low birth weight infants with congenital heart disease. *Clin Perinatol* 2005;32:999–1015.

In this work, Anne Ades and colleagues reviewed the impact of low birth weight on outcomes following surgical correction of congenital cardiac disease. Causes of postnatal failure to gain weight are discussed, along with strategies for management.

- Einarson KD, Arthur HM: Predictors of oral feeding difficulty in cardiac surgical infants. *Pediatr Nurs* 2003;29:315–319.

The time to discharge from hospital for infants after open heart surgery is contingent on the ability to consume and tolerate enteral nutrition. This study identifies factors influencing oral feedings in infants less than 1 month of age following congenital cardiac surgery. The authors determined that difficulties in feeding occurred most often in infants with injured vocal cords, prolonged intubation, and low weight at the time of surgical intervention.

- Kogon BE, Ramaswamy V, Todd K, et al: Feeding difficulty in newborns following congenital heart surgery. *Congenit Heart Dis* 2007;2:332–337.

In this study, the investigators showed that difficulties in feeding were common after congenital cardiac surgery, especially in patients with complex disease and those requiring prolonged intubation. A significant number of patients required a prolonged time to reach the goals of feeding, prolonged time to transition to oral feeds, and procedures to facilitate feeding.

- Meert KL, Daphtary KM, Metheny NA: Gastric vs small-bowel feeding in critically ill children receiving mechanical ventilation: A randomized controlled trial. *Chest* 2004;126:872–878.

This randomised clinical trial evaluated the effect of positioning a feeding tube in the stomach as opposed to the small bowel on the delivery of nutrition and associated complications in critically ill children. The authors found a significant increase in the amount of nutrition delivered in those having the tube placed in the small bowel, but found no difference in the tolerance of feedings or aspiration.

- McElhinney DB, Hedrick HL, Bush DM, et al: Necrotizing enterocolitis in neonates with congenital heart disease: Risk factors and outcomes. *Pediatrics* 2000;106:1080–1087.

This study demonstrated that risk factors for developing necrotizing enterocolitis include prematurity, hypoplastic left heart syndrome, common arterial trunk, and periods of low cardiac output. Necrotizing enterocolitis led to longer stays in hospital, but was not associated with higher mortality.

- Chan EH, Russell JL, Williams WG, et al: Postoperative chylothorax after cardiothoracic surgery in children. *Ann Thorac Surg* 2005;80:1864–1870.

In this study the authors identified the incidence of chylothorax in children following congenital cardiac surgery, and discuss risk factors and strategies for management, including a care map. The documented increased incidence may be related to differences in the characteristics of the patients and more complex surgical procedures.

- Vogt K, Manlhiot C, Van Arsdell G, et al: Somatic growth in children with single ventricle physiology. *J Am Coll Cardiol* 2007;50:1876–1883.

In this study, the investigators showed that infants with functionally univentricular physiology have impaired gain in weight, but that catch-up growth occurred after the bidirectional Glenn procedure. The group at highest risk included those with systemic venous collateral channels.

- Ono M, Dietmar B, Goerler H, et al: Somatic development long after the Fontan operation: Factors influencing catch-up growth. *J Thorac Cardiovasc Surg* 2007;134:1199–1206.

In this study, the investigators showed that somatic growth declined before conversion to the Fontan circulation, but catch-up growth occurred during long-term follow-up. Early unloading appeared to be related to improved somatic growth. A prior atrioseptectomy, construction of a central shunt, and reconstruction of the pulmonary arteries were all associated with impaired growth.

- Rychik J: Protein-losing enteropathy after Fontan operation. *Congenit Heart Dis* 2007;2:288–300.

In this work, Jack Rychik proposed a causative theory that includes a combination of mechanisms leading to the development of protein losing enteropathy following conversion to the Fontan circulation. These conditions include altered haemodynamics, mesenteric vascular resistance, and enterocyte basal membrane glycosaminoglycan, as well as systemic inflammation. Manifestations of the disease and clinical management are discussed.

- Pinto NM, Marino BS, Wernovsky G, et al: Obesity is a common comorbidity in children with congenital and acquired heart disease. *Pediatrics* 2007;120:e1157–e1164.

In this study, Nelangi Pinto and colleagues showed that obesity is common in children with congenitally malformed hearts. The long-term impact of obesity on various types of congenital cardiac disease is discussed, as well as the implications for out-patient follow-up and treatment.

Formulary

EDWARD J. BAKER

Clinical trials of medicines for children have been limited, and often therapeutic decisions are made on the basis of evidence of efficacy and safety in adult patients. Caution in the use of new, unlicensed medicines, without evidence in children is therefore inevitable. This means that the choice of medicines is much more limited than in adult practice. Here, I present a summary of medicines commonly used for cardiovascular disorders in children ([Table 67-1](#)). This list does not attempt to be comprehensive, as practice will vary internationally, and some drugs in common use in one part of the world are hardly used elsewhere. The paucity of evidence makes this unavoidable. This summary, therefore, is not a replacement for local guidelines. To avoid confusion, I have used the recommended international non-proprietary names for the medicines covered. Where there is a common alternative name, I have included it, but

I have not tried to include local or proprietary names, as these vary internationally.

I have included the important cardiac indications for the medicines covered, and their major contra-indications and side effects. I have not been able to cover all possibilities, and readers are advised to consult detailed prescribing information and the information sheets for these medicines before prescribing them. As a guide, I have included the typical regime for dosing children between birth and 10 years, but prescribers should consult their local guidelines for more details, particularly for preterm neonates and older children, for whom the dosage may vary. The formulary does not include medicines that have a much wider application than cardiac conditions, such as antibiotics and anti-coagulants, but focuses purely on the cardiovascular use of the drugs described.

TABLE 67-1

SUMMARY OF MEDICINES COMMONLY USED FOR CARDIOVASCULAR DISORDERS IN CHILDREN

Drug	Indications	Contra-indications	Major Side Effects	Typical Dose and Frequency	Comments
Adenosine	Diagnosis of arrhythmias and termination of supraventricular arrhythmias	Heart block, asthma	Chest pain, dyspnoea, bronchospasm, severe bradycardia	Fast intravenous bolus of 100 µg/kg to maximum of 300 µg/kg for the neonate, or 500 µg/kg for the older child	Electrocardiographic monitoring and recording during the administration of the bolus is essential. The bolus can be repeated after 2 minutes with the dose increased progressively until electrocardiographic changes occur.
Alprostadil (prostaglandin E ₁)	Maintenance of the patency of the ductus arteriosus in the neonate		Apnoea, tachycardia, hypotension, fever, cortical proliferation of long bones, necrotising enterocolitis	Intravenous infusion of initially 10 ng/kg per minute, can be increased to 50 ng/kg per minute according to response	Monitor heart rate, respiration, and temperature. Ventilation may be required for apnoea.
Amiloride	Potassium sparing diuretic	Hyperkalaemia, renal failure	Hyponatraemia, hyperkalaemia, hypotension	Orally 200 µg/kg twice per day Maximum of 20 mg per day	Weak diuretic used in combination with thiazide or loop diuretics
Amiodarone	Supraventricular and ventricular arrhythmias	Bradycardia, heart block, hypotension	Bradycardia, thyroid disorders, hepatotoxicity, corneal microdeposits, photosensitivity, gray skin discolouration, neuropathy, anaemia	Orally initially 5 mg/kg two to three times per day, reduce to maintenance dose after 7 days Maintenance 5 mg/kg once per day or based on measurement of plasma levels Intravenous infusion initially 25 µg/kg per hour for 4 hours then 5 to 15 µg/kg per minute. Maximum of 1.2 g per day	Long-term administration should be avoided because of the incidence of side effects. Careful monitoring of hepatic, thyroid and visual function is required. Photosensitivity and skin discolouration can be severe, and sun block is required. Monitor the heart rate during intravenous infusions, and adjust the dose as necessary. Therapeutic plasma level of amiodarone and its active metabolite is 0.6 to 2.5 mg/L.
Aspirin	Low-dose antiplatelet prophylaxis against thrombosis High dose anti-inflammatory agent for Kawasaki disease	Viral infections, with the risk of Reye's syndrome, peptic ulceration bleeding disorders	Reye's syndrome, bleeding especially gastrointestinal, bronchospasm	Low-dose antiplatelet: orally 5 mg/kg (maximum of 75 mg) once per day High-dose antiplatelet: orally 20 to 25 mg/kg 4 times per day for approximately 14 days, then reduce to low dose	High-dose aspirin is also used in acute rheumatic fever (see Chapter 54A) and post-pericardectomy syndrome (see Chapter 53).
Atenolol	Hypertension, supraventricular and ventricular tachycardias	Asthma, heart block, hypotension, depressed myocardial function	Bradycardia, heart failure, bronchospasm, heart block, peripheral vasoconstriction, fatigue	Orally 1 to 2 mg/kg once per day Maximum of 100 mg per day	Use smaller doses in renal and hepatic impairment.
Captopril	Cardiac failure, hypertension	Renal impairment, renovascular disease, coarctation, left ventricular outflow or inflow obstruction	Hypotension particularly with initial doses, renal impairment, tachycardia, photosensitivity, persistent dry cough	Orally initially 100 µg/kg three times per day, increasing to 1 mg/kg three times per day	ACE inhibitor, in heart failure usually combined with a loop diuretic. Do not give with potassium sparing diuretics. Initiate carefully under close supervision, usually in an in-patient to ensure close monitoring of blood pressure and renal function.
Carvedilol	Cardiac failure	Asthma, heart block, hypotension, depressed myocardial function	Bradycardia, cardiac failure, bronchospasm, heart block, peripheral vasoconstriction, fatigue	Orally initially 50 µg/kg (maximum of 3.125 mg) twice per day. Increase at 2-week intervals eventually up to 350 µg/kg (maximum of 25 mg) twice per day	Used as a third-line treatment for chronic cardiac failure as an adjunct to diuretics and inhibitors of angiotensin-converting enzyme. As yet, there is no evidence of long-term benefit in children.
Clopidogrel	Antiplatelet prophylaxis against thrombosis as an alternative to low-dose aspirin		Haemorrhage, neutropenia	Orally 1 mg/kg once per day (maximum of 75 mg)	Used as a second-line treatment after aspirin

Digoxin	Supraventricular arrhythmias, cardiac failure	Heart block, renal failure, Wolff-Parkinson-White syndrome, ventricular tachycardia	Anorexia, abdominal pain, heart block, arrhythmias	Orally, neonates to 5 years: 10 µg/kg/day Children 5 to 10 years: 6 µg/kg/day Maximum 250 µg/day	In urgent circumstances, loading doses (digitalisation) may be needed over first 24 hours. Dose should be reduced in preterm neonates and renal failure. Is of limited value in cardiac failure, and rarely used as first choice Intravenous administration is rarely justified. Therapeutic plasma digoxin concentration 0.8 to 2.0 µg/L
Dinoprostone (prostaglandin E ₂)	Maintaining the patency of the ductus arteriosus in the neonate		Apnoea, tachycardia, hypotension, fever, cortical proliferation of long bones, necrotising enterocolitis	Intravenous infusion of initially 5 ng/kg/min, can be increased to 20 ng/kg/min according to response	Monitor heart rate, respiration, and temperature. Ventilation may be required for apnoea.
Dipyridamole	Antiplatelet prophylaxis against thrombosis as an alternative to low-dose aspirin	Heart failure, aortic stenosis	Hypotension, tachycardia, bronchospasm	Orally 2.5 mg/kg twice per day Over age 12 years: 100 to 200 mg three times per day	Dipyridamole has also been used to treat pulmonary hypertension. Antiplatelet action may be synergistic with aspirin.
Dobutamine	Inotropic support in low cardiac output	Left ventricular outflow obstruction	Tachycardia, hypotension	Intravenous infusion 2 to 20 µg/kg/min	
Dopamine	Hypotension and low cardiac output	Tachycardia, arrhythmia	Hypertension, tachycardia, arrhythmias	Intravenous infusion 2 to 20 µg/kg/min	There is little evidence that low doses have beneficial vasodilatory effects in clinical practice.
Enalapril	Heart failure, hypertension	Renal impairment, renovascular disease, coarctation, left ventricular outflow or inflow obstruction	Hypotension particularly with initial doses, renal impairment, tachycardia, Raynaud's syndrome, Stevens-Johnson syndrome, alopecia, muscle cramps, persistent dry cough	Orally initially 0.1 mg/kg/day, increasing according to response up to a maximum of 1.0 mg/kg/day	ACE inhibitor, in heart failure usually combined with a loop diuretic. Do not give with potassium sparing diuretics. Initiate carefully under close supervision, usually as an in-patient to ensure close monitoring of blood pressure and renal function.
Epinephrine (adrenaline)	Acute hypotension	Hypertension	Tachycardia, hypertension, arrhythmias	Intravenous infusion of 100 ng/kg/min, up to 1.5 µg/kg/min	
Esmolol	Emergency management of arrhythmias and hypertension, cyanotic spells in tetralogy of Fallot	Asthma, heart block, hypotension, depressed myocardial function	Bradycardia, heart failure, bronchospasm, heart block	Intravenously initial dose of 500 µg/kg administered over 1 to 2 minutes Can be followed by an infusion of 25 to 50 µg/kg/min Can be increased to a maximum of 200 µg/kg/min in resistant cases	Relatively cardioselective β-blocker Reduce dose if hypotension or bradycardia occurs. Higher dose of infusion may be required to terminate severe cyanotic spells in tetralogy of Fallot.
Flecainide	Ventricular tachycardia, arrhythmias in Wolff-Parkinson-White syndrome, atrioventricular re-entry tachycardias	Heart failure, heart block, hypokalaemia	Precipitation of life-threatening arrhythmias particularly in structural heart disease Depression of myocardial function especially when used with β-blockers or calcium-channel blockers	Orally 2 mg/kg two to three times per day Adjust dose according to plasma levels Intravenously 2 mg/kg per dose Infusion of 100 to 250 µg/kg/hr until arrhythmia controlled (maximum total dose of 600 mg in first day)	Monitor electrocardiogram during slow intravenous administration. If intravenous infusion lasts more than 24 hours, monitor plasma levels (therapeutic range 200 to 800 µg/L).

(Continued)

TABLE 67-1

SUMMARY OF MEDICINES COMMONLY USED FOR CARDIOVASCULAR DISORDERS IN CHILDREN—CONT'D

Drug	Indications	Contra-indications	Major Side Effects	Typical Dose and Frequency	Comments
Furosemide (frusemide)	Cardiac failure, pulmonary oedema, hypertension	Hypokalaemia, hypotension	Hyponatraemia, hypokalaemia, hypomagnesaemia, nephrocalcinosis, hypotension, deafness (with rapid intravenous infusion)	Orally 0.5 to 2 mg/kg two to three times per day (maximum of 12 mg/kg/day or 80 mg/day in total, whichever is lower) Intravenously 0.5 to 1 mg/kg up to four times per day, or continuous infusion of 0.1 to 2 mg/kg/hr	In oliguria, much higher doses may be needed, titrated against the urine output.
Ibuprofen	Closure of the patent arterial duct in preterm neonates	Hepatic impairment, pulmonary hypertension, bleeding disorders, necrotising enterocolitis, infection	Bleeding especially intracranial bleeding, renal impairment, necrotising enterocolitis	Slow intravenous infusion of 10 mg/kg Second and third doses at 24 and 48 hours of 5 mg/kg	Reduce dose with renal impairment, and monitor hepatic function.
Indomethacin	Closure of the patent arterial duct in preterm neonates	Renal impairment, infection, bleeding, especially intracranial bleeding, necrotising enterocolitis	Haemorrhage, including intracranial bleeding, oliguria or anuria, fluid retention	Intravenous infusion over 30 minutes Neonate under 48 hours: 200 µg, followed by two doses of 100 µg separated by 12 to 24 hours Neonate 2 to 7 days: 200 µg, followed by two doses of 200 µg separated by 12 to 24 hours Neonate over 7 days: 200 µg, followed by two doses of 250 µg separated by 12 to 24 hours	Monitor urinary output, and delay second and third doses until it recovers. Indomethacin is also used as an anti-inflammatory agent in post-pericardiectomy syndrome.
Isoprenaline	Bradycardia, complete heart block	Hypotension	Hypotension, tachycardia, arrhythmias	0.02 µg/kg/min increasing to a maximum of 0.5 µg/min (neonate maximum of 0.2 µg/kg/min)	
Lidocaine (lignocaine)	Ventricular fibrillation, ventricular tachycardia	Heart block, myocardial dysfunction, hepatic failure, renal failure	Central nervous system depression, respiratory depression, hypotension bradycardia	Intravenous bolus of 500 µg to 1 mg/kg over 1 minute Repeat at 5-minute intervals up to a maximum of 3 mg/kg, followed by an intravenous infusion of 1 to 3 mg/kg/hr	Monitor electrocardiogram during administration. Reduce dose in presence of hepatic or renal impairment.
Lisinopril	Heart failure, hypertension	Renal impairment, renovascular disease, coarctation, left ventricular outflow or inflow obstruction	Hypotension particularly with initial doses, renal impairment, tachycardia, alopecia, persistent dry cough	Orally initially 0.1 mg/kg/day, increasing according to response to 0.5 to 1.0 mg/kg/day. Maximum 40 mg/day	ACE inhibitor; in heart failure usually combined with a loop diuretic. Do not give with potassium sparing diuretics. Initiate carefully under close supervision, usually as an in-patient to ensure close monitoring of blood pressure and renal function.
Losartan	Heart failure, hypertension	Renal impairment, renovascular disease, coarctation, left ventricular outflow or inflow obstruction	First-dose hypotension, hyperkalaemia	Orally 0.5 mg/kg once per day, increasing to a maximum of 2 mg/kg once per day	Angiotensin II receptor antagonist with similar effects to inhibitors of angiotensin-converting enzyme, but it does not cause the characteristic dry cough of the inhibitors of the enzyme and is a useful alternative. Use a lower dose in renal or hepatic impairment. Introduce with caution because of the risk of hypotension

Milrinone	Heart failure, low cardiac output, shock	Renal failure, hypotension	Arrhythmias, hypotension	Intravenous infusion of 30 to 45 µg/kg/hr	Phosphodiesterase inhibitor with positive inotropic and vasodilator effects Loading dose of 50 to 75 µg/kg for first hour, omit if hypotension occurs Reduce dose in renal failure. Short-term use only
Norepinephrine (nor-adrenaline)	Hypotension secondary to severe vasodilation	Hypertension	Hypertension, severe vasoconstriction and peripheral ischaemia, arrhythmias	20 to 100 ng/kg/min up to maximum of 1 µg/kg/min	
Propranolol	Hypertension, supraventricular and ventricular tachycardias, cyanotic spells in tetralogy of Fallot	Asthma, heart block, hypotension, depressed myocardial function	Bradycardia, heart failure, bronchospasm, heart block, peripheral vasoconstriction, fatigue	Tetralogy of Fallot: intravenously 15 to 20 µg/kg, increasing to 100 to 200 µg/kg given slowly under electrocardiographic control Arrhythmias: orally 250 to 500 µg/kg three times per day Can increase up to 1 mg/kg three times per day Intravenously 10 to 50 µg/kg slowly under electrocardiographic control	Do not give with verapamil. Use smaller doses in renal and hepatic impairment.
Sildenafil	Pulmonary hypertension	Hypotension	Dyspepsia, headache, visual disturbances, priapism	Orally 0.5 mg/kg every 4 to 6 hours, increasing according to response to a maximum of 2 mg/kg every 4 hours	Reduce dose in hepatic or renal impairment. Used to treat pulmonary hypertension following cardiac surgery and to wean from inhaled nitric oxide
Sotalol	Atrial flutter, supraventricular and ventricular tachycardias	Asthma, heart block, hypotension, depressed myocardial function, hypokalaemia, hypomagnesaemia, prolonged QT interval	Bradycardia, heart failure, bronchospasm, heart block, arrhythmias, prolongation of QT interval, torsades de pointes	Orally 1 mg/kg twice daily, increasing as needed every 3 to 4 days to maximum of 4 mg/kg twice per day (maximum of 80 mg twice per day)	Monitor the QT interval. Do not administer with other drugs that prolong the QT interval. Therapeutic range is 0.04 to 2.0 mg/L
Spironolactone	Potassium sparing diuretic (aldosterone antagonist)	Hyperkalaemia, hyponatraemia	Hyperkalaemia, hyponatraemia, hepatotoxicity, gynaecomastia, osteomalacia	Orally 0.5 to 1 mg/kg up to three times per day	Typically used with loop diuretics Should not be given simultaneously with inhibitors of angiotensin-converting enzyme

 colour Doppler myocardial imaging and, 83
 Doppler tissue imaging and, 82–83
 M-mode measures of atrioventricular ring
 displacement and, 82
 pulsed Doppler assessment of, 83, 84f
 speckle tracking and, 83
 β -myosin and, 75
 systolic function of, 81
 troponin and, 75
- Fetal heart rate, variability of, 86–87, 87f, 88f
- Fetal hydrops, direct fetal treatment of for, 206
- Fetal intervention for hypoplasia of the right
 ventricle, 660
- Fetal left ventricular inflow obstruction, atrial
 septostomy for, 216, 217f
- Fetal pressure-volume loops, 85–86, 86f, 87f
- Fetal pulmonary valvuloplasty
 patient selection for, 215
 reasons for, 214–215
 results and outcome with, 215–216, 216f
 technique of, 215, 215f
- Fetal structural cardiac disease, catheter
 intervention for, 210
- Fetal vascular programming, 87–89
 following fetal coarctation, 89, 89f
 restricted growth and, 88–89
 in twin-twin transfusion syndrome, 89
- Fetal ventriculo-vascular coupling, 85–87
- Fetoplacental circulation, 76
- Fetus
 cardiac development in, 77–81
 cerebrovascular physiology of, 1270, 1271f
 listing for transplantation, 278–279
 systemic pressures in, 85, 86f
 tachyarrhythmia in, 199–206
 treatment of, 200, 201t, 202t
 thyrotoxicosis in, 206–207
 vascular physiology of, assessment of, 84–85
- Fever
 in infective endocarditis, 1138
 in rheumatic fever, 1104
- Fibre, infant requirement for, 1288t
- Fibrillin, arteries and, 91–92
- Fibrillin-1 genotype, arterial dysfunction and,
 111–112
- Fibromas, cardiac, 1062, 1062f
- Fibrous skeleton of heart, 30–31, 30f
- Filters for cardiopulmonary bypass, 229–230
- Fistulas
 arterio-venous, coronary, 1037–1043
 clinical features of, 1038–1039
 investigations in, 1039, 1039f, 1040f
 management of, 1040–1043, 1041f, 1042f
 morphology of, 1037–1038, 1037f, 1038f
 pathophysiology of, 1038
 coronary arterial, 938–940, 939f
- Flecainide, 385, 1300t
 for tachyarrhythmia, fetal, 201t, 202t, 204–205
- Fluid(s), infant requirement for, 1288t
- Fluid management for haemodynamically
 significant arterial duct, 187
- Fluoroscopy, radiation risk and, 398
- Folate, infant requirement for, 1288t
- Fontan circulation
 exercise testing and, 434–435
 for hypoplasia of the right ventricle, 660
 for isomeric atrial appendages, 482
 mechanical ventilation and, 242, 243t
 neurological outcomes following, 1275–1276
 nutrition and, 1296
 physiology of, 115, 691–693
 in pregnancy, 1234
 pulmonary hypertension and, 1150, 1154–1155
 for univentricular hearts, 689, 690t
 complications of, 693–695
 arrhythmias as, 693
 cyanosis as, 694
 exercise intolerance as, 694
 hepatic dysfunction as, 693–694
 plastic bronchitis as, 694–695, 695f
 protein-losing enteropathy as, 694
 thrombo-embolic events as, 693–694
- failure of
 cardiac transplantation for, 695
 revision of circuit for, 695
 long-term outcomes of, 690–691
 modifications of, 689–690
 physiology of, 691–693
 basic principles of, 691
 pulmonary vascular bed and, 693
 systemic vascular bed and, 692
 veno-pulmonary circuit and, 692–693
 ventricle and, 691–692
 ventricular-vascular coupling and, 692
- Forearm resistance vessels, endothelial function
 assessment of, 104
- Foreign body removal, pulmonary venous stenosis
 and, interventional cardiac catheterisation
 for, 309
- Formalin, infiltration of, for persistently patent
 arterial duct, 891
- 45, X syndrome, 165
- arterial dysfunction and, 110
- 4-D echocardiography, perfusion estimation
 using, 84
- Frequencies of ultrasound, 313–314
- Friedreich's ataxia
 cardiac involvement in, 1181–1182
 hypertrophic cardiomyopathy and, 1006
- Friedreich's cardiomyopathy, monitoring of, myo-
 cardiac Doppler for, 360
- Frusemide, 1300t–1303t
- Fucosidosis, cardiac involvement in, 1169
- Fungal endocarditis, 1137–1138
- Fungal infections, endocarditis due to, 1144
- Furosemide, 1300t–1303t
 for hypertension, 1215t
 for systemic hypertension, in preterm infants, 193f
- G
 Galactosialidosis, cardiac involvement in, 1169
 α -Galactosidase A deficiency, cardiac involvement
 in, 1170–1171
- Gangliosidosis, cardiac involvement in,
 1171–1172
- Gap junctions, 70
- Gastroesophageal reflux, oral intake and, 1294
- Gastrointestinal disorders with univentricular
 hearts, following surgical palliation, 688
- Gastrostomy tube feeds, 1293
- Gastrulation, 38, 38–39f
- Gata4*, cardiac development and, 162–163
- Gaucher's disease, cardiac involvement in, 1170
- Genetic factors. *See also under specific conditions.*
 in congenital heart disease, 161–162
 prevalence and, 150–153
 regulating cardiac formation, 162
- Genetic mutations
 bicuspid aortic arch due to, 169–170, 170f
 frequency in congenital heart disease, 170, 170t
 septation defects due to, 168–169, 168f, 169f
- Gerbode defect, 565f
- Gigantism, pituitary, cardiac involvement in, 1172
- Glenn shunt
 bidirectional, for Ebstein's malformation, 728
 for univentricular hearts, 689
- α -1,4-Glucan-6-glucosyltransferase deficiency,
 cardiac involvement in, 1165–1166
- Glucose control for cardiopulmonary bypass, 234
- Glucose-6-phosphatase deficiency, cardiac
 involvement in, 1163
- Glucose-6-phosphatase translocase deficiency,
 cardiac involvement in, 1163
- α -1-4-Glucosidase deficiency, cardiac involvement
 in, 1163–1165, 1165f, 1166f
- Glutaraldehyde fixation of bovine pericardium,
 224
- Glycogen storage diseases, cardiac involvement in,
 1163–1172
- Glycoprotein degradation disorders, cardiac
 involvement in, 1169–1170
- Glycosylceramidosis, cardiac involvement in, 1170
- Gordon's syndrome, hypertension in, 1212
- Gore-Tex grafts, 224
- Great arteries, morphology of, 7, 7f
- Great cardiac vein, 34–35, 34f
- Ground substance, arterial, 92
- Growth
 following cardiac transplantation, 287
 delay of, assessment of, 1287
 failure of, mechanisms of, 1285–1287
 growth factor hormone as, 1286–1287
 hypermetabolism as, 1286
 inadequate caloric intake as, 1286
 malabsorption as, 1286
 physical, assessment of, 1287
 transposition of the great arteries and, 804
- Growth factors
 cardiac development and, 163
 growth and, 1286–1287
- Guide-wires for cardiac catheterisation, 292
- H
 HACEK group, endocarditis and, 1137
- Haemangiomas, cardiac, 1063–1064
- Haematocrit, during bypass, neurological
 outcomes and, 1272
- Haematological dysfunction with univentricu-
 lar hearts following surgical palliation,
 687–688
- Haemochromatosis, cardiac involvement in, 1184
- Haemoconcentrators for cardiopulmonary bypass,
 229–230
- Haemodilution for cardiopulmonary bypass, 230
- Haemodynamic compromise, postoperative,
 following palliation for hypoplasia of left
 heart, 644
- Haemodynamic monitoring of preterm infants,
 183–185
 approach for, 185, 185f
 hypotension and brain injury and, 184–185, 184f
 reliability of blood pressure as measure of circu-
 latory stability and, 183–184, 184f
- Haemodynamics
 cardiac development and, 164
 in Ebstein's malformation, 725
 echocardiographic measurements and, 336–337
 of mean pressure gradient, 336–337, 337f
 in hypoplasia of the right ventricle, 658–659
 optimisation of, prior to cardiac transplantation
 for restrictive cardiomyopathy, 1029
 during pregnancy, 1229
 in pulmonary stenosis, 904–905
 in tetralogy of Fallot, 766–767

 Pulmonary veno-occlusive disease
 pulmonary arterial hypertension in, 140
 pulmonary hypertension and, 1148–1149, 1148f
 Pulmonary venous anomalies, 497–522 *See also* Partially anomalous pulmonary venous connection. *See also* Totally anomalous pulmonary venous connection.
 anomalous pulmonary-to-systemic collateral veins and laevoatrial cardinal vein as, 518, 518f
 anomalous venoatrial connections as, with isomeric atrial appendages, 465–467, 466f
 atresia of common pulmonary vein as, 513–514
 anatomy of, 513, 513f
 clinical presentation and investigation of, 513
 imaging of, 513
 management of, 513–514
 Pulmonary venous anomalies (*Continued*)
 pathophysiology of, 513
 computed tomographic evaluation of, 375, 377f
 echocardiographic quantification and identification of patterns of flow and, 334, 334f
 pulmonary varix as, 521
 stenosis or atresia as, 518–521
 anatomy of, 518, 519f
 cardiac catheterisation in, 520
 chest radiography in, 519
 computed tomography in, 520, 521f
 course and prognosis of, 521
 differential diagnosis of, 520–521
 echocardiography in, 519–520, 520f
 electrocardiography in, 519
 interventional cardiac catheterisation and, 308–309
 foreign body or device removal and, 309
 stenting and, 308–309, 309f
 magnetic resonance imaging in, 520
 management of, 521
 of most or all pulmonary veins, 520–521
 of one or two pulmonary veins, 520
 pathophysiology of, 519
 presentation and symptoms of, 519
 radionuclide angiography in, 520
 traditional angiography in, 520, 520f
 unilateral atresia of, 514
 unilateral pulmonary venous atresia as, 514
 with univentricular hearts, surgical management of, 684
 Pulmonary venous obstruction
 pulmonary hypertension and, 1149
 totally anomalous pulmonary vein connection and, 502
 Pulmonary-to-systemic veins, anomalous, laevoatrial cardinal vein and, 518, 518f
 Pulsatility index, 78, 78f
 Pulse contour analysis, 99–100
 Pulse transit time, 101–102, 101f
 Pulse wave velocity, 101
 Pulsed Doppler assessment of long-axis function of fetal heart, 83, 83f
 Pulsed wave Doppler echocardiography, 315–316
 optimising settings for, 317
 Pulseless disease, cardiac involvement in, 1185
 Pulse-wave velocity, fetal, 85
 Pumps for cardiopulmonary bypass, 229
 Purkinje sell tumours, 1064
 P-values, 444
 clinical relevance versus statistical significance and, 445
 limitations of, 444–445
 type I and II error and power and, 445–446
 Q
 Quality of life
 following cardiac transplantation, 287
 for children with cardiac disease, 1252
 Quantitative echocardiography, 332–336
 quantification of echocardiographic dimensions using, 333, 333f
 quantification of flow and identification of patterns of flow using, 333–336
 in abdominal aorta, 334, 334f
 in atrioventricular valves, 334–335, 334f
 in left ventricular outflow tract and ascending and descending aorta, 335–336, 336f
 in pulmonary veins, 334, 334f
 in right ventricular outflow tract and pulmonary trunk, 335, 335f
 of systemic venous flow, 333–334, 334f
 Quantitative variables, 438
 R
 Radiation exposure, ablation and, 398
 Radiation hazard with computed tomography, 374–375, 374f
 Radiofrequency ablation, 381–386, 382f
 equipment for, 382
 results of, 398
 tachycardia mapping and, 384–385
 activation, 384–385
 electroanatomic, 385, 385f
 entrainment, 385
 pace, 385

- Radiofrequency ablation (*Continued*)
 technique for, 382–383
 atrioventricular conduction and, 383
 burst pacing and, 383
 catheter placement and, 383, 384f
 conduction intervals and, 383, 385f
 extrastimulus testing and, 383
 incremental pacing and, 383
 programmed stimulation and intra-cardiac recordings and, 383
 sinus node function and, 383
 tissue effects of radiofrequency energy and, 382
 for ventricular tachycardia, 394, 394f
- Radiotherapy
 cardiac disease induced by, 1187
 during pregnancy, 1238
- Ramp protocol, 424, 424f
- Random samples, inference based on, 443–444
- Randomised clinical trials, 452
- Rastelli classification, 562, 563f
- Rastelli procedure, 812, 812f
- Rate(s), definition of, 143–144
- Rate of work, exercise testing and, 427
- Ratio variables, 438
- Re-entry tachycardia
 atrioventricular nodal, 390–391
 ablation for, 391
 arrhythmic substrate and, 390–391, 391f
 electrophysiologic findings in, 391
 intra-atrial, 393
- Referrals
 communication for, 1279–1284
 timing of, 1282–1283
- Reflection of ultrasound waves, 313–314
- Refraction of ultrasound waves, 313–314

- Septomarginal trabeculum, 22, 23f
- Septoparietal trabeculations, 22, 23f
- Septum primum, 44f, 45f, 45
- Septum secundum, 524, 525f
- Sequential segmental analysis, 3f, 5f, 6f, 7f
 transthoracic echocardiographic diagnosis using, 326–327

- Sequential segmental analysis (*Continued*)
atrioventricular junction analysis and, 327
determination of atrial arrangement and, 326–327
ventriculo-arterial junction analysis and, 327
SERCA, 60–61, 61f
Serial measures analysis, 448
Serotonin, control of circulation and, 95
Serotonin fluoxetine, persistent pulmonary hypertension of the newborn and, 124
Sex chromosomes, aneuploidy of, 165
Shock, hypoplasia of left heart and, 631
Shprintzen syndrome, 165
Shunt(s)
aortopulmonary
three-dimensional echocardiography of, 344
for univentricular hearts, 688, 689t
Blalock-Taussig
modified, for univentricular hearts, 689t
for univentricular hearts, 689t
cavopulmonary, bidirectional, for univentricular hearts, 684–685
Glenn
bidirectional, for Ebstein's malformation, 728
for univentricular hearts, 689
left-to-right
in pregnancy, 1233–1234
totally anomalous pulmonary vein connection and, 502
Potts, for pulmonary hypertension, 1158
right-to-left, totally anomalous pulmonary vein connection and, 502
systemic-to-pulmonary arterial, extracorporeal lift support and, 251
in transposition of the great arteries, 803–804
Waterston, for univentricular hearts, 689t
Shunting
across atrioventricular septal defect, 561, 561f
atrial, atrioventricular septal defects and, 567
ventricular, atrioventricular septal defects and, 567
ventriculo-atrial, atrioventricular septal defects and, 567
Sialidosis, cardiac involvement in, 1169
Siblings, effects of child's cardiac disease on, 1256
Sickle cell haemoglobinopathy, cardiac involvement in, 1188–1189
Sideris buttoned device, 544–545
Sildenafil, 1300t–1303t
for pulmonary hypertension, 136
Single gene defects, 166–167
Sinotubular junction, 28–29
Sinuatrial valves, embryology of, 52–53
Sinus node
anatomy of, 31, 31f
in isomeric atrial appendages, 469
Sinus node function, ablation and, 383
Sinus of Valsalva
aneurysms of, 1044–1046, 1044f
clinical features of, 1044–1045
investigations in, 1045
management of, 1045–1046, 1045f, 1046f
anomalous origin of coronary artery from opposite sinus and, 936
Sinus septum, 20, 20f, 21f, 29, 44f, 45
Sinus tachycardia, inappropriate, 396
Sinus venosus
defects of, 527–529, 528f, 529f
inferior, 525, 526f
superior, 525, 526f
embryology of, 42–43
Situs ambiguus, 463. *See also* Atrial appendages, isomerism of.

 physiology of, 1127
 of aortic valve, 1118, 1119f
 histologic features of, 1119, 1119f
 of mitral valve, 1117–1118, 1117f, 1118f
 mitral regurgitation as, 1119–1123
 clinical features of, 1120–1123, 1121f, 1122f, 1123f
 physiology of, 1120
 mitral stenosis as, 1123–1126
 clinical features of, 1123f, 1124–1126, 1124f, 1125f, 1126f, 1127f
 percutaneous interventions for, 1131
 physiology of, 1123–1124
 secondary pulmonary changes and, 1119
 surgical management of, 1132–1133
 of tricuspid valve, 1118–1119, 1129–1130
 clinical features of, 1129–1130, 1130f
 physiology of, 1129
 Valves. *See* Cardiac valves; *specific valves.*
 Valvitis
 in infective endocarditis, 1138
 subclinical, in rheumatic fever, 1101–1102, 1101t
 Valvotomy, surgical, for pulmonary stenosis, 910–911, 911f
 balloon dilatation vs., 911–912, 911f
 Variables, 437
 Variation of data, 438
 Vascular access
 for ablation, 396
 for cardiac catheterisation, 292
 Vascular impedance, 98–99, 98f
 Vascular occlusion, interventional cardiac catheterisation for, 294
 Vascular physiology, fetal, assessment of, 84–85
 Vascular programming, fetal, 87–89
 following fetal coarctation, 89, 89f
 restricted growth and, 88–89
 in twin-twin transfusion syndrome, 89
 Vascular resistance
 pulmonary. *See* Pulmonary vascular resistance.
 ventricular afterload and, 97–98
- Vascular smooth muscle
 endothelial regulation of, 93
 function of, 93
 Vascular tone, endothelial regulation of, 92–93
 Vascular tumours, cardiac, 1063–1064
 Vasculitis, childhood, arterial dysfunction and, 109
 Vasculopathy of cardiac allograft, 282–284
 management of, 284
 risk factors and diagnosis of, 282–284, 282f, 282t, 283f, 283t
 Vasodilators for hypertension, 1203–1204, 1215t
 Vasomotor regulation in preterm infants, 190
 Vasopressin
 for circulatory collapse, in preterm infants, 190–191
 control of circulation and, 95
 Vasopressor agents
 for circulatory collapse, in preterm infants, 190–191
 for hypotension, in preterm infants, 190–191
 Vein(s). *See* Systemic venous entries; Venous entries; *specific veins.*
 Vein of Galen, aneurysm of, 1035–1037
 clinical presentation of, 1035
 diagnosis of, 1036, 1036f
 management of, 1036–1037, 1036f, 1037f
 Velo-cardio-facial syndrome, 165
 Venoaortic connections, anomalous, with isomeric atrial appendages, 465–467, 466f, 467f, 468f
 surgical treatment of, 482
 Veno-occlusive disease, pulmonary, pulmonary hypertension and, 1148–1149, 1148f
 Veno-pulmonary circuit, Fontan circulation and, 692–693
 Venous anatomy, ablation and, 396
 Venous anomalies, systemic. *See* Systemic venous anomalies.
 Venous components, embryology of, 42–44, 42f, 43f, 44f
 Venous duct
 fetal circulation and, 76–77, 76f, 77f
 flow in, fetal, 78–79, 79f
 Venous physiology, fetal, 85, 85f
 Ventilation
 for haemodynamically significant arterial duct, 187
 mechanical
 for acute circulatory failure, 241, 243t, 254t
 cardiovascular system and, 241, 242f
 with diastolic dysfunction, 242
 with functionally univentricular circulation, 242–243
 with systolic ventricular dysfunction, 241–242
 as haemodynamic tool, 243, 243t
 minute, 421
 voluntary, maximal, 421
 Ventilatory anaerobic threshold, 416
 evaluation of, exercise testing for, 427
 Ventricles
 Fontan circulation and, 691–692
 left. *See also* Left ventricular entries.
 anatomy of, 24–26, 24f, 25f, 26f, 27f
 double-outlet, 844–845
 repair of, 855–856
 in hypoplasia of the right ventricle, 654
 systemic, in biventricular circulation, 115–116
 volumetrics of, three-dimensional echocardiographic quantification of, 344
 morphology of, 5f, 6f
 origin of arterial trunks from, 13–14
 relationships of, 13
 right. *See* Right ventricle; Right ventricular entries.
 solitary, 7, 7f
 superi-inferior, 999
 topology of, 6f, 13
 topsy-turvy arrangement and, 999, 1000f
 in univentricular hearts, 670–672, 670f
 Ventricular afterload, arterial impedance as, 97–99
 Ventricular assist devices, 249, 250t
 for dilated cardiomyopathy, 1025
 Ventricular compliance, interatrial communication and, 531–532

- Ventricular dysfunction
 effect on systemic circulation, 113
 systolic, mechanical ventilation and, 241–242
- Ventricular function, 57, 57f
 impact of arterial dysfunction on, 112–113
 monitoring of, in intensive care unit, myocardial Doppler for, 359–360, 360f
- Ventricular loop, embryology of, 47, 48f
- Ventricular septal defects, 591–624
 angiocardiology in, 616–617, 617f, 618f, 619f
 atrioventricular canal-type of, 566
 cardiac catheterisation in, 616
 categorisation of, 591–592, 592t
 clinical presentation of, 609
 computed tomography in, 615–616
 course of, 619–620
 description of defects and, 592–594, 592f, 593f, 594f, 595t
 diagnosis of, 617–619
 echocardiography in, 611–614, 611f, 612f, 613f, 614f, 615f
 Doppler, 614–615
 transesophageal, 615
 electrocardiography in, 610
 interventional cardiac catheterisation for, 300–301, 301f, 302f
 isolated/simple perimembranous, risk factors for, 151t
 juxta-arterial, doubly committed, 597, 597f, 604–605, 606f, 607f
 juxtacuspids, 597, 605
 magnetic resonance imaging in, 615, 615f, 616f
 management of, 620–623
 catheter-based, 621–622, 621f
 post-surgical course and, 622–623
 surgical, 621
 morphogenesis of, 605–606
 morphology of, 591–606
 multiple/multiplex perimembranous, risk factors for, 151t
 muscular, 594, 596f, 604, 604f, 605f
 non-perimembranous, 597, 605
 nuclear angiography in, 616
 pathophysiology of, 606–609
 cardiac response to flow between ventricles and, 608–609
 pulmonary outflow tract obstruction and, 608
 pulmonary vascular resistance and, 608
 size of defect and, 606–608
 perimembranous, 594–597, 596f, 600–604, 600f, 601f, 602f, 603f
 relation to components of right ventricle, 598, 598f
- Ventricular septal defects (*Continued*)
 periventricular, with atrioventricular septal defects, 565, 565f
 physical examination in, 609–610
 position of, 597–598, 598f, 599f
 prevalence of, 591
 prognosis of, 619–620
 pulmonary hypertension with, 131–132, 132f
 radiology in, 610–611, 611f
 size and shape of, 598–600, 606–608
 three-dimensional echocardiography of, 343–344
 in transposition of the great arteries, 800–802, 801f, 804
 transposition of the great arteries with, surgical management of, 811
 with univentricular hearts, 673–674, 673f
 variability in margins of, in tetralogy of Fallot, 756–759, 757f, 758f
- Ventricular septum, anatomy of, 29–30, 30f
- Ventricular stimulation testing, 380–381
- Ventricular tachycardia, 394–395
 benign, 394
 arrhythmic substrate and, 394
 electrophysiologic findings in, 394
 radiofrequency ablation for, 394, 394f
 polymorphic, catecholaminergic, 395
 post-operative, 394–395
- Ventricular-vascular coupling, Fontan circulation and, 692
- Ventriculo-arterial connections in univentricular hearts, 670
- Ventriculo-arterial coupling, 113–115, 114f
- Ventriculo-arterial junctions, 13–15, 28–29
 arterial relationships and, 14
 echocardiographic analysis of, 327
 infundibular morphology and, 14–15, 15f
 in isomeric atrial appendages, 469
 origin of arterial trunks from ventricular mass and, 13–14
- Ventriculo-arterial valves, overriding of, 697–698, 699f
- Ventriculo-coronary connections in hypoplasia of the right ventricle, 654
- Ventriculo-infundibular fold, 14–15
- Verapamil, 385
 for tachyarrhythmia, fetal, 202t, 203t
- Very low birth weight, definition of, 182b
- Vestibular defects, 525, 526f, 529, 529f
- Video assisted thoracic surgery, 222, 223f
- Vinculin, cytoskeleton and, 68, 68f
- Visceral heterotaxy. *See* Atrial appendages, isomerism of.
- Vitamin A, infant requirement for, 1288–1290t
- Vitamin B₁, infant requirement for, 1288t–1290t
- Vitamin B₂, infant requirement for, 1288t–1290t
- Vitamin B₆, infant requirement for, 1288t–1290t
- Vitamin C, infant requirement for, 1288t–1290t
- Vitamin D, infant requirement for, 1288t–1290t
- Vitamin E, infant requirement for, 1288t–1290t
- Vitamin K, infant requirement for, 1288t–1290t
- Vocal cord paralysis, oral intake and, 1294
- Volume loading, atrioventricular septal defects and, 567
- von Gierke's disease, cardiac involvement in, 1163
- W**
- Warfarin for pulmonary hypertension, 136
- Water
 infant requirement for, 1288t–1290t
 retention of, in chronic cardiac failure, 262
- Waterston shunt for univentricular hearts, 689t
- Waterston's groove, 20, 21f
- Wave reflection, 99
- Wave reflection indices, 102–103, 102f, 103f
 blood pressure indices as, 103
- Weaning for mechanical support, 251–253
- White coat hypertension, 1195–1198
- Williams syndrome
 arterial dysfunction and, 109
 supravalvular aortic stenosis in, 166
- Wilms' tumour, renal hypertension and, 1210
- Windkessel model, 96–97, 97f
- Wolff-Parkinson-White syndrome
 accessory pathways in, 389–390
 management of, 389–390, 390f, 390t
 risk of sudden death in, 389–390, 390t
- Wolman's disease, cardiac involvement in, 1170
- Work rate, oxygen consumption and, 416, 417f
- X**
- Xenobioprosthetic valves, 225–226, 225f
- Y**
- Young adults, transition from paediatric to adult care for. *See* Transition from paediatric to adult care.
- Young infants, aortic stenosis in. *See* Aortic stenosis, valvar, in neonate and young infant.
- Young's modulus, 100–101, 100t
- Z**
- Z-disc, 67–68, 68f, 69f
- Zinc, infant requirement for, 1288t–1290t
